Numerical Example

Although an examination of equation (18) provides qualitative information about the time path of land values in a support-price world, explicit specification of the parameters and variables in the model is necessary to assess the quantitative impact of farm-policy changes. Suppose the model is evaluated for a cash-grain situation in which corn is the single commodity produced and where the following parameter and variable values are reasonable for the cash-grain example: $Q_t = 100$ bushels per acre, $C_{t-1} = \$150$ per acre, $\delta = 1.00$, $V_0 = \$1{,}667$ per acre, $RG_t = \$2.00$ per bushel, $a = 0.02667$, and $b = 0.00001$. Also, assume that the policy parameters initially are set as follows: $\lambda = 0.09$, $\gamma_C = 1.00$, and $\gamma_L = 0$.

In this setting, the initial support price X_0 is \$1.50 per bushel, so the farmers' subjective probability distribution for corn prices ranges from \$1.50 per bushel to \$3.50 per bushel, with an expected value of \$2.50 per bushel. The capitalization rate k is 0.06.[6] Policy makers are

[6] It is more nearly correct to assume that the capitalization rate for farmland is given by equation (4) as modified in footnote 3. Thus, the income capitalization rate is given by the difference between the owners' required rate of return and the expected growth rate ($k - g$). For example, in terms of the parameters in the numerical example, a 6% capitalization rate (r) is consistent with a required rate (k) of 12%, a risk-free rate (a) of 2.667%, a risk premium ($b\sigma_{R_t}^2$) of 9.333%, and a growth rate (g) of 6%.

assumed to allow a return on land λ equal to 0.09, a long-term average of mortgage rates on farm real estate loans. Furthermore, the support-price policy is established by covering 100% ($\gamma_C = 1.00$) of operating costs and 0% ($\gamma_L = 0$) of land charges. Operating costs are assumed constant over all future periods. The time path of land values for this scenario is shown in column 2 of table 1. Land values remain constant at $1,667 per acre, and the support price is constant at $1.50 per bushel.

If policy makers decide to set the support price formula to recapture a portion of land costs ($\gamma_L > 0$), however, the path of land values increases over time. Solution values for the model for selected values of γ_L greater than zero are shown in columns 3 through 8 of table 1. The equilibrium value for land increases from $1,667 per acre to $6,665 per acre as γ_L is changed from 0 to 0.50. Thus, the greater the proportion of land charges that policy makers allow to be recaptured through the support price, the larger is the long-run equilibrium price of land. In other words, any guaranteed return to land—above and beyond operating costs—is capitalized into the price of land. An increase in the value of land necessitates an increase in the support price, which increases the expected returns to land, which increases land value, which requires a further increase in the support price, and so on.

In this numerical example, as long as $\gamma_L\lambda < 0.06$, land values increase at a decreasing rate over time. With $\lambda = 0.09$, however, if $\gamma_L > 0.667$, land values explode—values increase at an increasing rate. An illustration of exploding land value is given in column 10 of table 1. In that instance, $\gamma_L = 0.70$; thus, $\gamma_L\lambda = 0.063$, which is greater than the market capitalization rate of 0.06.

Table 2 presents the dollar and percentage changes in land values over time for each of the policy schemes. For example, row 5 shows that after five years land values have increased $294 per acre or 18% for $\gamma_L = 0.10$. Over that same time interval, land values have increased $3,812 per acre or 229% if γ_L is set at 0.50. Thus, the particular scheme used to implement a support-price policy could have substantial impact on the future path of land values.

Also, the potential social cost of the different schemes could differ substantially. For the first year of policy implementation, the difference between the required support prices for the $\gamma_L = 0$ case and the $\gamma_L = 0.50$ case is $0.75 per bushel (table 1). By year five, that support-price differential increases to $2.29 per bushel. At their equilibrium levels, the difference in support prices is $3.00 per bushel.

Summary and Conclusions

In this paper, policy makers are allowed to control the percentage of nonland operating costs and the percentage of land costs covered by commodity support prices. If policy authorities establish a support-price formula that recaptures all nonland operating costs but no return on land, the time path of land values is level or constant. Thus, implementation of that type of policy has a once-and-for-all impact on land values, raising them to a new equilibrium level.

Table 1. Support Prices and Land Values for Selected Policy Schemes

	$\gamma_L = 0$		$\gamma_L = 0.10$		$\gamma_L = 0.30$		$\gamma_L = 0.50$		$\gamma_L = 0.70$	
t	X_t	V_t	X_t	V_t	X_t	V_t	X_t	V_t	X_t	V_t
0	$1.50	$1,667	$1.50	$1,667	$1.50	$1,667	$1.50	$1,667	$1.50	$1,667

8	·	·	·	·	·	3,028	4.20	6,165	11.52	18,373
9	·	·	·	·	·	3,029	4.27	6,290	13.07	20,957
10	·	·	·	·	·	3,030	4.33	6,384	14.70	23,670
15	·	·	·	·	·	·	4.46	6,598	24.15	39,409
30	1.50	1,667	1.68	1,961	2.32	3,030	4.50	6,665	71.19	117,807

Note: t = time period; γ_C = proportion of nonland costs covered by support price = 1; γ_L = proportion of land costs covered by support price; X_t = support price per bushel; and V_t = land value per acre.

Table 2. Cumulative Land Value Changes for Selected Policy Schemes

t	$\gamma_L = 0.10$		$\gamma_L = 0.30$		$\gamma_L = 0.50$		$\gamma_L = 0.70$	
1	$250	15%	$750	45%	$1,250	75%	$1,750	105%
2	287	17	1,087	65	2,187	131	3,587	215
3	293	18	1,239	74	2,890	173	5,516	331
4	294	·	1,307	78	3,417	205	7,541	452
5	·	·	1,338	80	3,812	229	9,668	580
10	·	·	1,363	82	4,717	283	22,003	1,320
15	·	·	·	·	4,931	296	37,742	2,264
30	294	18	1,363	82	4,998	300	116,140	6,967

Note: t = time period; γ_C = proportion of nonland costs covered by support price = 1; γ_L = proportion of land costs covered by support price; $ = dollar change in land value per acre over t time periods; and % = percentage change in land value per acre over t time periods. For $\gamma_L = 0$, $ = % = 0.

If, however, policy makers allow a portion of the rate of return on land to be included in the support-price formula, land values increase over time and approach an equilibrium value greater than for the situation in which no land costs are included in the support price. Both the level of the new equilibrium and the rate at which land values approach that equilibrium are affected by the proportion of land charges included in the support-price formula. In the extreme case, if policy makers inadvertently allow an effective return on land greater than the market capitalization rate, land values explode.

Thus, the particular scheme used to implement a general cost-indexed support-price policy is likely to be crucial to the resulting impact on future land values and also to the possible social cost of the farm program for years in which actual commodity price falls below the support price. It is unreasonable to expect that policy makers would allow an explosive mechanism to track very far into the future. Implementation of a policy that guaranteed a rate of return on land greater than the market capitalization rate, however, could have substantial impact on land values before the policy parameters could be adjusted.

The model could be used to consider a wide range of schemes, other than those considered above, to implement inflation-indexed support-price programs. For example, one suggested support-price formula would have the support price include a fixed dollar return to land (Sharples and Krenz). The model suggests that such a policy would result in a constant land value over time as long as operating costs were constant ($\delta = 1$). Or, the model could be used to evaluate the consequences of inaccurate measurement of nonland operating costs. Preliminary analysis suggests that, for example, an overestimate of nonland operating costs in a support-price formula generates the same time path of land values as the model results obtained with $\delta = 1$, $\gamma_L = 0$, and $\gamma_C > 1$.

The model was developed using simplifying assumptions that, when relaxed, might alter the conclusions of the analysis. Without doubt, quantitative results would be changed, although the qualitative implications of the model likely would remain intact. For example, the variance of the expected price distribution was assumed to remain constant as the support price increased. It is possible that as the support price increased the variance of the distribution would decline. In such a case, for the uniform distribution, the expected value would increase less, and thus, *ceteris paribus*, land values would not increase as much as for the constant variance case. As the variance narrowed, risk would decline, the capitalization rate would fall and cause a *ceteris paribus* increase in land values. The net effect of a constant variance assumption would depend on the relative sensitivity of land values to changes in expected returns and risk.[7]

Also, it was assumed that farmers naively expect new support prices to hold forever. In reality, farmers likely would anticipate the future movement of the support price and build that anticipated movement into their expected return from land. Land values in such an anticipatory model would increase at a faster rate than those in the naive model.

In addition, the farmers' distribution of expected prices was assumed uniform to make the mathematical model tractable. The use of

[7] For purposes of numerical analysis, the model was modified by assuming that the upper limit on the probability distribution of prices U_t was constant. In that situation, as the support price X_t increased, the expected value of the distribution increased and the variance decreased as the range narrowed. Consequently, the capitalization rate declined each time the support price increased. The quantitative results of the model were more extreme because the capitalization rate was quite sensitive to changes in the variance.

some other distributional form likely would not significantly change the results of the model if the distribution was symmetrical and variance was assumed constant. With variance constant, a shift in any symmetrical distribution brought about by a change of x units in the support price would produce a shift in the expected value of the distribution by that same x units. If, however, the variance of the distribution changed as the support price changed, the form of the distribution could have an effect on the quantitative results of the model.

Finally, the time paths of land values were developed in a *ceteris paribus* context, where only policy variables were allowed to change. In the real world, many other factors besides farm policy affect land values, so the time path of land values will not follow the track of those generated by the model. But, if nothing else, this analysis demonstrates the potential importance of the selection of an appropriate scheme for the implementation of well-intentioned social and policy goals.

Analysis of the Impact of Alternative U.S. Dairy Import Policies

Larry Salathe, William D. Dobson, and Gustof A. Peterson

A simulation model is used to measure the impact of four U.S. dairy import plans on Wisconsin farm milk prices and other variables. Estimates for different plans show that each additional billion pounds of milk equivalent in dairy imports would depress Wisconsin farm prices initially by $0.14 to $0.21 per hundredweight. Wisconsin farm milk prices initially would fall by 18% if the milk equivalent of butter and cheese imports rose to 12 billion pounds. Within three years, milk prices would recover. But this recovery would occur only after about 13% of Wisconsin's milk producers had exited from dairying.

Key words: dairy imports, farm numbers, international trade, milk prices, simulation model.

U.S. trade officials in recent years have striven to reduce barriers—particularly those in the European Economic Community (EEC) countries—to exports of U.S. agricultural products. The results achieved by U.S. negotiators have been meager. Agricultural trade negotiations during the Kennedy round, which began in 1967, did little to reduce barriers to expanded exports of U.S. farm products. Moreover, bilateral negotiations by U.S. officials with other countries since the Kennedy round and recent negotiations in multinational forums (e.g., those authorized by the Trade Act of 1974) have achieved no agricultural trade expansion breakthroughs as of early 1977.

These failures have spawned proposals for different negotiating strategies, including the "selective goal" strategy of the Flanigan International Trade Report (Council on International Economic Policy). This strategy would have the U.S. seek freer trade in a few agricultural products rather than across-the-board agricultural trade liberalization. Authors of the Flanigan report said that the U.S. should, if necessary, give up its dairy import quotas to gain freer access to foreign markets for feed grains and soybeans. Under a full-market orientation option examined in this report, the U.S. would substantially expand feed grain and soybean exports while importing manufactured milk products containing 12 billion pounds of milk equivalent by 1980. The 12 billion pounds of milk equivalent represent about 10% of total U.S. milk consumption and the equivalent of 25% of U.S. manufactured milk product consumption. The Atlantic Council argued that it would be reasonable for the U.S. to permit imports of dairy products to increase from the present 1.5% of domestic consumption to 10% of domestic consumption by 1980. Authors of the Flanigan and Atlantic Council reports contend that economic adjustments that would be required of the U.S. dairy industry to accommodate dairy product imports equal to 10% of U.S. consumption would be small—almost imperceptible over a ten-year period according to the Atlantic Council report (p. 247).

The Flanigan and Atlantic Council reports aroused concern in the U.S. dairy industry for several reasons. First, dairy import quotas were thought to be the only major agricultural concession that the U.S. had to offer in trade negotiations. Accordingly, it was feared that U.S. trade negotiators might seek permission to put the quotas "on the table" to be exchanged for trade concessions from other nations. Second, the administration temporarily lifted import quotas on some manufactured milk products during 1973 and 1974, contributing to a 20% decline in U.S. average manufac-

tured milk prices in 1974. The lifting of quotas was interpreted by some in the dairy industry as evidence that the U.S. government was implementing the recommendations of these reports. Third, many thought that the U.S. dairy industry would need to make major, painful economic adjustments if larger manufactured milk product imports were permitted. Fourth, there was concern that, if larger dairy imports were permitted, then the U.S. dairy price support program would be eliminated or modified.[1]

Partly in response to these concerns, the U.S. Congress directed the U.S. Department of Agriculture to study the effects of expanding dairy imports in 1973. Among other things, this study, which was forwarded to Congress in 1975, examined effects of an open U.S. market policy that assumed no U.S. dairy import quotas or price-support program. Under this policy, the U.S. would have imported the milk equivalent of 12.2 and 13.4 billion pounds of manufactured dairy products in 1975 and 1976, respectively, and smaller quantities in subsequent years. The USDA estimated that every billion pounds of milk equivalent imported would reduce U.S. farm milk prices by about $0.18 per hundredweight. Consequently, the assumed 1975 dairy product imports would have caused 1975 U.S. average farm milk prices to fall to a level about $2 (22%) below the $8.90 price that would prevail under present dairy import laws. The USDA concluded that U.S. dairy farmers initially would experience harsh economic conditions but that those who survived the depressed prices of the open U.S. market policy for two or three years would see their returns rise to levels about equal to those that would prevail under present dairy programs.

The Comptroller General's 1976 report to the U.S. Congress on import restrictions also suggested that the U.S. should reduce barriers to dairy imports. However, this report concluded that complete and sudden elimination of all barriers to dairy imports would be disruptive and could result in unreasonably adverse impacts on domestic milk producers. The report called for studies of the impact of policies that permit moderate increases in dairy imports in order to identify viable alternatives to present U.S. dairy programs.

The previous reports yield insights about the effects of larger dairy product imports. However, the earlier studies, especially the Flanigan and Atlantic Council reports, give little detailed information about the nature of the adjustments the domestic dairy industry would need to make if U.S. dairy imports were increased substantially. The estimates of the Flanigan, Atlantic Council, and the USDA reports apparently conflict with respect to the amount of damage the domestic dairy industry would sustain if dairy imports were increased sharply. The USDA seems to conclude that the damage would be substantially greater than suggested in the Flanigan and Atlantic Council reports. Moreover, the earlier studies deal primarily with the entire U.S. dairy industry or larger economic aggregates. Therefore, they show little about how larger manufactured milk imports would affect the dairy industry of major milk-producing states such as Wisconsin, where economic damage from dairy imports could be most severe.

This study evaluates the impact of larger U.S. dairy product imports on the dairy economy of Wisconsin, examines economic adjustments that would occur in the Wisconsin and U.S. dairy economies, and helps to reconcile conflicting findings with respect to the extent the U.S. dairy economy would be depressed by larger dairy imports. Specific objectives of the study were to examine the economic effects on the Wisconsin and U.S. dairy industry of the following policies: (*a*) annual import level I (1.7 billion pounds of milk equivalent per year for 1976–80), consisting of net cheese imports of 170 million pounds, net butter imports of 5 million pounds, and net imports of other dairy products having a milk equivalent of 0.2 billion pounds; (*b*) annual import level II (3.2 billion pounds of milk equivalent per year for 1976–80), consisting of net cheese imports of 340 million pounds, net butter imports of 10 million pounds, and net imports of other dairy products having a milk equivalent of 0.2 billion pounds; (*c*) annual import level III (6.2 billion pounds of milk equivalent per year for 1976–80), consisting of net cheese imports of 680 million pounds, net butter imports of 20 million pounds, and net imports of other dairy products having a milk equivalent of 0.2 billion pounds; and (*d*) an-

[1] Such concerns were well founded. Import quotas now are authorized under Section 22 of the Agricultural Adjustment Act as amended to prevent imports of price-supported commodities from reducing the effectiveness of the price-support program or interfering with the operations of the program. Thus, if larger dairy imports were permitted, then presumably the U.S. dairy price-support program would need to be eliminated or revised, since without such changes the USDA at times would be forced to support world prices of dairy products.

nual import level IV, consisting of dairy imports equivalent to those considered by the USDA in its recent study of the open U.S. market policy. U.S. dairy imports under this policy equaled 12.2, 13.4, 10.5, 9.2, 8.0, and 6.7 billion pounds of milk equivalent for 1975, 1976, 1977, 1978, 1979, and 1980, respectively.

The composition of the hypothetical imports (i.e., the percentage of imports comprised of cheese, butter, and other dairy products) for import levels I, II, and III is similar to the actual composition of U.S. dairy imports in 1976. The composition of the imports in import level IV approximately is proportional to the composition of U.S. domestic consumption of butter, cheese, and other manufactured dairy products. Import level I represents a dairy import program similar to the one presently used. Therefore, findings for this policy serve as a benchmark against which results for other policies are compared.

Model Used in Study

A computerized, recursive simulation model that measures the effects of alternative manufactured milk import policies on farm milk prices, milk production, farm numbers, wholesale butter prices, wholesale cheese prices, and retail prices for milk, cheese, and butter was employed for analysis of the impacts of the four import levels. Most components of the model relate to the Wisconsin dairy industry, but the model has equations linking it to the U.S. manufactured milk industry, the USDA's manufacturing milk price-support program, and the Chicago regional federal milk order. The model contains forty-two equations (estimated behavioral equations and identities). Behavioral equations in the model containing one or more current endogenous variables were estimated by two-stage least squares. Other behavioral equations in the model were estimated by ordinary least squares. Readers wishing to obtain a detailed description of the model should consult Salathe, Dobson, and Peterson (pp. 4–15).

The sequence of operations performed by the quarterly model is outlined: (*a*) Base period values are read for the following variables: cow numbers, dairy herd replacement data, farm milk prices, farm wage rates, milk production per cow, grain concentrate prices, feeding rates, and number of dairy farms for Wisconsin; U.S. cheese and butter stocks, federal milk order data, Chicago wholesale butter prices, and Wisconsin wholesale cheese prices. (*b*) Current values are calculated or read for the following exogenous variables: U.S. all food price index, percentage of U.S. butter and cheese produced in Wisconsin, percentage of Wisconsin Grade A milk marketed under the Chicago federal milk order, class I price differential and class I price premiums for the Chicago federal order milk market, butter stocks, cheese stocks, disposable income, population, and transportation costs for the U.S.; farm wage rates, cattle prices, and grain concentrate prices for Wisconsin.

(*c*) Current values are predicted for feeding rates, milk production per cow, dairy herd replacement data, cow numbers, Grade A and Grade B milk marketings for Wisconsin; and (*d*) current values are predicted for the U.S. retail prices for butter and cheese, Chicago retail price for fluid milk, U.S. per capita consumption of butter and cheese, U.S. commercial disappearance of butter and cheese, and fluid milk sales under the Chicago federal milk order.

(*e*) Levels for the dairy import policy variables, U.S. net imports of butter and cheese, are specified; and then (*f*) equilibrium conditions are employed to predict current values for butter and cheese production for Wisconsin and the remainder of the United States, and the quantity of Grade A milk marketed under the Chicago federal milk order from Wisconsin and the remainder of the United States. (*g*) Current values are also predicted for the quantity of Wisconsin milk used for butter and cheese production, Chicago wholesale butter price, Wisconsin wholesale cheese price, Chicago federal order milk utilization percentages and producer milk prices, and the Minnesota-Wisconsin manufacturing milk price. (*h*) Current values are then predicted for the price of Grade A milk, price of Grade B milk and all milk price for Wisconsin, and the number of Wisconsin dairy farms. (*i*) Finally, steps (*b*) through (*h*) are repeated until the desired calculations have been completed.

An explanation of step (*b*) in the above sequence may be helpful. When the model is employed to compare the effects of an alternative dairy import policy with one that existed during a historical period, actual values for the variables listed in step (*b*) are read into the computer. Alternatively, if the model is used to predict how the effects of higher dairy im-

ports would differ from the effects of continuing dairy imports at present levels, then different values are entered at step (*b*). In the latter case, predictions of the values for the step (*b*) variables under a scenario where present import policies continue during the future period of interest are entered into the computer at step (*b*).

The model functions in such a way that, when increases in butter and cheese imports are simulated, this increases the available supply of manufactured dairy products in the United States. This supply increase, unless offset by a comparable simulated increase in butter and cheese purchases by the USDA under the price-support program, causes the model to establish the lower equilibrium wholesale butter and cheese prices required to clear the market of the increased domestic supplies of these dairy products. Such a change in wholesale butter and cheese prices for the current quarter t causes a reduction in farm milk prices for quarter t, a reduction in retail prices for fluid milk, butter, and cheese for quarter $t + 1$, and a reduction in milk production for quarter $t + 1$. The quantity of butter and cheese produced in quarter t is predicted to increase or decrease depending on the relative changes in the wholesale prices of butter and cheese in quarter t. The percentage change in milk, butter, and cheese production that occurs after the increase in dairy imports and the fall in wholesale prices is the same for Wisconsin and the remainder of the United States. In subsequent quarters, lower milk production tends to offset the impact of the increase in imports on farm, wholesale, and retail milk and dairy product prices. The following description of the model's equations suggests how changes that originate with changes in wholesale butter and cheese prices influence other variables in the system.

Retail prices of butter, cheese, and fluid milk for the current quarter are determined in the model by wholesale prices for these dairy products for the previous quarter, current transportation costs, and seasonal variables. Thus, the retail price equations reflect the passing along to retail customers of changes in transportation costs for the current quarter and wholesale price increases that occurred during the previous quarter. Per capita consumption of butter and cheese were determined by their current prices, per capita disposable income and, in the case of butter, the price of margarine.

Wisconsin Grade B farm milk prices for the current quarter are determined in the model by changes in wholesale cheese prices, wholesale butter price changes, Grade B milk prices lagged one quarter, and seasonal variables. Wisconsin farm Grade A milk prices are determined by price formulas similar to those used to compute blend prices under the Chicago federal milk order. The current Wisconsin all milk price, which influences milk production in succeeding quarters, is a weighted average of current Grade A and Grade B milk prices.

Adjustments in Wisconsin milk production occur under the model because of changes in milk production per cow, cow numbers, and the number of dairy farms. Milk production for the current quarter is predicted as the product of milk production per cow and the number of milk cows. The number of cows in Wisconsin is a function of the grain concentrate-lagged milk price ratio, the culled cow-lagged milk price ratio, the lagged number of cows and heifers kept as replacements, and seasonal variables. Milk production per cow is a function of grain fed per cow during the current quarter, milk production per cow lagged one quarter, and seasonal variables. Amount of grain fed per cow for the current quarter is determined by a grain-lagged all milk price ratio, amount of grain fed per cow during the previous quarter, and seasonal variables. The number of Wisconsin dairy farms is a function of the current Wisconsin all milk price, current farm wage rates, and current milk cow numbers.

Model Validation

The model was validated by determining how well it would reproduce the actual time paths of seventeen variables for 1969–73. Dairy product imports and USDA purchases of butter and cheese under the price-support program were set equal to their actual levels during the validation run. In the validation run, the model reproduced actual values for number of cows, milk production per cow, and number of Wisconsin dairy farms with an average error of less than 2%. The average error was between 2% and 3% for Grade A milk price, U.S. retail cheese price, cheese production for Wisconsin, cheese disappearance for the U.S., and the Chicago retail price of fluid milk. The average error also was relatively small (3% to 5%) for all other variables

except those relating to U.S. butter prices and Wisconsin butter production, which averaged from 7% to 11%. However, the errors in the butter price and butter production forecasts did not introduce large errors into predictions for related variables. The model also predicted accurately the relatively large increases in farm milk prices that occurred in 1973. Therefore, since the model reproduced actual time paths for most variables in the study with reasonable accuracy, no systematic biases appeared in results generated during the validation run and the coefficients of the estimated behavioral equations had correct signs, it was concluded that the simulation model was suitable to use for examining the effects of alternative manufacturing milk import policies.

Results

Procedures and assumptions involved in generating the results for import levels I, II, III, and IV should be noted. In the four experiments, purchases of manufactured milk products under the USDA's price-support program were set equal to zero in the model. This was done primarily because there was no way to accurately predict the amount and composition of these purchases for the full period of the experiments. Second, if plans II, III, and IV involving dairy imports of from 3.2 billion pounds to as high as 13.4 billion pounds of milk equivalent were operating, then price support purchases probably would be terminated, since otherwise the USDA would be involved in the costly business of supporting world dairy prices. Third, setting price-support purchases equal to zero for all experiments permitted results for import level I to serve as a benchmark run, which was comparable with the other runs except for the difference in dairy import levels.

The butter, cheese, and other dairy product imports for the computer experiments associated with import levels I, II, and III were established at the fixed levels associated with each of these import levels (e.g., manufactured dairy products equal to 0.8 billion pounds of milk equivalent per quarter for import level II) during the first quarter of 1976 and remained fixed at their respective levels through 1980. Simulated dairy imports associated with import level IV were fixed within years but varied from year to year during 1975–80.

In the experiments the following values and rates of increase were employed for exogenous variables. Wisconsin beef prices were projected to average $38.70 per hundredweight during 1976–80. Wisconsin farm wage rates, Wisconsin grain concentrate prices, U.S. transportation costs, U.S. disposable income, and the U.S. all food price index were projected to increase by 22.5%, 8.4%, 19.3%, 18.9%, and 29.6%, respectively, during 1976–80.

Normal caveats are applicable when interpreting the results. The results for the different import levels are presented in specific terms. However, given the uncertainties that can influence the exogenous variables (e.g., drought and unforeseen developments in international markets for feed grains), it is likely that the results will be more useful for showing the direction and approximate magnitude of adjustments under the different import levels and for gauging the relative impact of the different import policies than for predicting with great accuracy the economic impact of specific plans.

Import Level I

Milk prices, milk production, and cheese production for Wisconsin increase during 1976–80 under this hypothetical plan. The Wisconsin all milk price was projected to increase from $8.88 per hundredweight in 1976 to $9.57 per hundredweight in 1980, an 8% increase (table 1). Milk prices increase mainly because of a projected strong demand for cheese. Under import level I, milk production for Wisconsin is projected to rise from 17.5 billion pounds in 1976 to 19.2 billion pounds in 1980. This reflects the effects of moderately strong milk prices and beef prices, which fail to encourage any massive culling of cattle from dairy herds. Cheese production in Wisconsin plants would increase from 1.25 billion pounds in 1976 to 1.50 billion pounds in 1980, a 20% increase. Butter production in Wisconsin plants, on the other hand, continued to fall, declining 24% from 1976 to 1980. U.S. cheese and butter prices and fluid milk prices for Chicago were projected to increase by 13%, 1%, and 16%, respectively, during 1976–80, reflecting the impact of moderate increases in raw product costs and higher projected transportation costs. Sizable reductions in the number of dairy farms were projected to occur despite the small departure from present programs represented by this import plan. Dairy farm numbers were projected to decline from

Table 1. Simulated Values for Fourteen Variables at Three Different Levels of Imports, 1976–80

Variable	Import Level	Years				
		1976	1977	1978	1979	1980
Wisconsin all milk price ($/cwt.)	I	8.88	8.95	9.02	9.31	9.57
	II	8.56	8.80	8.95	9.26	9.53
	III	7.96	8.52	8.80	9.15	9.45
Wisconsin Grade A milk price ($/cwt.)	I	8.99	9.13	9.21	9.48	9.72
	II	8.70	8.98	9.12	9.42	9.67
	III	8.14	8.69	8.96	9.29	9.56
Wisconsin Grade B milk price ($/cwt.)	I	8.70	8.65	8.65	8.89	9.05
	II	8.34	8.48	8.56	8.82	9.00
	III	7.64	8.15	8.38	8.68	8.90
Percentage of Wisconsin milk produced as Grade A	I	62.8	64.1	67.6	72.6	78.7
	II	63.7	65.8	69.6	74.6	80.7
	III	65.5	69.2	73.7	78.9	84.9
Number of Wisconsin dairy farms (1,000)	I	49.5	46.4	44.1	42.0	39.6
	II	48.2	45.4	43.0	40.6	38.1
	III	45.6	43.4	40.7	37.8	35.0
Gross farm cash receipts from sale of Wisconsin milk (million $)	I	1,558	1,611	1,679	1,759	1,839
	II	1,486	1,545	1,614	1,692	1,771
	III	1,349	1,413	1,483	1,558	1,635
Wisconsin milk production (million lbs.)	I	17,544	18,003	18,618	18,892	19,219
	II	17,362	17,553	18,039	18,273	18,583
	III	16,943	16,590	16,858	17,025	17,299
Cheese production in Wisconsin plants (million lbs.)	I	1,251	1,303	1,371	1,437	1,504
	II	1,191	1,241	1,306	1,370	1,436
	III	1,072	1,114	1,175	1,236	1,302
Butter production in Wisconsin plants (million lbs.)	I	144	136	130	121	109
	II	148	138	131	120	109
	III	156	140	131	120	109
Cheese consumption in U.S. (million lbs.)	I	3,273	3,403	3,571	3,734	3,899
	II	3,294	3,417	3,578	3,738	3,902
	III	3,338	3,443	3,593	3,746	3,909
Butter consumption in U.S. (million lbs.)	I	729	691	661	612	554
	II	756	703	668	616	557
	III	807	724	680	623	563
Cheese price at retail in U.S. ($/lb.)	I	1.48	1.56	1.58	1.62	1.67
	II	1.44	1.53	1.56	1.61	1.66
	III	1.36	1.48	1.52	1.59	1.64
Butter price at retail in U.S. ($/lb.)	I	1.16	1.17	1.16	1.16	1.17
	II	1.13	1.15	1.15	1.15	1.16
	III	1.05	1.12	1.13	1.14	1.15
Fluid milk price at retail at Chicago (¢/½ gal.)	I	72.7	75.6	78.2	81.3	84.5
	II	72.3	75.3	78.0	81.1	84.5
	III	71.7	74.9	77.8	80.9	84.3

49,500 in 1976 to 39,600 in 1980, a 20% reduction. In summary, the figures suggest that many familiar production, consumption, and milk price trends would continue if a dairy import program similar to the one now employed were continued.

Import Level II

Import level II represents an intermediate dairy import policy (3.2 billion pounds milk equivalent) of the type that the Comptroller General identified as needing study. This level also was of interest since dairy imports under this plan are similar in size to actual U.S. dairy imports in 1973 and 1974, which totaled 3.9 billion pounds and 2.9 billion pounds of milk equivalent, respectively, and which were identified by the U.S. dairy industry as a major cause of a reduction in milk prices that occurred in 1974.

The model predicted that under import level II the Wisconsin all milk price, Grade A milk price, and Grade B milk price would be $8.56,

$8.70, and $8.34, respectively, in 1976 (table 1). This would have put the all milk price, Grade A price, and Grade B milk price $0.32 (3.6%), $0.29 (3.2%), and $0.36 (4.1%) lower, respectively, than under import level I.[2] Since dairy imports under import level II exceed those for import level I by 1.5 billion pounds, each billion pounds of milk equivalent of dairy imports under import level II over and above those for import level I would have reduced the Wisconsin all milk price, Grade A milk price, and Grade B milk price by $0.21, $0.19, and $0.24, respectively, for 1976. After three years, farm milk prices were projected to recover substantially. For example, by 1978, the Wisconsin all milk price under import level II was projected to rise to within $0.07 of the price for import level I, and by 1980 the Wisconsin all milk price was up to within $0.04 of the price under import level I. The recovery of milk prices occurred largely because milk production increased by a smaller amount under import level II than under import level I. This smaller increase in production reflected short-term supply response and the exit of farmers from the dairy business. The model projected that the increased imports under import level II would cause the number of dairy farms in Wisconsin to fall by an additional 1,500 (3.8%) by 1980 compared with farm numbers under import level I.

For the five years 1976–80, farm cash receipts from sales of Wisconsin milk were projected to be $338 million (4.0%) lower under import level II than under import level I (table 1). On a per farm basis, the cash receipts averaged 1.1% lower under import level II than under import level I during 1976–80.

Cheese production in Wisconsin plants would average about 5% lower under import level I than under import level II during 1976–80. However, U.S. cheese consumption would average less than 1% higher for 1976–80 under import level II than under import level I. Thus, the model forecasts some displacement of Wisconsin cheese by the imports, but little overall change in cheese consumption in the U.S. under import level II.

Consumer prices for cheese and butter in the U.S. and fluid milk prices in Chicago were forecast to average 1.4%, 1.3% and 0.3% lower, respectively, under import level II than under import level I during 1976–80. This result is perhaps not surprising since dairy imports under level II differ only modestly from those for import level I. Moreover, transportation cost increases that the model passes along to consumers in the form of higher prices offset much of the reduction in consumer prices that the increased dairy product imports would have produced.

The near doubling of imports under import level II compared with those for the benchmark run was projected to have a fairly moderate impact on farm milk prices in particular.[3] This was surprising in view of the large drop in farm milk prices that followed the increase in dairy imports in 1973 and 1974.[4] The explanation lies in factors other than dairy imports. In 1974, the impact of increased dairy imports was exacerbated by a recovery of milk production, some weakening of demand for dairy products, and an increase in butter imports at a time when butter prices already had begun to fall. In this study, a stronger market situation was forecast for 1976–80 than existed in 1974. The underlying market strength was forecast to more nearly offset the effects of increased imports on milk prices than was the case in 1974. This accounts for the price strength forecast for 1976–80 in the face of the larger dairy imports.

Import Level III

Import level III represents a larger departure from present import programs. However, this plan might be counted among the feasible plans, since both the USDA and the Comptroller General suggest that foreign suppliers (mainly those from EEC countries, Australia, and New Zealand) could supply the United States with as much as 6.2 billion pounds of

[2] The differential impact of the larger dairy imports under import level II on Grade A and Grade B milk prices is related to the uses made of these two grades of milk. Grade B milk meets only the sanitary standards for producing manufactured milk products. Grade A milk can be used to produce both fluid milk and manufactured milk products. Thus, as expected, the Grade B milk price was depressed to a greater extent by the larger dairy imports than was the Grade A milk price.

[3] However, the yearly average figures obscure the more pronounced reductions in farm milk prices that were projected to occur under import level II. For example, for the first quarter of 1976, the model projected that the Wisconsin all milk price would fall $0.51 below the comparable price for import level I. This was a $0.19 larger reduction than was projected to occur for the year 1976 as a whole.

[4] The Wisconsin all milk price declined from $8.70 in March 1974 to $6.77 in July 1974 (23%). The decline in the Minnesota-Wisconsin manufacturing milk price was from $8.15 to $6.29 (23%) during this same period. These reductions in farm milk prices occurred after U.S. dairy import quotas were relaxed to permit imports of 447 million pounds of cheese, 87 million pounds of butter, and 381 million pounds of nonfat dry milk during 1973 and early 1974.

milk equivalent in manufactured milk products yearly if U.S. dairy import quotas did not exist.

Projections were that under import level III, the Wisconsin all milk price, Grade A milk price, and Grade B milk price would be $7.96, $8.14, and $7.64, respectively, in 1976. This placed the Wisconsin prices for all milk, Grade A milk, and Grade B milk $0.92 (10.4%), $0.85 (9.5%), and $1.06 (12.2%) lower, respectively, than under import level I for 1976. Each billion pounds of milk equivalent of dairy imports under import level III over and above those for import level I would have reduced the Wisconsin all milk price, Grade A milk price, and Grade B milk price by $0.20, $0.19, and $0.24, respectively, for 1976.

As was the case under import level II, Wisconsin farm milk prices would recover substantially during 1976–80. For example, in 1980 the Wisconsin all milk price under import level III was only $0.12 less than the price for import level I. The impetus for the price recovery again stems from factors that reduce milk supplies. The number of Wisconsin dairy farms was projected to fall to about 35,000 in 1980 under import level III, which was a 12% greater drop in farm numbers than was projected for import level I. This decline in farm numbers plus supply adjustments by farmers remaining in business were projected to cause Wisconsin milk production to average about 8% less during 1976–80 under import level III than under import level I.

Farm cash receipts from sale of Wisconsin milk for the five years 1976–80 were projected to be $1.0 billion (12.1%) lower under import level III than under import level I (table 1). On a per farm basis, the cash receipts averaged 3.2% lower under import level III than under import level I during 1976–80.

Under import level III, the amount of cheese produced in Wisconsin plants would be substantially lower, but limited change was projected for U.S. cheese consumption and retail cheese prices. Cheese produced in Wisconsin plants would have been about 14% lower under import level III than under import level I in 1980. U.S. cheese consumption was 2.0% larger under import level III in 1976, but by 1980 this difference declined to 0.3%. Retail prices of cheese averaged about 4.0% lower over 1976–80 under import level III than under import level I. However, in 1980 the cheese price was only 1.8% lower under import level III than under import level I. The modest reduction in retail prices for cheese under import level III occurs because increased transportation costs and other factors largely offset the impact of larger dairy product imports on the retail prices.

Grade A milk production rises from 65.5% of the Wisconsin total in 1976 to 84.9% of the total in 1980 under import level III (table 1). Thus, in 1980 the percentage of milk produced as Grade A milk was projected to be 6.2% higher under import level III than under import level I. Under import level III, the Grade A milk price would increase by $1.42 during 1976–80 or by $0.16 more than the Grade B price. This widening of the differential of the Grade A milk price over the Grade B milk price accounted for the accelerated conversion to Grade A milk production. The increase in the percentage of Grade A milk would make more of Wisconsin's milk eligible for fluid markets. Such an increase might make Wisconsin's dairy economy less vulnerable to damage from dairy product imports and other factors that impinge most heavily on manufacturing milk prices.[5]

Import Level IV

The simulated dairy product imports under import level IV are identical in terms of milk equivalent to those considered by the USDA in the study of the open U.S. market policy. Thus, the imports equal 12.2, 13.4, 10.5, 9.2, 8.0, and 6.7 billion pounds of milk equivalent for 1975, 1976, 1977, 1978, 1979, and 1980, respectively. The decline in manufactured milk imports after 1976 reflects the assumption that dairy product exports to the United States would not be maintained at the 12 to 13 billion pounds of milk equivalent level because dairy product surpluses available for export from EEC countries would decline after 1976. In general, the open U.S. market policy represents a scenario where the United States would eliminate dairy price supports and import quotas, but other countries would be free to pursue dairy export policies of their own choosing. Consult the USDA's 1975 dairy import study for a full discussion of the assumptions relating to this policy.

Under import level IV, U.S. cheese imports

[5] However, reduced vulnerability is by no means certain. In order for the increase in proportion of Grade A milk production to have such an impact, it would be necessary for producers to find or develop new fluid markets for the larger supplies of Grade A milk.

ranged from 1,100 million pounds in 1976 to 550 million pounds in 1980, and U.S. butter imports ranged from 200 million pounds in 1976 to 100 million pounds in 1980. On a pounds of manufactured product basis, cheese imports comprised about 85% of the total and butter imports comprised 15% of the total. However, in terms of milk equivalent, cheese imports comprised only 68% of the imports and butter comprised 32% of the total under import level IV. Butter imports comprised a larger percentage of the dairy imports under import level IV than under import levels I, II, and III.

Comparison of Results

A new run was made with the model for 1975–80 with dairy imports set at level I (1.7 billion pounds of milk equivalent) to secure benchmark figures that could be compared with those reported by the USDA for these years. The new benchmark run was identical to that described earlier for 1976–80, except that actual values were used for the exogenous variables when possible.

The model predicted that the Wisconsin all milk price, Grade A milk price, and Grade B milk price under import level IV would be \$6.56, \$6.85, and \$6.05, respectively, in 1975. This would place the 1975 Wisconsin prices for all milk, Grade A milk, and Grade B milk \$1.47 (18%), \$1.37 (17%), and \$1.68 (22%) lower, respectively, than under import level I.

Each additional billion pounds of milk equivalent in dairy product imports in addition to the 1.7 billion pounds for import level I reduced the Wisconsin all milk price, the Wisconsin Grade B milk, and the Wisconsin Grade A milk prices by \$0.14, \$0.16, and \$0.13 per hundredweight, respectively, for 1975 as compared with prices under import level I. Thus, the additional units of dairy imports were projected to reduce farm milk prices by a smaller amount than was the case for import levels II and III. This occurred because of the different composition of the imports associated with import level IV. The model simulates a pattern of behavior under which dairy imports displace cheese and butter produced in Wisconsin and the remainder of the United States in proportion to their historical shares of production of these products. A relatively small share of the milk produced in Wisconsin has been processed into butter in recent years. In 1975, for example, only about 13% of the milk produced in Wisconsin was processed into butter, while 54% of the state's milk was processed into cheese. Thus, since butter comprised a larger percentage of the dairy imports under import level IV than under import levels II and III, the impact per billion pounds of milk equivalent imported on Wisconsin farm milk prices was projected to be lower under import level IV than under import levels II and III.

Wisconsin milk production would rise 4.1% from 16.3 billion pounds in 1975 to 17.0 billion pounds in 1980 under import level IV, which is substantially less than the 9.3% increase projected for import level I. The differing levels of milk production under the two plans are due, in part, to differences in the rate of decline in farm numbers. There were projected to be 5,100 (13%) fewer Wisconsin dairy farms in operation under import level IV than under import level I by 1980.

Consumer prices under import level IV exhibit a pattern similar to that under import levels II and III. For example, U.S. retail cheese and butter prices under import level IV for 1975 were 14% and 17% lower, respectively, than under import level I. However, by 1980 retail cheese and butter prices under import level IV were nearly the same as under import level I.

Comparison with the USDA's Results

The USDA projected that U.S. wholesale milk prices would have declined by 22% from \$8.94 under present programs to \$6.94 during 1975 under the open U.S. market policy. The comparable reduction predicted for import level IV in the present study was from \$8.03 to \$6.56 (18%) for 1975 (table 2). The USDA's figures imply that each additional billion pounds of milk equivalent imported over and above 1.7 billion pounds under present dairy programs would have depressed U.S. wholesale milk prices by \$0.19 per hundredweight in 1975. As indicated earlier, the comparable reduction projected for the Wisconsin all milk price was \$0.14 per hundredweight. The price reductions predicted by the two studies for 1975 under the open U.S. market policy are of similar size. Also the pattern of price recovery projected by the two studies was similar for 1975–80 (table 2). The moderately faster recovery forecast for Wisconsin farm milk prices occurs partly because Wisconsin milk production was projected to fall

Table 2. Milk Prices and Milk Production under the Open U.S. Market Policy

	USDA Study		This Study	
	U.S. All Milk Wholesale Price	U.S. Milk Production	Wisconsin All Milk Price	Wisconsin Milk Production
	% of Benchmark Values[a]			
1975	78.0	96.7	81.6	92.6
1976	88.0	91.6	91.0	84.1
1977	95.4	92.6	100.7	83.1
1978	99.0	93.0	101.3	85.2
1979	101.7	93.4	101.9	87.2
1980	104.9	93.8	103.4	88.5

[a] The benchmark figures for both the USDA study and the present study were developed with U.S. dairy imports of 1.7 billion pounds of milk equivalent per year.

by a larger percentage and to rebound less by 1980 than production for the United States as a whole under the open U.S. market policy (table 2).

The USDA projected that U.S. dairy farm numbers would decline by an additional 17,300 (8.5%) by 1980 under the open U.S. market policy as compared with the situation that would exist if present dairy programs were continued. This estimate was 4.5 percentage points smaller than the 13% reduction that was projected for Wisconsin for 1980 under import level IV. However, the two estimates appear to be consistent, since a moderately larger decline in farm numbers might be expected in Wisconsin where a larger percentage of the milk produced enters the production of manufactured milk products. Thus, both the present study and the USDA study suggest that sizable reductions in dairy farm numbers would result if an import program involving substantially larger dairy imports were adopted.

Summary and Implications

A computer experiment was conducted for 1976–80 with dairy imports established at 3.2 billion pounds of milk equivalent (designated as import level II). This experiment suggested that the 1976 Wisconsin farm all milk price would have been only about $0.32 (4%) lower under import level II than under a program with dairy imports at 1.7 billion pounds of milk equivalent. This projected reduction in farm milk prices was smaller than one that occurred in 1974 after actual U.S. dairy imports reached a level similar to that of import level II. In 1973–74, increasing milk production, weakness of the demand for some dairy products, and the timing of imports exacerbated the impact of dairy imports on domestic milk prices. In this study, more normal conditions were assumed to exist during the period of the experiment. Thus, the projected impact of the imports on farm milk prices was less. In general, the study suggests that imports in the 3.0 to 4.0 billion pounds of milk equivalent range would necessitate only moderate adjustments by the Wisconsin and U.S. dairy industries if such imports entered the U.S. when markets for dairy products were generally strong. Imports of this size could be disruptive and destabilizing under other circumstances.

A similar computer experiment was conducted for 1976–80 with dairy imports established at 6.2 billion pounds of milk equivalent (designated as import level III). This experiment indicated that 1976 Wisconsin farm milk prices under import level III would have fallen $0.92 (10%) below the level that would have prevailed in 1976 if dairy product imports had equaled 1.7 billion pounds of milk equivalent. Wisconsin all milk prices under import level III were projected to recover by 1980 to within $0.12 of those that would have existed if imports had been 1.7 billion pounds of milk equivalent, as farmers adjusted milk production and exited from the business. Wisconsin dairy farm numbers were projected to be 12% lower in 1980 under import level III than programs with imports equal to 1.7 billion pounds of milk equivalent. For 1976–80, total farm cash receipts from sale of Wisconsin milk were projected to be $1.0 billion (12%) lower under import level III than under the program with dairy imports at 1.7 billion pounds of milk equivalent.

The effects of operating under a hypothetical open U.S. market were simulated for 1975–80. Wisconsin's all milk price for 1975

under the open U.S. market policy would have been about $1.50 (18%) lower than the price for 1975 under a program where dairy imports equaled 1.7 billion pounds of milk equivalent. After about three years under the open U.S. market policy, Wisconsin farm milk prices would recover to levels near those that would exist under present dairy import programs. But this recovery would occur because many dairy farmers would be forced out of business. The study projected that within five to six years after adopting the open U.S. market policy the number of dairy farms in Wisconsin would fall about 13% below the number that would remain in business under present dairy import programs. Thus, these findings are consistent with the USDA's findings with respect to the impact of larger U.S. dairy imports equivalent to 25% of U.S. consumption of manufactured milk products. However, they tend to dispute claims of the Atlantic Council and Flanigan reports that the U.S. dairy industry would be required to make only small adjustments to accommodate these larger dairy imports.

The Impact of Imports of Manufactured Milk Products on the U.S. Dairy Industry

Andrew M. Novakovic and Robert L. Thompson

Recent events have sparked a debate over the effects of increased dairy imports on the U.S. dairy industry. This study attempts to estimate these impacts via an econometric model of the U.S. dairy sector. The time paths of adjustment of consumption, production, and price of specific dairy products and raw milk are estimated under three alternative levels of manufactured milk product imports. The analysis suggests that much larger than historically "normal" import levels are required to bring about a substantial impact upon the dairy industry in the longer run.

Key words: agricultural policy, capital theory, dairy imports, dairy products, milk, trade policy.

Considerable debate on U.S. dairy policy has been generated by events in 1972–75. Section 22 of the Agricultural Adjustment Act authorizes the president of the United States to impose quotas on imports of manufactured dairy products. These quotas permit the domestic dairy price support program to function without supporting dairy prices throughout the rest of the world. From the late 1960s into the 1970s, dairy imports were restricted to about 1.5% of domestic consumption. This relationship quiescently persisted until, as production of milk declined, domestic prices of manufactured dairy products rose substantially above support levels in 1972. As prices continued to rise, the government repeatedly increased quotas on American cheese, butter, and nonfat dry milk for brief intervals over a period from 1973 to mid-1974. The quotas were raised above normal levels once for butter, twice for cheese, and five times for nonfat dry milk.[1] These quota changes resulted in the annual import levels reported in table 1. Although the exact effect of these increased imports is not known, it appears that the reduction of dairy product prices in early 1974 can be partially attributed to the high level of imports.

The Tokyo round of multilateral trade negotiations under the General Agreement on Tariffs and Trade (GATT) has also generated interest in the impact of changes in dairy trade policy on the U.S. dairy industry. In the negotiations, the United States is seeking reductions in barriers to its agricultural exports in the face of stiff opposition from the European Community (EC). Several studies of the impact of freer trade on U.S. agriculture indicate that, while an increase in exports could be expected for most agricultural products, an inflow of dairy products could be expected; i.e., the United States has a comparative disadvantage in manufactured dairy products (U.S. Congress; Johnson 1973, 1975; Vermeer et al.). Hence, it has been suggested that the United States should open its dairy market to the EC in exchange for greater access to the EC for American feed grains.

One concern is the potential impact of freer trade on the U.S. dairy industry. Johnson es-

Andrew M. Novakovic is a graduate research assistant and Robert L. Thompson is an assistant professor in the Department of Agricultural Economics, Purdue University.

Journal Paper No. 6611, Indiana Agricultural Experiment Station. Helpful comments and criticism were received in the course of this study from E. M. Babb, R. F. Fallert, R. G. Lattimore, B. A. McCarl, G. L. Nelson, G. E. Schuh, J. K. Whittaker, two anonymous *Journal* reviewers, and the editor of this *Journal*. The authors bear responsibility for any remaining errors or deficiencies in the final product.

[1] The butter import quota was raised from about 0.7 million pounds to 84 million pounds from 1 November to 31 December 1975. The American cheese quota was raised from approximately 10 million pounds to 64 million pounds from 25 April to 31 July 1973 and again to 100 million pounds from 3 January to 31 March 1974. The nonfat dry milk quota of about 1.8 million pounds was raised to five different levels during five periods as follows: 25 million pounds from 30 December 1972 to 15 February 1973; 60 million pounds from 11 May to 30 June 1973; 80 million pounds from 19 July to 31 August 1973; 100 million pounds from 29 August to 31 October 1973; and 150 million pounds from 6 March to 30 June 1974.

Table 1. Raw Milk Production and Consumption and Imports of Selected Major Products, in Million Pounds

Year	Raw Milk Production	Fluid Milk Consumption	American Cheese		Butter		Nonfat Dry Milk	
			Consumption	Imports	Consumption	Imports	Consumption	Imports

Sources: Butter and nonfat dry milk import levels obtained from USDA (1976). American cheese import levels obtained from various issues of the USDA *Dairy Situation*.

Note: All figures are reported in actual product weight except for fluid milk consumption, which is the milk equivalent on a fat-solids basis of all fluid milk products. The USDA (1965) reports the following factors for converting pounds of American cheese, butter, and nonfat dry milk into a raw milk equivalent on a fat-solids basis, respectively: 8.703, 21.702, and 0.216 pounds of raw milk equivalent per pound of dairy product.

[a] Estimated.

timates a possible reduction of 25% to 30% in domestic milk production as a result of free agricultural trade (1973). Buxton and Frick, on the other hand, suggest that imports would remain a very small percentage of domestic production and only slightly depress production and prices under conditions of free dairy trade. The U.S. Department of Agriculture study (1975) of the impact of imports on the U.S. dairy industry supports the more optimistic view reported by Buxton and Frick.

Previous studies of dairy trade policy appear to rely heavily upon professional familiarity with world and local dairy conditions. This has been backed up by use of coefficient estimates from existing models to predict the impacts of changes in dairy imports measured in terms of a milk-equivalent aggregate. Our research adds to the existing literature by estimating the time paths of adjustment within specific dairy product sectors to changes in the levels of individual manufactured product imports via one unified model.

The Conceptual Model

An annual simultaneous equations model of the U.S. dairy industry is used to analyze the domestic impacts of increased dairy imports.[2] The model describes the dairy industry at three market levels: farm, wholesale, and retail. Raw milk is produced at the farm level; supply and use of major manufactured dairy product groups are explained at the wholesale and retail levels. Five major product groups are considered: fluid milk products, American cheese, butter, nonfat dry milk, and frozen desserts. All other products, such as specialty cheeses, condensed, evaporated, and canned milk, and dried whey, are treated as a sixth "other products" category.

The price determination mechanism is consistent with the federal Milk Marketing Order system. The Minnesota-Wisconsin base price, specified as a function of manufactured product and input prices, determines the price of class II milk (the milk used in manufactured products). The class II price is, in turn, used to determine the price of class I milk (the milk used in fluid products). Class I and II prices are then weighted by the respective proportions of class I and class II utilization to obtain the farm level (blend) price. Class I and II

[2] Several dairy sector models cast in the system of equations framework are currently available in the literature (Goldman, Hallberg and Fallert, Prato). Nonetheless, this paper explores several areas that have not been examined in detail in previous dairy sector modeling. First, a significant departure from the recent literature is the disaggregation of the model in terms of the number of dairy products. Certain other pieces of research have focused on specific products, some in greater detail than that used in this work. Yet, no study has looked at the import question in the detail used herein. Furthermore, no simultaneous estimation of dairy product supply and demand including a complete dairy sector is known to be available or in use for the United States (Sahi and Harrington's Canadian model does have this feature). See Novakovic (appendix A) for a more detailed review of this literature.

prices also affect wholesale prices of fluid and manufacturing milk products. Finally, retail product prices are determined as a function of wholesale prices via margin relations.

The retail-wholesale components of the model are similar for each of the five major product groups. In general, the wholesale level consists of equations to determine production, year-end commercial stocks, year-end government stocks, and wholesale price. The retail level component of the model consists of equations to determine consumption and retail price. Of course, not all aspects of the general retail-wholesale component of the model apply to each product. Model details are specified in the econometric model presented below and in Novakovic.

The farm supply component of the model developed for this paper draws upon the work of Jarvis, Yver, Lattimore, and Freebairn and Rausser on the supply of beef. Their approach takes as a point of departure the fact that the cattle herd is a capital stock. Changes in that stock represent investment or disinvestment decisions. The capital value of a dairy animal equals the sum of the discounted values of the future stream of net income from the sale of milk produced by the animal, the salvage value of the animal, and the net value of future calves (the value of a heifer calf being determined by the discounted value of the milk it will produce and its future calves, and so forth *ad infinitum*) (Jarvis, p. 506). An increase in the expected price of milk raises the dairy animal's capital value. Therefore, farmers are expected to retain more animals for use in future production when there is an increase in the expected price of milk, *ceteris paribus*. Furthermore, for a given change in the expected price of milk, the change in the capital value of an animal is greater for those animals further from expected slaughter. Therefore, different retention behavior is hypothesized for each age cohort in response to a given change in the price of milk.

Imports of butter, American cheese, and nonfat dry milk are treated as exogenous. The supply of imported products is implicitly taken to be perfectly price inelastic due to the section 22 quotas on imports. This assumed exogeneity of imports has implications for the range of applicability of the model. This is demonstrated in figure 1.

Line *AB* represents the positively sloped excess supply curve of the rest of the world (for given exchange rates), and *CD* represents

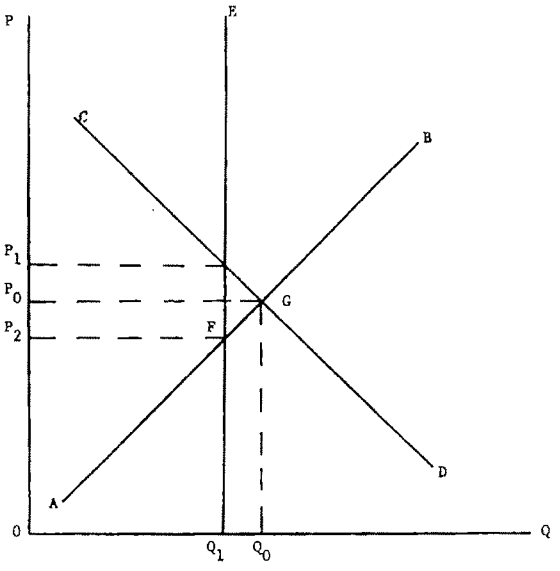

Figure 1. Domestic and world market price effects of a dairy import quota

the excess demand of the United States for a particular product.[3] Under free trade the equilibrium price is OP_0 and the quantity of imports is OQ_0. However, the imposition of a quota that limits imports to any level less than OQ_0, such as OQ_1, raises the domestic price to OP_1 and depresses the world market price to OP_2. With such a quota, the effective excess supply curve is *AFE*. However, treating imports as exogenous implies that the effective excess supply curve is Q_1E. This presents no problem as long as the quota is binding, i.e., *F* is left of *G*. If this assumption is violated such that *CD* intersects the effective excess supply curve along the segment *AF*, the model employed overstates the level of imports and understates the market price. The model would behave as if the quota was binding even though in reality it is not.

Such a problem is unlikely for import levels of about 1.5% of domestic consumption, the level at which imports were held in the United States prior to the increases in 1973 and 1974. Nonetheless, this discussion suggests a limita-

[3] The excess demand curve is the locus of the differences between the U.S. demand curve and the U.S. supply curve at given U.S. prices. The excess supply curve is computed as the locus of the differences between the supply curve and demand curve of the rest of the world and reflects the foreign (trade weighted) currency price. The price arguments of the U.S. excess demand function are denominated in U.S. dollars; hence, the price arguments of the excess supply curve of the rest of the world must be converted into U.S. dollars via an appropriate trade weighted exchange rate. Exchange rate changes or changes in foreign dairy price policy shift the foreign excess supply curve in U.S. dollar space.

tion of treating imports exogenously in this model (or any other model). When the level of imports is parametrically increased to estimate the domestic effects of increases in the quota, at some point a situation is reached in which the specified level exceeds OQ_0, and the analysis breaks down. To pinpoint quantity OQ_0, knowledge of the slope and position of the excess supply curve of the rest of the world, AB, is required. Estimation of the export supply structure of the rest of the world, a research effort of major proportions, is beyond the scope of the present study.

The Statistical Model

The parameters of the simultaneous equations model were estimated via two-stage least squares (2SLS) using annual data for 1955–74. Since the number of observations is less than the number of exogenous variables in the model, nine principal components, which explained at least 95% of the variation in the predetermined variables, were computed. These components were used in the first stage of the 2SLS procedure.[4] All estimated equations are linear. Variables in the model are defined in table 2.

Empirical results are reported in tables 3 through 8. Some experimentation was involved before the estimates shown were obtained. Due to a high degree of intercorrelation among many variables, it is difficult to

[4] Estimates obtained in this manner are statistically consistent, but little is known of their small sample properties. For a more detailed discussion, see Kloek and Mennes.

Table 2. Definition of Variables

Endogenous Variables

EC	$= NC_{t-1} + NH_{t-1} - NC$ (thousands of cows)
EH	$= NHC_{t-1} - NH$ (thousands of heifers)
NC	= Thousands of cows and heifers two years old and over kept for milk, on farms 1 January in year $t + 1$
NH	= Thousands of one- to two-year old heifers kept for milk cows, on farms 1 January in year $t + 1$
NHC	= Thousands of heifer calves under one year kept for milk cows, on farms 1 January in year $t + 1$
$PAC(R)$	= Average retail price of cheese in leading cities (¢/1/2 lb. package)
$PAC(W)$	= Average wholesale price of American cheese at Wisconsin assembling points (40 lb. block) (¢/lb., f.o.b.)
$PB(R)$	= Average retail price of butter in leading cities (¢/lb.)
$PB(W)$	= Average wholesale price of 92 score butter in Chicago (¢/lb.)
$PFM(R)$	= Average retail price of fresh, grocery milk in leading cities (¢/1/2 gal.)
$PFM(W)$	= Weighted average f.o.b. price of standard grade, 3.5% milk paid by dealers for distribution in fluid form ($/cwt.)
PI	= Average price received by farmers for milk eligible for the fluid market ($/cwt.)
$PIC(R)$	= Average retail price of ice cream in leading cities (¢/1/2 gal.)
$PIC(W)$	= Wholesale price index for bulk ice cream (1967 = 100)
PII	= Average price received by farmers for manufacturing grade milk ($/cwt.)
PMW	= Price received for Minnesota-Wisconsin 3.5% manufacturing grade milk ($/cwt.)
$PNFDM(W)$	= Manufacturer's average selling price of nonfat dry milk (¢/lb.)
PPC	$= \frac{QRM}{NC} \cdot 1{,}000$ (lb./cow)
PRM	= Average price received by farmers for all milk sold to plants ($/cwt.)
$QAC(RD)$	= Commercial civilian disappearance of American cheese excluding donations (millions of pounds)
$QAC(WS)$	= Production of American cheese (cheddar plus other American) (millions of pounds)
$QB(RD)$	= Domestic civilian disappearance of butter excluding donations (millions of pounds)
$QB(WS)$	= Production of butter (millions of pounds)
$QFD(RD)$	= Domestic civilian disappearance of net milk used in frozen dairy products (millions of pounds)
$QFD(WS)$	= Production of frozen dairy products (millions of pounds of net milk used)
$QFM(RD)$	= Domestic civilian disappearance of fluid milk and cream products excluding donations (millions of pounds of raw milk equivalent on a fat-solids basis)
$QFM(WS)$	$= QFM(RD) + DFM + QFM(M)$ (millions of pounds of raw milk equivalent on a fat-solids basis)
$QNFDM(WD)$	= Domestic civilian disappearance of nonfat dry milk (millions of pounds)
$QNFDM(WS)$	= Production of nonfat dry milk (millions of pounds)
QO	$= QRM - QFM(WS) - 10.0QAC(WS) - 21.2QB(WS) - 11.4QNFDM(WS) - QFD(WS)$ (millions of pounds of raw milk equivalent on a fat-solids basis)
QRM	= Production of all dairy products and fluid milk (millions of pounds of raw milk equivalent on a fat-solids basis)

Table 2, cont.

SAC(C), SB(C), SNFDM(C)	= Ending commercial stocks of American cheese (*AC*), butter (*B*), and nonfat dry milk (*NFDM*) (millions of pounds)
SAC(G), SB(G), SNFDM(G)	= Ending USDA stocks of American cheese (*AC*), butter (*B*), and nonfat dry milk (*NFDM*) (millions of pounds)
Exogenous Variables	
AFNFDM	= Utilization of nonfat dry milk in animal feed (millions of pounds)
AI	= Dairy cows bred artificially to dairy and beef bulls (percentage of *NC*)
CPIAF, CPIF, CPINF, CPISSP	= The consumer price index for all foods (*AF*), frankfurters (*F*), nonfoods (*NF*), and sugar and sweet products (*SSP*) (1967 = 100)
DIFFI	= *PI* − *PII* ($/cwt.)
DIFFII	= *PII* − *PMW* ($/cwt.)
DAC, DB, DFM, DNFDM	= USDA donations of American cheese (*AC*), butter (*B*), fluid milk products (*FM*), and nonfat dry milk (*NFDM*) (millions of pounds)
MAC, MB, MFD, MNFDM	= Imports of American cheese (*AC*), butter (*B*), frozen desserts (*FD*), and nonfat dry milk (*NFDM*) (millions of pounds)
PAC(S), PB(S), PNFDM(S)	= USDA purchase price of natural cheddar cheese grade A or higher (*AC*), butter grade A or higher (*B*), and nonfat dry milk, extra grade, spray process (*NFDM*) (¢/lb.)
PF	= Estimated value of concentrate rations fed to milk cows ($/cwt.)
PO	= Price of colored oleomargarine in leading cities (¢/lb.)
QAC(M), QB(M), QFD(M), QFM(M), QNFDM(M)	= Domestic military disappearance of American cheese (*AC*), butter (*B*), frozen desserts (*FD*), fluid milk products (*FM*), and nonfat dry milk (*NFDM*) (millions of pounds)
W(R)	= Average hourly earnings of production and nonsupervisory workers on private nonagricultural payrolls in grocery, meat, and vegetable stores ($/hr.)
W(W)	= Average hourly earnings of production and nonsupervisory workers on private nonagricultural payrolls in the dairy products industry ($/hr.)
T	= 1 for 1955, 2 for 1956, . . . , 20 for 1974.
XAC, XB, XNFDM	= Exports and shipments of American cheese (*AC*), butter (*B*), and nonfat dry milk (*NFDM*) (millions of pounds)
Y	= Total disposable personal income (billions of dollars)

Note: Sources of the data are listed in Novakovic, appendix E. In general, data were obtained from standard USDA and other governmental publications.

distinguish the relative effects of some explanatory variables. Several variables suggested as relevant by theory or logic are omitted from individual equations. The criteria for eliminating variables are primarily the consistency of each parameter estimate's sign with a priori expectations and the size of the standard error relative to the parameter estimate (see Novakovic, pp. 54–68, for details).

Several problems were encountered in es-

timating the retail-wholesale submodels. The most persistent, if not perplexing, problem was that the sign of the estimated coefficient of the price of cheese was contrary to a priori expectations. This suggests that factors causing rightward shifts in the demand for cheese, such as increasing preference for cheese, were not adequately accounted for by the set of explanatory variables originally specified. This hypothesis is supported by the fact that consumption has been increasing as the price of cheese has increased. Attempts to account for a shifting demand with various price and trend variables were not successful. Hence, the retail demand equation was reestimated with the cheese price coefficient constrained to equal −5,210.4, an estimate based on Boehm's cross-section demand study.[5]

[5] Boehm reports an own price elasticity of demand for American cheese of −1.44, based on an analysis of cross-sectional economic and demographic data collected during late 1972 and early 1973. Using comparably measured price and quantity data, the model for this paper was constrained to have the same price elasticity for the 1972–73 period as that computed by Boehm.

Wholesale supply:
$$PNFDM(WS) = \underset{(5.69)}{-29.452} + \underset{(0.00215)}{0.00365}QNFDM(WS) + \underset{(1.61)}{15.218}PII - \underset{(1.95)}{5.912}W(W)$$

Market clearing:
$$QNFDM(WS) = QNFDM(WD) + SNFDM(C) + SNFDM(G) + DNFDM + QNFDM(M) + XNFDM + AFNFDM - MNFDM - SNFDM(C)_{t-1} - SNFDM(G)_{t-1}$$

Estimation of a reasonable own-price coefficient also proved to be a problem in the butter demand equation. In this case leftward shifts in demand were inadequately represented by the original set of explanatory variables. One likely factor explaining this shift is a change in consumer preference resulting from concern about the level of fat and cholesterol in the diet. Use of a trend variable results in a more plausible estimate of the price parameter.

The equation that determines the quantity of other products supplied is specified as an identity; hence, no estimation is required. It is necessary, however, to determine technical coefficients that would convert the product supply variables into raw milk equivalents on a fat-solids basis. Coefficients reported by the USDA (1965) are used to convert American cheese, butter, and nonfat dry milk quantities to raw milk equivalents on a fat-solids basis.

The results for the raw milk supply submodel reported in table 8 represent the most significant departure from previous dairy sector models. Other studies have found the price of beef to be an important variable explaining the quantity of milk produced (for example, Wipf and Houck). Such studies typically model the supply of milk as a single equation, expressing the quantity of milk supplied as a function of the price of beef. The price of beef is included in these models on the rationale that an increase in the price of beef causes farmers to reduce their herd size, which in turn reduces total milk production.

The estimated coefficients of the price of beef in the herd size equations suggest that an increase in the price of beef tends to increase the herd size at all age cohorts and thus increase current production of milk, as well as to provide the basis for future increases in milk production, *ceteris paribus*. This result is consistent with those obtained in analyses of the beef sector, which used a capital theoretic

formulation of the supply of beef. For example, Jarvis found that among Argentine beef ranchers an increase in the price of beef led to a short-run decrease in slaughter. An increase in capital value, brought about by a beef price increase, implies that it is profitable to retain animals longer, i.e., delay slaughter, and thereby increase future slaughter through short-run investment in the herd.

It appears that other studies have found a significant negative relationship between the price of beef and raw milk production because a rather high negative correlation exists between the price of beef and raw milk production (−0.78 in our data). In other words, studies using a single milk supply equation may have obtained the expected result for the wrong reason. The evidence from this study suggests that an increase in the annual beef price, *ceteris paribus*, tends to encourage short-run expansion of the dairy herd in response to the associated increase in the capital value of the dairy animal.

The Impact of Import Levels

In order to estimate the effects over time of changes in manufactured milk product import levels, the Gauss-Seidel technique is used to simultaneously solve the thirty-seven equations in the model.[6] The model is first solved for a base period, year 1, using the observed values of all predetermined variables. Next, import levels for American cheese, butter, and nonfat dry milk are parametrically varied from those in the base year, and the model is solved recursively for ten years (years 2 through 11) to estimate the time paths of adjustment to the specified changes in import levels. Lagged endogenous variables equal the appropriate values from the previous year. Imports are held constant at the levels established in year 2; i.e., changes are assumed to be once and for all. All other exogenous variables are maintained at their base period levels. The base year chosen is 1974, the last year for which data are available and the second of the two years in which dairy product imports are permitted substantially above their historical levels.

[6] The model presented in this paper contains several nonlinearities in the form of price ratios in demand equations and multiplication of endogenous variables to determine the supply of raw milk and the blend price. These nonlinearities preclude use of the more familiar matrix inversion technique of Theil and Boot to solve the system. A more detailed discussion of the Gauss-Seidel technique and its uses can be found in Heien, Matthews, and Womack.

Three different scenarios are evaluated. Scenario 1 investigates a return of import levels from their 1974 highs to the more or less normal levels observed in the earlier 1970s (about 1.5% of consumption). Specifically, scenario 1, the "normal" case, sets imports at 20 million pounds for American cheese, 2 million pounds for butter, and 2 million pounds for nonfat dry milk. An analysis of the impact of import levels twice that of the "normal" case is provided in scenario 2. This level is approximately the level that a USDA study (1975) suggests might initially result from free trade in dairy products. Specifically, the levels examined in the "twice normal" case are 40 million pounds for American cheese and 4 million pounds each for butter and nonfat dry milk. Scenario 3 is a "high" import quota case, examining the impact of continuing American cheese, butter, and nonfat dry milk imports at approximately the 1973–74 levels—100, 50, and 100 million pounds, respectively.

The simulated impacts of the import levels in each of the three scenarios on production, consumption, and prices of the various dairy products and raw milk are summarized in table 9. Selected results are also illustrated graphically to better display the basic trends and patterns of adjustment.

Figure 2 illustrates the adjustment made at the farm level in the price of raw milk. Following an initial increase, the price of raw milk in scenarios 1 and 2 converges to a level approximately equal to the base period level after three years. Continuation of relatively high import levels in scenario 3 results in a price that is 14¢ per hundredweight lower than the base price by year 11.

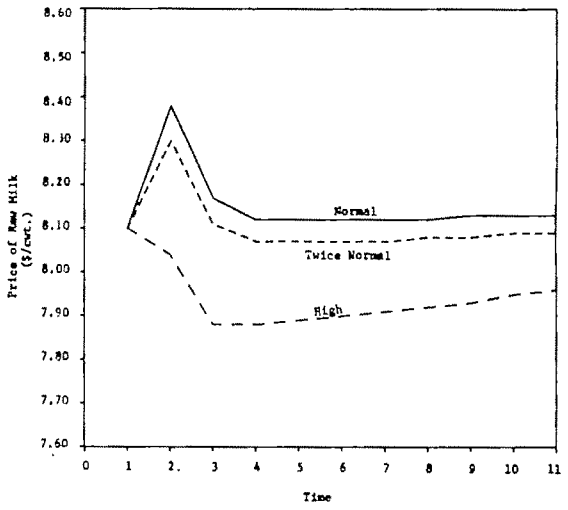

Figure 2. The effect of import levels on the price of raw milk

Milk production, shown in figure 3, initially increases but then decreases in the following years. By the eleventh year, production is down 2.7% under scenario 1 and 13.5% under scenario 3, when compared with the base year. (Adjustments in the dairy cow herd follow a similar pattern.)

Figures 4 through 6 illustrate the adjustments at the wholesale level. In general,

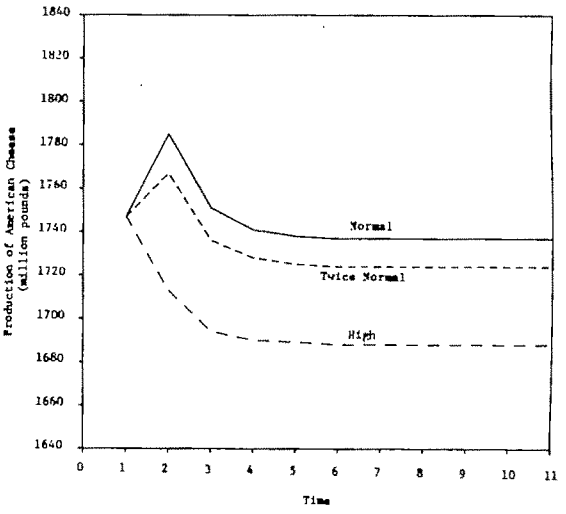

Figure 5. The effect of import levels on the production of American cheese

wholesale prices and production tended to be higher with lower import levels, as would be expected. Nevertheless, there were several exceptions. Figure 4, which shows the changes in the quantity of fluid milk produced, illustrates the pattern of the production response in both the fluid and frozen dairy products sector. Production is higher in all periods under scenario 3 than under scenario 1. These results seem to occur because of the changes in class I and II prices. As these prices decrease, production of fluid milk and frozen desserts is stimulated. This implies that raw milk is diverted to the production of nonimported products as manufactured product imports increase.

Production adjustments in the cheese and butter sectors are represented by the results for American cheese shown in figure 5. In both cases, higher imports lead to lower production. However, nonfat dry milk production responds somewhat differently. Nonfat dry milk imports in 1974 total 115 million pounds. In scenarios 1 and 2, import levels are set much below this level at 2 and 4 million pounds, respectively. At these low levels, production under scenario 2 is higher than that under scenario 1. In scenario 3, in which nonfat dry milk imports equal 100 million pounds, import levels are so high that they bring about lower production levels than those for the

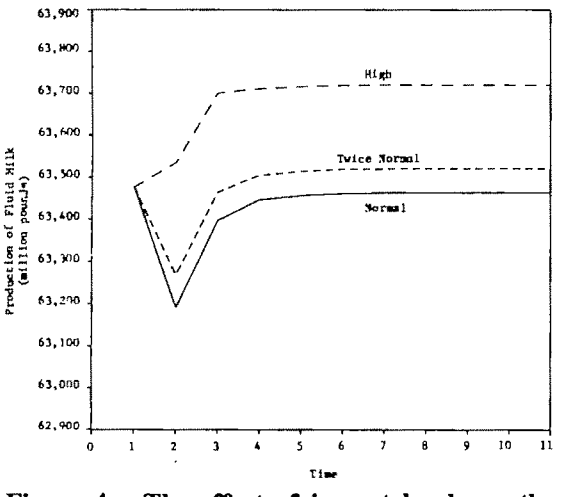

Figure 4. The effect of import levels on the production of fluid milk

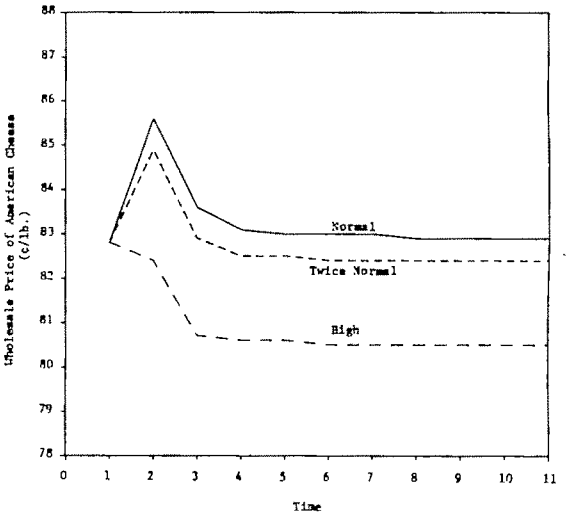

Figure 6. The effect of import levels on the wholesale price of American cheese

"normal" case. This response can be explained as follows. Cross-price effects are also found to be insignificant in the nonfat dry milk supply equation. Thus, as the class II price decreases relatively more under scenario 2 than under scenario 1, nonfat dry milk production is stimulated in the same way as fluid and frozen dairy product production. However, imports are so high under scenario 3 that the own price effect dominates the effect of cheap input prices and thus leads to a lower level of nonfat dry milk production.

Wholesale price responses, illustrated by the price of American cheese in figure 6, are similar for all variables except butter. The wholesale price of butter is lower at lower import levels apparently because a cross-price effect is present in this case. Specifically, the coefficient of the price of nonfat dry milk as estimated in the butter supply equation reflects a complementary relationship between nonfat dry milk and butter. Thus, the higher price of nonfat dry milk at low import levels stimulates butter production, which leads to a lower butter price.

At the retail level, increased imports are generally associated with increased consumption and decreased prices. The response in the butter sector is just the opposite, i.e., consumption decreases and price increases. Because the wholesale butter price is higher with higher imports, the retail price increases, and thus consumption decreases. In any case, there is practically no difference in the price or consumption of butter among the three scenarios. In each, butter consumption fluctuates between 900 and 899 million pounds.

The impacts of changes in import levels on the consumption and retail price of American cheese are illustrated in figures 7 and 8, respectively, and are representative of the impacts on the remaining dairy products.

The difference in the magnitudes of the endogenous variables between scenarios 1 and 2 seldom exceeds 1% in any given year (table 9). The differences between scenarios 1 and 3 are typically in the range of 1% to 5%. Nonfat dry milk production, consumption, and price, raw milk production, the number of cows, and other product production tend to be the more volatile variables, especially other product production.[7] Furthermore, following some

[7] Since the quantity of other products produced is computed as a residual, it is subject to the largest potential prediction error. Hence, the larger differences between scenarios 1 and 3 (up to 70% by year 11) are not surprising.

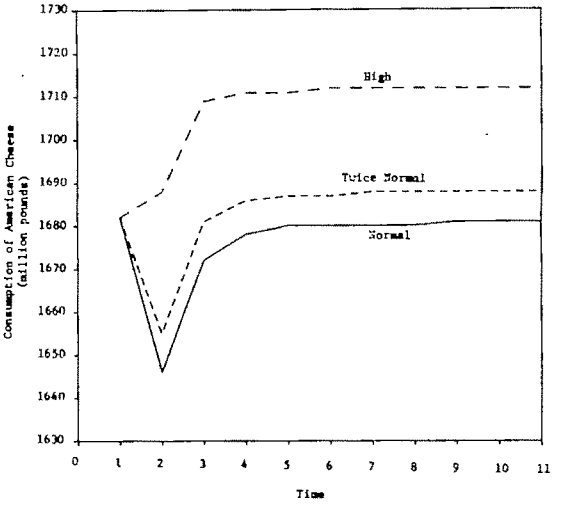

Figure 7. The effect of import levels on the consumption of American cheese

initial fluctuations, most variables under scenarios 1 and 2 tend to converge to a level approximately equal to the base year value by year 4. Only production of butter, nonfat dry milk, other products and raw milk, and the number of cows and heifers deviated more than 1% from the base year by the eleventh year under scenario 1.

Several facts should be borne in mind when comparing specific results. One is that the ratio of base year import levels to those under the three scenarios varies markedly for butter, American cheese, and nonfat dry milk. American cheese imports under scenarios 1 and 3 equal about 18% and 90% of base year American cheese imports, respectively. Nonfat dry

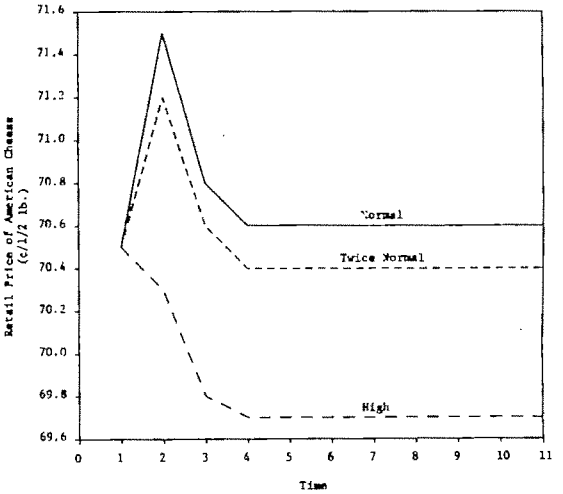

Figure 8. The effect of import levels on the retail price of American cheese

milk imports under scenarios 1 and 3 equal about 2% and 87% of base year nonfat dry milk imports, respectively. Imports of butter had already returned to historically normal levels by 1974, the base year. Thus, butter imports under scenarios 1 and 3 are 100% and 2500% of that in the base year, respectively. This suggests that the impact of a change in imports on the different dairy products within any scenario should not be expected to be identical.

The different ratios of imports to consumption of the various dairy products under the three scenarios also affect interproduct comparisons. For example, imports of American cheese, butter, and nonfat dry milk under the "high" import case represent 4.7%, 5.3%, and 14.7% of observed consumption, respectively. With this in mind, it becomes apparent why three of the variables that deviated most from scenario 1 values under scenario 3 are nonfat dry milk production, consumption, and price.

Implications

Rather large changes in import levels are required to bring about substantial impacts on the dairy industry. As table 9 illustrates, the difference in the magnitudes of almost all endogenous variables under "normal" and "twice normal" import levels is less than 1%. Only when imports are a much larger proportion of consumption, as in scenario 3, does a significant impact upon the dairy sector appear. For example, in scenario 3, the price of raw milk is 17¢ or 2% lower than that in scenario 1 by the eleventh year. Even at the widest divergence between raw milk prices in scenarios 1 and 3 (in year 2), the difference is only 4% or 34¢.

Although comparisons of these results with those obtained in other studies are difficult because of the different techniques and models used, these results suggest a more modest impact than that derived in other studies. The USDA (1975) estimates a decline in the raw milk price of 18¢ per hundredweight for each additional billion pounds of aggregate dairy imports measured in terms of milk equivalents. Using this value, the level of imports under scenario 3 should result in a raw milk price that is about 30¢ lower than that in scenario 1. This is about the same as our computed short-run response in years 2 and 3, but it is much greater than the computed difference by year 11. Using "open U.S. market" import levels from the USDA study, Salathe, Dobson, and Peterson estimate that an increase in aggregate imports of one billion pounds is accompanied by an 11¢ decrease in the price of raw milk in Wisconsin.[8]

When comparing these results, several factors should be kept in mind. The USDA and Salathe, Dobson, and Peterson studies are based on imports much higher than those under current programs. The "open U.S. market" policy assumes aggregate imports representing 25% of manufactured milk consumption; this compares with an average import of about 1% to 2% during the last twenty years. Such high levels were not examined in this study because it was felt that extrapolating so far beyond the range of the data would severely strain the credibility of the results. In addition, as discussed in connection with figure 2, one runs the risk of setting imports above the level that actually would enter the market under free trade, in which case erroneous implications would result.

The aggregate impacts of changes in imports are unlikely to be distributed uniformly over the milk-producing regions of the United States. Quite different impacts of increased butter and cheese imports would likely be felt by dairy farmers in Wisconsin, New York, Iowa, and California.[9] In regions characterized by different alternative uses for their resources, the fixity of capital and labor is likely to be an important factor determining the nature of the response and the ability of the farmers to respond. Asset fixity may also be an important element affecting the rate of adjustment of the dairy processing sector. Were data on the capital stocks of the dairy farming and dairy processing sectors available, an analysis of their adjustments could be cast in the same capital theoretic framework as were dairy herd adjustments in this model.

Perhaps an even more basic question than that of the regional impacts is the question of just how high dairy imports would be under a freer dairy trade policy. This paper does not

[8] Since Wisconsin produces a relatively much larger proportion of manufactured milk than the United States as a whole, it is plausible that the impact of dairy imports would be more harsh in Wisconsin than in most of the rest of the country. In that case, Salathe, Dobson, and Peterson's results would imply that the aggregate impact on the U.S. market would be much less than that predicted by the USDA (1975).

[9] Salathe, Dobson, and Peterson have investigated that impact of dairy imports on Wisconsin. To estimate the differential impact of dairy import policy on various regions of the United States, a regional model of the U.S. dairy industry would be required.

attempt to answer this question. To do this would require structural estimates of export supply functions for butter, cheese, and nonfat dry milk for each of the important dairy exporting countries. The relationship between prices and excess supplies of dairy products in the rest of the world remains one of the most critical questions in dairy trade policy. To the authors' knowledge, no rigorous modeling efforts exist in the literature that estimate these critical relations, and there is little agreement on the likely orders of magnitudes of price-quantity relationships.

As indicated previously, one deficiency of this U.S. model is that it applies only to import levels below those which would be experienced under free trade, i.e., at levels below OQ_0 in figure 1. Without more information concerning the slope and position of the excess supply relations of the important dairy exporting countries, that level cannot be estimated with much certainty. To this end the authors suggest the need for modeling efforts for the dairy sectors of at least the European Community and Oceania.

Notes

Technically Efficient Movement Patterns and Manufacturing Plant Locations under Regionally Coordinated Milk Assembly

William T. Boehm and M. C. Conner

The organization and subsequent marketing activities of regional dairy producer cooperatives in the United States have recently been the subject of public debate (Hudek, Hutt). The debate has centered on what role, if any, such regional organizations should be permitted in the assembly, movement, and processing of raw milk. To date, these public discussions have focused attention on what effect, if any, the regional dairy cooperatives have had on the level of raw milk prices. A related question within the context of these public sector concerns is how the activities of these regional organizations affect the technical operating efficiencies (i.e., the costs) involved in performing the raw milk assembly function. For the most part, this question has been ignored. It has been simply assumed that an atomized milk assembly system would also be technically efficient.

The research reported in this paper is an attempt to determine the seasonal raw milk movement patterns and manufacturing plant locations that would minimize the combined costs of assembling all raw milk produced in a specific geographic region and processing the raw milk not delivered to bottling plants for fluid use into a manufactured product form. It is hypothesized that if (*a*) the economies of size in manufactured product processing are substantial relative to transportation costs, so that the optimal number of such plants "needed" within the region is small, and (*b*) the optimal movement patterns from production areas to all plants in the region are seasonal in nature, then cost minimization for the region can only be accomplished with a relatively high level of coordination in the handling of raw milk and within an organizational structure that allows individual producers to be indifferent as to the ultimate disposition of their production.

The analysis is conducted within the southeastern region of the United States, roughly including the nine-state area east of the Mississippi River and extending south from Ohio and West Virginia. A regional dairy producer cooperative in the area makes *ex ante* commitments to deliver specified quantities of fluid eligible raw milk to the already existing bottling plants in the region. The raw milk produced but not sold for use in the fluid form is then processed into cheese, butter, or powdered milk by either the cooperative or proprietary handlers. Thus, taking as given the number, size, and location of the fluid bottling plants, the research problem becomes one of determining the seasonal movements for all milk and the number, size, and location of "hard-product" manufacturing plants that will minimize movement and processing costs. Obviously, the size and location of the manufacturing plants cannot be determined without simultaneously considering optimal movement patterns to the fluid bottling plants.

William T. Boehm is an assistant professor of agricultural economics and M. C. Conner is a professor of agricultural marketing at Virginia Polytechnic Institute and State University.

Research Procedures and Data

Mathematically, this research problem can be stated as a linear programming problem, and the solutions can be obtained using a modified version of the transportation algorithm. For this study, the algorithm is modified to permit transshipment and to incorporate approximately the effects of nonlinear economies of size in raw product processing.[1] Readers not familiar with the mechanics of these modifications or their effect on the nature of the solution obtained may refer to the referenced publications by King and Logan or Roe. The solution system developed for this study has been documented and is available from the authors (Boehm).

Grade A milk production by county and fluid milk deliveries to ninety-seven major fluid bottling centers in the region are developed for October 1974 and May 1975.[2] Counties in the relatively dense milk production areas of the region are identified as separate production sources. Milk from several

[1] The use of a nonlinear solution method would have been preferred. Practical considerations regarding both the computing time and storage capacity required for such a solution largely prohibit their use, given the level of disaggregation desired. Furthermore, since plants tend to operate at capacity, it is doubtful whether using nonlinear procedures would result in any significant changes in the final solution.

[2] During 1975 raw milk was packaged in roughly 200 plants in the study area. The quantities packaged in these plants were aggregated for ninety-seven geographic areas. In Kentucky, for example, eighteen plants were packaging fluid milk in 1975, but five of these plants were at locations with more than one plant. Therefore, only thirteen bottling centers are identified for Kentucky.

counties is aggregated to form a single raw milk source in the lower density production areas. While the bottling center locations are taken as given, thirty-one geographically dispersed sites are chosen as potential locations for the manufacturing plants.

Three transportation cost functions are developed to reflect the cost differentials associated with variations in the terrain and production density and in order to incorporate certain of the limitations imposed on milk movement by its highly perishable nature. The functions used for the study and a detailed description of the procedures employed in their development are contained in the report by Boehm and Conner.

Processing cost functions are developed using an engineering cost approach for both cheddar cheese and combination butter and powdered milk plants. The detailed procedures followed in deriving these relationships are reported by Conner, Boehm, and Pardue. The functional relationships, estimated by ordinary least squares, express total processing costs for each plant type as a function of the monthly quantity of raw milk processed and are as follows: $TCC = 42{,}466 + 0.5292q$, $R^2 = 0.997$, and $TCP = 49{,}730 + 0.4788q$, $R^2 = 0.998$, where TCC is the total cheese processing costs (dollars per month), TCP is the total butter-powder processing costs (dollars per month), and q is the quantity of raw milk processed (hundredweight per month).

These total cost functions have the same interpretation as those used by Stollsteimer. The intercept is interpreted as the minimum average annual long-run cost of establishing and maintaining a plant. The slope coefficient is an estimate of the marginal processing cost.

Monthly raw milk production levels allowed for the synthesized cheese plants range from 32,250 hundredweight for the minimal practical operation to 255,850 hundredweight for the largest plant operating at maximum capacity. Operating levels permitted for the combination butter and powder plants are from 34,060 to 331,000 hundredweight of raw milk per month.

The level of disaggregation proposed for the problem prohibits the use of a solution procedure that would simultaneously incorporate the effects of seasonality in production and in fluid consumption in determining the optimal number, size, location, and type of manufacturing plant (either cheese or combination butter and powder) as well as the associated optimal seasonal milk movement patterns to all plants in the region. Therefore, a solution to the cost-mimimization problem is obtained using the transportation algorithm, the data described above, and two research phases. In phase one, milk movement patterns to fluid bottling centers and optimal manufacturing plant locations are obtained for four independent and static situations. A movement pattern and plant location set is obtained for each season, May and October, given the assumption that all plants manufacturing excess Grade A milk in the region are cheese plants. Two additional solutions are obtained by assuming that, in each season, all manufacturing plants are combination butter and powder operations. These solutions permit the identification of a least-cost plant set for use in phase two. In that phase, least-cost movement patterns and operating levels are determined for the optimally located plant set in an effort to identify the movement patterns to all plants and the operating levels for the manufacturing plants that would result in minimizing the total costs of raw milk movement and manufactured product processing throughout the year.

Phase One Results

Manufacturing plant locations and their associated operating levels for the two product types in both May and October are summarized in table 1. The impact of processing economies on the ultimate

Table 1. Optimal Manufacturing Plant Location Sets During May and October

Cost summary ($)[a]				
Processing cost/cwt.	0.708	0.728	0.646	0.712
Assembly cost/cwt.	0.348	0.356	0.350	0.357

[a] Processing costs are for the manufactured product only. Assembly costs include the movement of raw milk used for both fluid bottling and manufactured product processing.

number of plant sites selected is obvious. Regardless of the season, manufacturing plants tend to operate at the maximum capacity permitted for the type of plant being considered. Plants are located in those areas where milk production is dense relative to fluid consumption.

In May, only five plant sites are selected by the model for manufacturing excess Grade A milk into cheese. Four of these plants operate at maximum capacity. In October, only two plants are needed to process the available milk into cheese. Average assembly costs for all milk increase from $0.348 to $0.356 when only two manufacturing plants are operated.

Average processing costs for combination butter and powder plants are $0.065 per hundredweight higher in October than in May. Less than 65% of the required capacity is utilized to process the raw milk available for manufacturing in that month. In May, almost 90% of the available capacity is utilized to process the available milk. Average assembly costs for all milk increase $0.007 per hundredweight from May to October, reflecting the increased movement necessary when fewer manufacturing plants are operated.

Long-haul movements through transfer stations are avoided in the cost-minimizing solutions obtained in phase one. In almost all cases, transport costs are less than $0.50 per hundredweight. When possible, milk production from nearby sources is used to satisfy fluid consumption requirements. In those areas where local production is not adequate, additional raw milk for fluid bottling is obtained by a process of "dominoing" milk toward the bottling center in a series of 100 or 150 mile movements. Milk for the manufacturing plants is also obtained from nearby production sources and not by transporting "excess" milk from widely separated fluid consumption areas. While the use of transfer stations is avoided by the model, neither the four-day fluid processing schedules nor the weekly or daily market shocks, which often necessitate raw milk storage facilities, are taken into account. Providing such facilities would undoubtedly increase total costs. Where they would be located is a researchable question, of course, but is not considered in this study.

Phase one results also indicate the importance of considering explicitly the seasonal variations in both production and consumption when solving for least-cost milk movement patterns. The least-cost pairing of milk sources with specific plants changes substantially from May to October. In the high production spring season (May), milk for fluid bottling is obtained from nearby sources generally moving milk toward the northern markets, where the milk in excess of fluid requirements could be most economically aggregated for manufacture. In October, the least-cost pairings indicate that milk for fluid bottling, while still coming from nearby sources, is transported in a north-to-south direction. In total, milk from only 174 of the 290 production sources goes to the same plant in both seasons. Quantities delivered indicate even more variability.

Phase Two Results

Information gained from these phase one solutions is used to select the locations and plant types for a single plant set, so that least-cost movement patterns and operating levels could be obtained for the entire marketing year. The five locations identified in table 1 are chosen as sites for the optimal manufacturing plant set. Three of these locations, 102, 112, and 128, are designated for cheese plants. The other two, 115 and 121, are designated as locations for combination butter and powder plants. This plant set provides the model with sufficient capacity to process all the milk available during the high production May season without substantial excess capacity and, implicitly recognizing the revenue considerations, also contains a combination of both cheese and butter-powder plants. The cheese plants are located in those areas that would permit, in so far as is possible, continual operation throughout the year. While per unit costs at high volumes of operation are lower in the butter and powder plants, the critical role skilled labor plays in the successful operation of a cheese plant and the need to meet market commitments from the current production of some cheeses persuade us to choose this alternative.

The least-cost milk movement patterns to all plants and the implied operating levels for each of the manufacturing plants in the specified plant set are determined for each season. The results of these analyses are summarized in table 2. Two of the cheese and one of the butter and powder plants operate at or near the maximum capacity permitted

Table 2. Impact of Seasonal Variation in Milk Availability on Processing

	Product Type	Volume Processed (Cwt.) May	October
Plant ID and location			
102, Kentucky	Cheese	250,379	133,900
112, Tennessee	Cheese	128,706	8,775
115, Tennessee	Butter-powder	318,347	113,727
121, N. Carolina	Butter-powder	234,642	100,347
128, Louisiana	Cheese	255,850	0
Cost summary ($)[a]			
Processing cost/cwt.		0.697	1.034
Assembly cost/cwt.		0.348	0.353

[a] Processing costs are for the manufactured product only. Assembly costs include the movement of raw milk used for both fluid and manufactured product processing.

for that product type during the May period. The average per unit cost of processing during that period is $0.697 per hundredweight. In October, none of the five plants operate at capacity. The cheese plant at location 128 actually ceased operating entirely. The other four plants operate at between 30% and 50% of capacity. Assuming the intercept of the cheese processing cost function is a reasonable estimate of fixed costs, per unit costs of processing the 43 million pounds of raw milk not consumed in the fluid form during October would be approximately $1.034. That represents almost a $0.34 per hundredweight increase from average processing costs in the May season.

The milk movement patterns indicated by these phase two solutions reinforce the earlier findings that cost-minimizing solutions imply the ability to make seasonal adjustments in the source to destination pairings. As in phase one, specific source to destination pairings change substantially from May to October. Average assembly costs for all milk, even in October, are approximately $0.35 per hundredweight.

Implications

The results indicate that, if total costs of milk assembly and hard product processing are to be minimized over the year, it must be possible to alter milk movement patterns on a seasonal basis. Furthermore, even within a season, individual producers must be indifferent as to the ultimate disposition of their production. This result may provide the best evidence that there are strong economic incentives encouraging the development of the highly coordinated regional milk assembly systems. It is significant that the milk movement patterns to the optimally located milk manufacturing plants identified in this study are substantially different than would likely be the case if the milk assembly function were not coordinated on a regional level. Under uncoordinated atomized systems, producers would be associated, on an annual basis, with specific, localized fluid-use outlets, and the seasonally variable amounts of "excess" fluid milk would accumulate near the bottling plants. If manufacturing facilities were maintained locally, they would likely be small-scale, high-cost operations. Alternatively, aggregating these geographically scattered quantities of "excess" milk in sufficient volume for efficient processing would undoubtedly increase transport costs. Under a regionally coordinated system, as shown in this study, neither situation arises, since combined costs are minimized for the region on a seasonal basis.

Supporting this conclusion is the fact that economies of size in the processing of raw milk into manufactured products tend to be relatively more important than transport costs in determining the optimal number of plants. Total costs continued to decline as plant numbers were reduced to the point where the number of the largest size plants operating at capacity was just adequate to process the available production. While this result tends to reaffirm the conclusions of earlier studies, it is significant that, even with substantially increased costs for energy, the relationship remains intact.

From a public viewpoint, consumer interest groups and others concerned about the effect of increasing industry concentration on retail prices for dairy products should at least be made more cognizant of the potential losses in technical efficiency that may occur if the milk assembly function is atomized. It appears that, for the U.S. dairy industry at least, reducing concentration in milk assembly in an attempt to improve pricing competition, which is difficult to specify at best, would not necessarily put long-run downward pressures on retail prices.[3]

The most dramatically apparent and easily identified inefficiency in the present system from producer through processor is the rather substantial seasonal variation in the amount of raw milk available for manufacturing. While total production in the region only varies by 12.6% over the year, the amount of milk available for manufacturing nearly triples from October to May, reflecting the fact that in this region milk for manufacturing is treated as a residual. There is some question about the ability of producers within the region to match production more nearly with seasonal fluid consumption. Clearly, however, since facilities with the sufficient capacity to handle the high production May season must be provided within the region, this inability is a costly component of the total system.

Both economic and political considerations severely limit the ultimate practicality of an industry organization similar to the one that results from this analysis (Kloth and Blakely). It appears, however, that substantial technical economies remain for an industry organization more concentrated and/or vertically coordinated than the one that exists today.

[3] If firms in any industry are forced by public policy measures to operate to the left of the minimum point on the long-run average cost curve, while there may be price competition, there can be no assurance that the actual market prices generated will be lower than if a monopolist, operating at or near the minimum point on the long-run average cost curve, set prices so as to maximize profit. Furthermore, while visible price competition may exist in the former case, the often heralded socially desirable consequences of perfect competition will remain unsatisfied.

Welfare Implications of Alternative Classified Pricing Policies for Milk

Boyd M. Buxton

Questions are being raised about the impact of federal regulations throughout our economic system. Some of these questions have focused on regulations in milk marketing. One particular concern is the impact of pricing milk according to its final use (usually referred to as classified pricing), a basic part of current federal milk marketing orders and many state regulations. In this note, a national aggregate model of the U.S. dairy economy is used to estimate the impact of changing the classified pricing policy on consumer prices of fluid and manufactured dairy products, returns to dairy farmers, and a measure of whether society gains or loses by such a policy change.

Under federal milk marketing orders or by individual state control, processors of fluid milk products are required to pay at least a minimum price for milk actually used in fluid products. In federal marketing orders, under which about 60% of the U.S. milk is marketed, this minimum class I price is calculated by formula utilizing the price paid for milk used in manufacturing in the Minnesota and Wisconsin area. Grade A milk not used for fluid consumption is sold for use in manufacturing at the lower manufacturing milk price. The Grade A milk that is not sold for fluid use, along with all manufacturing grade milk, makes up the available supply for manufacturing purposes. It is the supply of and demand for this milk available for manufacturing that determine the manufacturing milk price and, therefore, the market values of milk in the United States. The dairy price-support program currently places a floor under this manufacturing milk price.

In each federal order the total revenue from class I and manufacturing sales of Grade A milk is pooled and distributed back to Grade A milk producers as a blend price. Dairy farmers producing only manufacturing grade milk (mostly located in the North Central states) receive only the manufacturing milk price. The "all wholesale" milk price computed by the Statistical Reporting Service of the U.S. Department of Agriculture is a weighted price received by all dairy farmers.

The amount that the class I prices paid by processors of fluid milk products exceeds the U.S. average manufacturing milk price varies by region. In 1974, the actual or prevailing class I price (including premiums over minimum federal order prices) exceeded the U.S. manufacturing milk price by about $1.20 in Eau Claire, Wisconsin, while the difference was over $4.00 in Miami, Florida. For the continental United States, the average 1974 U.S. price per hundredweight paid by fluid processors for milk used for fluid ($9.57) exceeded the U.S. manufacturing milk price ($7.13) by $2.44. For this same year, the actual class I price per hundredweight in markets east of the Rocky Mountains exceeded the U.S. manufacturing price by about $1.20 plus 18.8¢ per 100 miles distance from Eau Claire, Wisconsin. In markets west of the Rocky Mountains (including California, which is not under a federal milk marketing order but under state control), class I prices per hundredweight were less than $1.20 plus 18.8¢ per 100 miles from Eau Claire, Wisconsin.

For the same year (1974), the "all wholesale" milk price received by farmers ($8.33) was $1.20 higher than the U.S. manufacturing milk price ($7.13). The difference between the U.S. manufacturing milk price and the "all wholesale" milk price usually has been about $1.00 per hundredweight. In summary, there are three basic prices determining milk supply and utilization in the United States: (*a*) the "class I" price paid by processors of fluid milk; (*b*) the "U.S. manufacturing" price paid by processors of manufactured milk products; and (*c*) the weighted "all wholesale" milk price received by dairy farmers.

Justification for Classified Pricing

Without classified pricing, there is potentially considerable class I price variability in fluid milk markets under current institutional arrangements. This variability would be expected because of the difficulty in balancing fluid demand with Grade A milk supply when fluid milk must be produced only days before it is consumed, must be produced under higher farm sanitary standards than Grade B milk, and is not produced in quantities equal to fluid demand throughout the year. Classified pricing is designed to encourage local production of enough Grade A milk during the low production season to meet the daily fluid requirement plus a reserve so

Boyd M. Buxton is an agricultural economist with the Economic Research Service, U.S. Department of Agriculture, and a professor in the Department of Agricultural and Applied Economics, University of Minnesota.

The author wishes to acknowledge the helpful suggestions of two anonymous reviewers.

that short- or long-supply conditions leading to potentially variable class I prices can be avoided.

Under the class I price differentials of the past, there has developed a trend toward all Grade A milk. In 1975, about 80% of total milk produced in the United States was Grade A, while only about 45% was used as fluid.[1] The amount of excess Grade A milk suggests that the differential between class I and manufacturing milk prices has been too large. Therefore, the average U.S. class I and manufacturing price differential likely would not be sustained by market forces if the minimum federal order class I differentials were reduced in all federal market orders.[2] The implications of a policy to change class I and manufacturing milk price differential are explored by Kessel.

Alternatives Analyzed and Model Used

The changes in milk prices, milk production, fluid consumption, and social welfare are estimated for three alternatives to the 1974 classified pricing policy. These alternatives are: (*a*) reducing the federal order minimum class I and manufacturing milk price differential in Eau Claire, Wisconsin, from \$0.90 to \$0.45 per hundredweight of milk and an equivalent decrease in all other markets (this would be approximately equivalent to lowering the U.S. average prevailing class I and manufacturing milk price differential from \$2.44 to about \$2.00); (*b*) reducing the federal order minimum class I differential in Eau Claire, Wisconsin, from \$0.90 to \$0.25 per hundredweight of milk and an equivalent decrease in all other markets (this would be approximately equivalent to decreasing the U.S. average prevailing class I and manufacturing milk price differential from \$2.44 to \$1.80); and (*c*) increasing the federal order minimum class I differential in Eau Claire, Wisconsin, from \$0.90 to \$1.14 and an equivalent increase in all other markets (this would be approximately equivalent to raising the U.S. average prevailing class I and manufacturing milk price differential from \$2.44 to \$2.68).

These alternatives reflect only changes in the classified pricing policy of milk and do not evaluate the elimination of classified pricing altogether. The reader should not interpret a zero class I differential as an evaluation of eliminating classified pricing because differences between class I and manufacturing prices, as currently measured, likely would still remain without a government classified pricing policy.

The conceptual framework used in this analysis is shown graphically in figure 1. The aggregate U.S. supply curve (labeled *S*) shows the quantity of milk produced in the United States at various all wholesale milk prices. The aggregate demand curve

[1] The 45% figure is milk equivalents on a fat solids basis. An estimated 49% of total milk was required to supply the product pounds of fluid milk and cream consumed in the United States in 1975.

[2] State milk marketing regulations, restrictions on the movement of milk for health standards or other reasons, and/or market power of farmer cooperatives could keep the class I and manufacturing milk price differentials from decreasing.

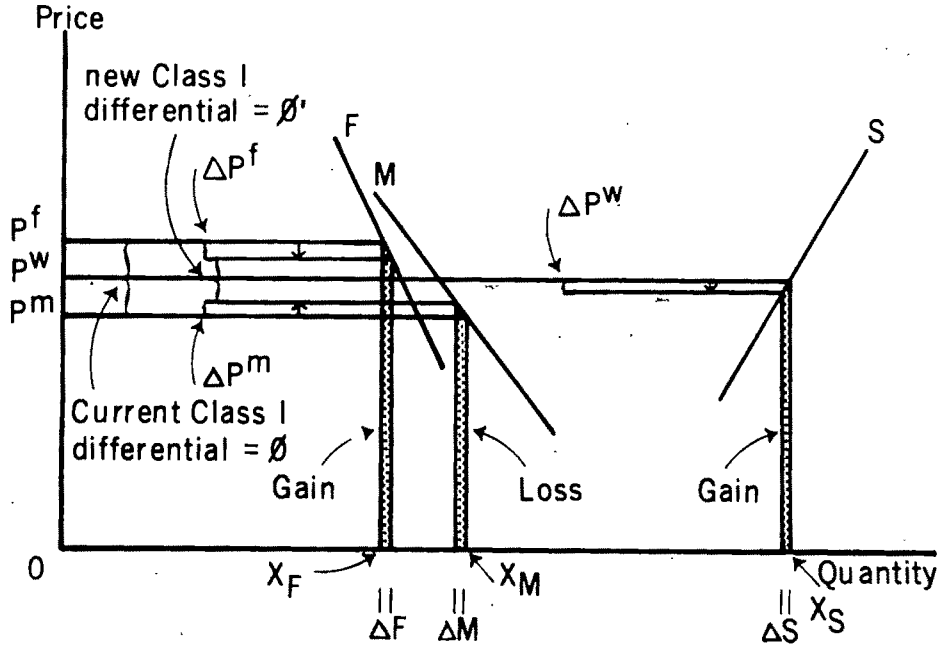

Figure 1. Partial equilibrium model illustrating the net social gain of reducing the U.S. average class I and manufacturing milk price differential

for fluid (labeled F) and manufacturing milk (labeled M) shows the quantity demanded at various fluid and manufacturing milk prices, respectively. The demand for manufacturing milk is derived from the demands for manufactured dairy products. Given the class I and the all wholesale milk price differentials above the U.S. manufacturing milk price, equilibrium is reached when the quantity demanded for fluid and manufacturing equals the total supply. This is represented in figure 1 when the distance OX_F plus OX_M is just equal to OX_S given the price differentials.

The model can be expressed as $F = a + bP^f$, $M = e + fP^m$, and $S = c + dP^w$, where a to f are intercept and slope parameters of the supply and demand equations, and F is the quantity of milk used in fluid products, M is the quantity of milk used in manufactured products, S is the total quantity of milk produced, P^f is the average U.S. class I milk price, P^m is the average U.S. manufacturing milk price, and $P^w = (FP^f + MP^m)/M + F$ = average all wholesale milk price received by farmers.

The policy variable determined under federal milk marketing orders is the size of the average differential between the U.S. class I and manufacturing milk price defined as $\phi = P^f - P^m$. The all wholesale and manufacturing milk price differential is then $\gamma\phi = P^w - P^m$, where γ is the proportion of total milk production used as fluid.

The equilibrium condition is $S - F - M = 0$. Lowering the class I and manufacturing milk price differential (from ϕ to ϕ' in figure 1) is expected to reduce, as shown by the model, the class I prices and the returns to the dairy farmers (lower all wholesale milk price). These price changes lead to an increase in fluid consumption and a decrease in total milk produced. This effectively reduces the quantity of milk available for manufacturing causing the manufacturing milk price to rise. The model, therefore, provides estimates of how the U.S. average fluid, manufacturing, and farm milk prices would change as a result of changing the class I and manufacturing milk price differential.

A Measure of Net Change in Well-Being

The conceptual basis for the measure of whether society is better off or worse off after a change in class I differentials includes an interpretation of what the supply and demand curves represent. (A more detailed discussion of these concepts is presented in Currie, Murphy, and Schmitz. Studies using a similar approach are reported in Wallace, Johnson, and Buxton and Hammond.) The area under the supply curve up to a given quantity produced is a measure of the total production costs in terms of all other goods and services that could have been produced with the resources used to produce that quantity of milk. The area under the fluid and manufacturing demand curves and above the horizontal axis up to the quantities consumed is a measure of the total value of milk consumed (net of processing costs) in terms of all other goods and services.

The gains and losses associated with reducing the class I milk price differentials in all markets are illustrated in figure 1. A new equilibrium, given the lower average U.S. differential, is estimated. The changes in the manufacturing, class I, and all wholesale milk prices and the changes in total milk supply, milk used as fluid, and milk used for manufacturing are then determined.[3] The shaded area under the demand curve for fluid milk represents the total gain to society brought about by lower fluid milk prices and the resulting higher fluid milk consumption. The shaded area under the manufacturing demand curve is a measure of the loss to society brought about by higher manufacturing milk prices and the resulting lower consumption. The shaded area under the supply curve is a measure of the gain, in terms of all other goods and services, to society brought about by using fewer resources to produce the smaller total milk supply.

Assuming the marginal utility of money is the same for all groups involved, a measure of whether society is better or worse off as the result of a decision to reduce the class I and manufacturing milk price differentials is obtained by adding the shaded areas under the fluid demand and supply curves and subtracting the area under the manufacturing demand curve.

Results

Table 1 shows the estimated milk prices, production and consumption, total value of sales, and the measure of net gain (loss) to society of changing the present classified pricing policy to each of the three alternative policies analyzed. Results are obtained using two assumptions about the elasticities of demand and supply: (*a*) the price elasticity of demand for fluid = −0.18, for manufacturing milk = −0.35, and for milk supply = 0.15, and (*b*) the elasticity of demand for fluid = −0.6, for manufacturing milk = −0.85, and for milk supply = 0.5.

Given the first elasticity assumption, the estimated net loss to society of increasing the class I milk price differential from $2.44 to $2.68 is $5.4 million annually (table 1). The dollar value of fluid milk sales would increase an estimated $67 million, while manufacturing milk sales would decline an estimated $32 million. Total revenue to dairy farmers would increase an estimated $35 million annu-

[3] This analysis assumes that the manufacturing milk price is at a market clearing level (above the price support). If the manufacturing milk price was at the price-support level with the government purchasing dairy products, lowering the class I and manufacturing price differential would not be expected to affect the manufacturing milk price. The full decrease in the differentials would be reflected in lower class I prices.

Table 1. Estimated Changes in Prices and Quantities and Annual Social Gain for Three Pricing Alternatives under Two Elasticity Assumptions

	1974 Actual	Alternative U.S. Average Class I and Manufacturing Milk Price Differentials

[a] An index of 100 was assigned to the U.S. average household purchases. Indexes then represent deviation of substrata considered from the U.S. average purchases of each dairy product.

ally or, based on 330,000 farms, $106 per farm. Fluid milk prices would rise an estimated 16¢ per hundredweight or about 0.7¢ per half gallon. Manufacturing milk prices would fall 8¢ per hundredweight or about 0.9¢ per pound of butter and 0.4¢ per pound of nonfat dry milk. Cheese prices would fall an estimated 0.8¢ per pound.

The estimated net gain to society of reducing the class I and manufacturing milk price differentials from $2.44 to $1.80 is $13.2 million annually. Fluid milk sales would decrease an estimated $186 million annually, while manufacturing milk sales would increase an estimated $84 million annually. Gross revenue to dairy farmers would decline $102 million or about $309 per farm. Fluid milk prices would fall an estimated 45¢ per hundredweight or about 2¢ per half gallon. Manufacturing milk prices would rise an estimated 20¢ per hundredweight or 2.2¢ per pound of butter and 1.1¢ per pound of nonfat dry milk. Cheese prices would be expected to rise about 2¢ per pound. The estimated impact of reducing class I differentials from $2.44 to $2.00 lies between the results just presented (table 1).

The results are sensitive to how consumers and dairy farmers would respond to price changes. The net social cost of decreasing the class I and manufacturing milk price differential from $2.44 to $1.80 increases from $13.2 million annually with elasticity assumption (*a*) to $33.1 million annually with elasticity assumption (*b*) (table 1).

Implications for Producers and Consumers

Lowering (raising) class I and manufacturing milk price differentials decreases (increases) aggregate returns to dairy farmers. The impact on prices received by farmers probably would not be proportional in all parts of the country. The regional differences are not considered in this paper, as the methodology is designed only to estimate the aggregate impact. Also, the impact on farm income would be much greater on large than on small farms.

Even though the net social gains reported in this study may be accurate, they are quite small relative to the impact on the dairy farmer's gross income and total consumer's expenditures. Hence, classified pricing of milk is much more important from the viewpoint of income transfers between consumers and producers than from the viewpoint of the net gain or loss to society in general.

Data from a 1972 national consumer panel showed that substratas of U.S. households who were heavy (light) consumers of fluid milk relative to the U.S. average tended to be heavy (light) consumers of manufactured dairy products (table 2). This implies that a decrease in fluid milk prices relative to manufactured dairy product prices would not greatly advantage one group relative to any other group within the U.S. population. However, the panel data indicated that relative to all other households the nonwhite and southern households probably would be advantaged somewhat, while households without children or with older children probably would be disadvantaged somewhat.

Wheat Protein Premiums and Price Differentials

Malcolm D. Bale and Mary E. Ryan

Agricultural commodity research typically investigates demand or supply response to changes in average price levels of a commodity or commodity group. Yet many production and marketing decisions depend upon relative prices of close substitute commodities and often the main demand or supply shifter for a product is the price of its closest substitute. Frequently, the substitute is a different quality, grade, or brand of the same commodity. (Tomek and Robinson provide a useful discussion on price differences, pp. 134–43.) These differences cannot be examined in empirical work where aggregate functions rather than separate, closely related functions are estimated. The research reported in this note investigates the relationships between different qualities of a commodity, adding to the sparse body of empirical work on this topic. A Lancaster "product characteristics" approach is used in differentiating classes of wheat by their protein content characteristic.[1] The specific objective is to generate a simple statistical model for analyzing the effect of changes in available supplies of wheat of various protein content on their relative prices. Prediction rather than complete behavioral understanding is the goal.

Historically, high protein wheats have been relatively scarce, bringing a higher price than lower protein wheats. The price differential is commonly called a "protein premium." The amount of premium for wheats of various protein content varies in response to changing supplies of, and demand for, the protein component of wheat. Demand for high protein wheat is derived from the demand for bread. The demand for low protein wheat is derived from the demand for biscuits, cakes and pastries, and livestock products.[2]

Occasionally, little or no premium is paid for protein. This occurred, for example, during several months in 1972, 1973, and 1974, a period when U.S. exports soared. Earlier research to investigate a possible negative impact of exports on protein premia found that supply factors were associated with much of the variability in the premia (Ryan and Bale, p. 31). Accordingly, this note focuses on the role of supply factors on relative price movements.

Protein is regarded as the differentiating characteristic in wheat. Since the object of this note is to estimate price variations, two price dependent functions of wheats of two different protein contents are specified. The quantity supplied of each commodity is assumed to be predetermined. No short-run supply response is possible because production and carry-in stocks are determined in the previous time period. Only one demand shifter is explicitly specified for each function—the quantity of the major competing wheat.

From the two price dependent functions, one function is formed for estimation, equation (1). The dependent variable is a ratio of the prices of the wheats. The price ratio defines protein premium rather than the more usual definition of price differences (Hyslop). We prefer a price ratio, since it avoids the need to deflate prices. The ratio can, of course, be converted to an absolute difference at any given level of either price:

$$(1) \qquad P_h/P_l = b_0 + b_1 S_h + b_2 S_l + b_3 PP_h + b_4 PP_l + e,$$

where P_h and P_l are the prices of high and low protein wheat, respectively, S_h and S_l are production plus carryover of high and low protein wheat, respectively, PP_h and PP_l are average protein percentages of the high and low protein crops, respectively, and e is an error term. Two variables in equation (1) account for the supply of protein available in each type of wheat. Protein supply varies with the quantity of wheat and its protein content. In both cases, an increase in supply is expected to be associated with a decrease in price of the commodity. Thus, the expected impact on the price ratio is negative for S_h and PP_h and positive for S_l and PP_l. (Opposite signs could occur if the cross-product effects exceed the own-product effects, a less typical case.)

Hard red spring (HRS) and hard red winter (HRW) wheats are selected to represent the high and low protein wheats of the model. Although HRW wheat is considered a "high" protein wheat relative to some other wheat classes, it is generally lower in protein content than HRS. U.S. produc-

(1.110)	(5.2)	(7.4)	(0.4)	(4.5)	(0.5)			

[a] t-ratios are given in parentheses, S is the standard error of estimate, and DW is the Durbin-Watson statistic.

Variable definitions: *PS13* and *PS14* are Portland prices of dark northern spring wheat, 13% and 14% protein content, respectively; *PW12* and *PWO* are Portland prices of hard winter wheat, 12% and ordinary protein, respectively; *MS15* and *MS13* are Minneapolis prices of dark northern spring wheat, 15% and 13% protein, respectively; *KW13* and *KWO* are Kansas City prices of hard red winter wheat, 13% and ordinary protein, respectively; *MTS* and *MTW* are Montana farm prices of HRS and HRW wheat, respectively; S_h is production plus carryover of HRS in the United States in billion bushels; S_l is production plus carryover of HRW in the United States in billion bushels; PP_h is average protein percentage of spring wheat produced in North Dakota, excluding durum; and PP_l is average protein percentage of winter wheat produced in Kansas.

tion and carryover data are employed for S_h and S_l. The average protein content of HRS and HRW crops in the two major producing states of each class are used for the protein percentage data. Price ratios analyzed are formed with prices from principal markets for HRS and HRW wheat and with farm prices from Montana where both classes of wheat are grown. Each ratio is formed with a HRS price in the numerator and a HRW price in the denominator.

The model is estimated by ordinary least squares, utilizing annual crop year data from 1965 to 1974. Earlier years were excluded because of the considerable impact of government programs on prices. The results are given in table 1, and figure 1 presents a plot of actual and estimated price ratios of the first equation.

The empirical results are consistent with the hypothesis that good estimates of relative wheat prices can be obtained from simple measures of protein supply. When the quantity of HRS protein increases, the spring to winter wheat price ratio (protein premium) decreases. Over 90% of the variation in each price ratio (except *PS13/PW12*) is associated with variation in the four supply variables. The addition of a linear trend variable to the *PS13/PW12* equation raises its R^2 to 0.98 and increases the significance of S_h, S_l, and PP_l.

The hard red spring wheat variables, S_h and PP_h, have larger and more significant impacts on all price

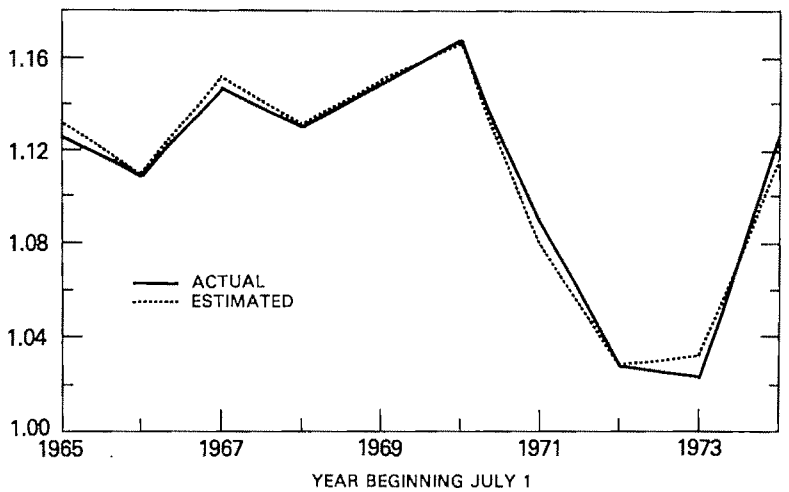

Figure 1. Actual and estimated values of the price ratio of Portland spring wheat 14% protein to winter wheat 12% protein

ratios than the HRW variables, S_t and PP_t. The supply of HRS wheat is the most important explanatory variable in each equation, according to the beta coefficients and t-ratios.

Some interesting differences among markets and pairs of prices are also revealed. Only in Portland, where both HRS and HRW wheats are marketed, do the HRW wheat variables (S_t and PP_t) have hypothesized signs and impacts approaching significance. Significant, but negative, relationships between PP_t and *MS13/KWO* and *MS15/KWO* emerged. Apparently, increased supplies of protein in the HRW crop caused a shift in the HRS demand curve that lowered Minneapolis 13% and 15% HRS prices relatively more than the reduction in the Kansas City price for HRW, ordinary protein wheat.

These results show that four supply variables can be employed in a simple formulation to estimate changes in relative prices of wheats with different protein content. Protein supplies in the HRS crop were more closely associated with changes in the HRS/HRW price ratios than protein supplies in the HRW crop. This note also illustrates that relative price movements between two closely related commodities can be explained by analyzing a common characteristic of the commodities.

Effects of Retail Pricing and Advertising on Fresh Beef Sales

T. F. Funk, Karl D. Meilke, and H. B. Huff

Beef products constitute a major source of revenue for Canadian supermarkets. It has been estimated that purchases of beef account for approximately 16% of total food expenditures by Canadian consumers (Hassan and Johnson). As a result, the development of effective marketing programs for beef is an important concern of retail food chain managers.

The purpose of this note is to present the results of a research project designed to estimate the retail demand for beef. Because of the management orientation of this research, all of the analysis is performed at the level of the individual supermarket chain and is oriented toward deriving price and advertising elasticities at an aggregate and individual cut level. Since the analysis only covers the period January 1974 through May 1975 and is restricted to the metropolitan Toronto market, extreme care should be taken in extrapolating these results to other time periods and other markets. However, the relatively simple methodology developed demonstrates the feasibility and ease with which individual chain analysts could conduct similar demand studies for their own market situations.

The Model

The basic model used in this research is a retail demand function in which the dependent variable is a measure of weekly beef sales for each chain, while the independent variables are own beef prices, competitors' beef prices, own substitute prices (pork, chicken, veal, and lamb), competitors' substitute prices, own advertising (beef, pork, and other meats), competitors' advertising, and seasonal factors. This formulation does not include three major classes of variables sometimes used in this type of analysis—retail availability, some measure of the "creative aspects" of advertising, and consumer income. In the case of retail availability, prior analysis showed that, during the seventeen-month period covered by the study, the number of retail outlets for each chain was almost constant. As a result, inclusion of this variable would not affect the results. In the case of the creative aspects of advertising, a review of the newspaper advertisements used by the chains reveals that the basic format and design of the advertisements were also more or less the same throughout the period. Thus, the assumption that the "creative variable does not vary" is plausible. Finally, in the case of consumer income, the time period covered by the study was short enough that this variable could not be expected to have any measurable effect.

In the model, local newspaper advertising is the only form of advertising used. The rationale for limiting the analysis to this single form of advertising is twofold. First, newspaper advertising constitutes over 60% of beef advertising expenditures and, hence, is by far the most important media used. Second, newspaper advertising is the only media in which specific products are highlighted (Funk and Meilke). Other media such as television, radio, and in-store displays are used by retail food chains, but the type of advertising used in these media is primarily oriented toward creating a favorable store or corporate image rather than pushing specific products.

To measure the sales response to advertising and price changes in the Toronto market, three classes of data are required: weekly sales levels of beef, weekly prices for beef and other meat products, and weekly newspaper advertising for beef and other meat products. Information on beef sales in Toronto was obtained from Dominion Stores Limited and Food City, two leading supermarket chains serving this market. Both chains were asked to supply data on weekly shipments of beef to all stores in their sales regions and to separate their total beef shipments into carcasses, front quarters, hind quarters, ribs, loins, chucks, hips, and manufacturing boneless beef.[1] Using procedures devel-

Thomas F. Funk is an associate professor and Karl D. Meilke is an assistant professor in the School of Agricultural Economics and Extension Education, University of Guelph; and H. Bruce Huff is an economist in the Economics Branch, Agriculture Canada, Ottawa.

This research was funded by the Commission of Inquiry into the Marketing of Beef and Veal. The views expressed in this paper are those of the authors alone and not necessarily those of the University of Guelph, Agriculture Canada, or the Commission of Inquiry into the Marketing of Beef and Veal.

[1] The fact that the analysis is based on shipments rather than sales is unfortunate, but there is no way to correct for weekly beef carryover by individual stores in the chains. Some of the beef shipped is not sold but held in inventory until the next week, causing some measurement errors in the dependent variables and causing the R^2 values to be lower than they otherwise would be. This point was verified by checking the residuals associated with each equation. In each case where the predicted value was substantially different from the actual value, this follows a week in which an unusually large shipment of beef was made. However, since

oped by the Canadian Cattlemen's Association, the carcasses, quarters, and primals were combined into carcass equivalents for the aggregate analysis and broken out into fourteen retail cuts for the individual cut demand analysis.[2] Although this procedure produces accurate estimates of carcass equivalents, it may introduce some error into the individual cut estimates, since it does not allow for differences in cutting percentages and procedures between chains.

The price data for beef and other meat products used in this research were obtained from the Ambler Pricing Service of Toronto. These data consist of weekly prices for eighteen major beef cuts sold by the five major Toronto food chains over the seventy-two-week period under study.

The advertising data were collected by means of a complete audit of the Toronto Star for the period January 1974 through May 1975.[3] The information collected in this audit consists of date, size of ad, chain, total number of advertised items, number of beef items, number of pork items, number of poultry items, number of veal items, number of lamb items, number of processed meat items, and the advertised prices for individual beef cuts.

Analysis and Results

Aggregate Demand Analysis

The first step in the analysis is to estimate aggregate demand functions for the two chains.[4] The dependent variable is total weekly beef shipments (carcass equivalents) to the stores, while the independent variables are: P is the own beef price, P_c is the competitors' beef price, RPP is the relative price of pork, RPL is the relative price of lamb, BA is the number of own beef ads, PA is the number of own pork ads, OA is the number of own other meat ads, BA_c is the number of competitors' beef ads, PA_c is the number of competitors' pork ads, and OA_c is the number of competitors' other meat ads.[5]

Table 1. Results of Aggregate Demand Analysis

Independent Variables	Dominion	Food City
Own price elasticities		
P	−1.52[a]	−5.97[a]
Cross-chain price elasticities		
P_c		3.77[a]
Cross-product price elasticities		
RPP	2.25	1.74
RPL		0.99[a]
Own advertising elasticities		
BA	0.12[a]	0.15[a]
PA	−0.13[a]	−0.04
OA	0.19[a]	−0.03
Cross-chain advertising elasticities		
BA_c	−0.02	0.07
PA_c	−0.14	−0.01
OA_c	0.12	−0.63[a]
R^2	0.56	0.60
D.W.	2.00	2.58

[a] Denotes elasticities computed from regression coefficients with t-ratios larger than 1.67.

The results of this analysis, in the form of elasticities, are shown in table 1. These elasticities can be interpreted as the percentage change in weekly beef sales associated with a 1% change in any of the independent variables, holding all other variables constant. Those elasticities shown with an "a" are computed from regression coefficients with t-ratios larger than 1.67.

At Food City, a relatively small Toronto chain, a decrease in beef prices holding competitors' prices constant resulted in a substantial increase in beef sales. Multicollinearity between Dominion's average beef price and its competitors' average price is too strong to allow for measurement of the separate effects of these two variables. The estimated own price elasticity of −1.52 in table 1 measures the sales increase generated by a change in the general beef price level rather than a change in price of beef at Dominion relative to its competitors. For this

this only occurs a few times during the seventy-two-week period of analysis, it is not felt that this seriously influences the results.

[2] To construct average carcass values, the prices of eighteen beef cuts are used. In the individual cut demand analysis, only fourteen cuts are analyzed, omitting stewing beef, flank steak, brisket, and shank center. These cuts, accounting for 9.4% of the carcass, are omitted because data on shipments of the brisket and flank primals were not collected. Stewing beef is left out because its source could not be identified.

[3] Only one Toronto newspaper is included in the advertising audit, since it is the only paper that regularly features food ads. Two other Toronto newspapers occasionally carry food ads, but the size of these ads and the frequency with which they appear are inconsequential compared with the ads in the Toronto Star.

[4] All of the demand functions are estimated using ordinary least squares. A single-equation approach is appropriate, since supply is perfectly elastic for a small local market within the North American beef industry. Likewise, there is no simultaneity on the demand side as long as retailers use standard mark-up techniques to determine their prices. The residuals in the aggregate supermarket demand functions may be correlated, but the lack of sufficient data to model the entire Toronto market makes the use of a seemingly unrelated regression procedure less attractive (Kmenta, pp. 517–28).

[5] The independent variables are calculated as follows. Own beef price is calculated as a weighted average of the eighteen retail cuts for which data were available. Competitors' beef price is calculated as a weighted average price of the eighteen retail cuts for the four other competitive retail firms. Relative price of pork is calculated by dividing the average price of pork loin chops and picnic roast for each chain by the average price of the four other competitors. Relative price of lamb is calculated by dividing the average price of leg of lamb, shank half, for each chain by the average price of the four other competitors. Own and competitors' ads are included in the model as the number of mentions, since no attempt is made in the newspaper audit to measure the amount of space devoted to each item.

reason, the less elastic direct price elasticity at Dominion relative to Food City is not surprising. For both chains, an increase in beef advertising is associated with an increase in beef sales; however, this effect is relatively small.

The sales response of beef to pork advertising for Dominion is negative, implying that as Dominion increases pork advertising beef sales decline. The sales response of beef to other meat advertising, on the other hand, is positive for Dominion. The direction of this relationship is somewhat surprising but apparently reflects the fact that other meat advertising at Dominion stimulates sales of all meats, including beef, instead of stimulating the sales of other meats at the expense of beef. Beef and pork advertising of competitors is not related to beef sales at the two chains under consideration in this analysis. However, other meat advertising of competitors has a negative and fairly substantial effect on beef sales at Food City.

Individual Cut Demand Analysis

An attempt is made to estimate separate demand functions for individual beef cuts. The basic model used in this part of the analysis is similar to that used in the aggregate analysis, with the exception that the prices and advertisements are not averaged over all cuts but rather inserted as separate variables in the equations.[6]

The large number of individual beef cuts considered, and the interaction possibilities among these cuts, leads to a situation where an extremely large number of independent variables are eligible for inclusion in any of the demand equations. Because of the inherent problems involved in estimating and interpreting equations of such size, a procedure was developed to reduce the size of each equation while preserving as much information as possible. This procedure consists of two steps. In the first step, an equation consisting of the own price and own advertising variables is estimated, while allowing for the possibility of any of the other variables entering the equation in a stepwise manner. The information obtained in this step then is used to select variables for inclusion in the equations in the next step, provided they meet two inclusion criteria. These criteria are that the variables have to have the correct (hypothesized) sign and that they have to have a t-value greater than 0.85. The second step in this procedure consists of reestimating each equation using a stepwise option to pull in all of the variables meeting the above criteria.[7]

The elasticities calculated from the regression equations for Dominion and Food City and the definition of symbols used are shown in tables 2 and 3.[8] The results in these tables are separated into different types of elasticities for each of the fourteen beef cuts considered at each chain.

Eight of the fourteen own price elasticities for Dominion are significant and negative as expected, compared with only two of the fourteen for Food City. All of the significant price elasticities are greater than one except for short rib roasts at Dominion. In general, there seems to be some relationship between the "quality" of the cut and its price elasticity, with higher quality cuts being more price elastic.[9]

The cross-cut price elasticities show the percentage change in sales of each cut given a 1% change in the price of some other cut. The results in tables 2 and 3 show that there are relatively few relationships between the sales of one cut and the price of another, but those relationships that are pesent are fairly strong, as evidenced by the large values found.

The cross-product price elasticities show the percentage change in sales of each beef cut given a 1% change in relative prices of pork, veal, and lamb. Again, the results show relatively few such cross-product relationships, but those that are present are fairly large. Also, it appears that pork is a better substitute for steaks than for roasts, given the number of significant cross-product elasticities between the categories of products.

The own meat advertising elasticities show the percentage change in sales of each beef cut given a 1% change in the number of beef, pork, and other meat ads run by the chain. The signs of these elasticities are hypothesized to be positive for beef ads, negative for pork ads, and either for other meat ads. With the single exception of the relationship between the sales of short rib roasts and pork ads at Dominion, all of the signs are in the hypothesized direction, and all are found to be less than one.

The final section of tables 2 and 3 shows the effect of specials on the sales of individual beef cuts. Because of the discrete nature of this variable (a cut is either specialed or it is not), it is included in each demand equation as a dummy variable. As a result, it is not meaningful to calculate an elasticity for this variable. Instead, positive or negative signs are shown for each statistically significant variable, indicating the direction of the effect of the special.

The first row under the heading effect of specials (SP) shows the effect of specialing a cut on the sales of that cut. As expected, all the significant variables

[6] A seemingly unrelated regression procedure was tried in estimating the individual cut demands for each supermarket, but the results were similar to the ordinary least squares estimates.

[7] Given the search procedure followed in selecting the variables included in each equation, the standard statistical tests should be interpreted very carefully; i.e., the stated level of significance is distorted (Freund, Freund and Debertin).

[8] The beef price variables in the individual cut demand analysis are expressed as actual prices for each individual chain. Prices relative to those in other chains were used in preliminary analysis and found to give results inferior, in terms of goodness of fit and expected signs, to those using actual prices.

[9] This result is confirmed by MacAulay when he found the direct short-run price elasticities for non-fed beef to be substantially lower than for fed beef in western Canada, eastern Canada, and the United States.

here for both chains are positive. It is particularly interesting to observe the differences between the two chains wth respect to this variable. In the case of Dominion, only four cuts are found to respond significantly to specials, whereas in the case of Food City, twelve cuts show a significant response.

The other entries under the heading effect of specials show the effects of specialing one cut on the sales of another. Here, negative signs would be expected for cuts that are substitutes and positive signs for cuts that are complements. Only a few of these cross-cut advertising relationships are found, and most of them are negative.

Conclusions

Several tentative conclusions are possible. For individual chains, aggregate beef sales are price elastic. This implies there is some incentive for chains to lower average prices, since such a strategy results in an increase in total revenue, assuming everything else remains the same. In the aggregate, cross-product prices appeared to play a small role over the study period.

Own advertising elasticities both in the aggregate and for individual cuts tend to be positive but substantially less elastic than own price elasticities. This does not, however, imply that reducing prices is preferable to increasing advertising if the objective of the firm is profit maximization. Such a determination obviously depends on the costs of the two approaches.

Pork advertising tends to have a negative effect on beef sales, while other meat advertising has a positive effect. In general, the advertising of competitors was not found to be very important.

Substantial differences exist between chains in terms of the magnitude of price and advertising effects. While these are probably due to differences in store location, store types, etc., sufficient data were not available to determine the exact reasons for these differences.

Perhaps the most important contribution of this research is to indicate how easily chain store managers could conduct similar demand studies to help in selecting a basic marketing strategy. The type of data used in this study are readily available to industry analysts and, in fact, could be improved upon by accounting for in-store meat carryover and meat-cutting differences between stores. The demand analysis could be used to determine where the major sales effects of price and advertising changes should be focused and therefore how to increase sales and profits.

The Effect of Income Tax Progressivity on Valuations of Income Streams by Individuals

Roy D. Adams

The effect of taxes upon investment patterns in agriculture is an important policy consideration that has received attention in past issues of this *Journal*. However, some authors have inadequately adjusted income-stream valuation formulas for the effect of the individual income tax and have consequently reached incorrect conclusions regarding both the present value of future income and the effect of income tax progressivity on the relative valuations of individuals in different tax brackets. Rodewald (1969, 1971) and Devino consider the effect of taxes and financing upon investment decisions, but their incomplete treatments of income taxes produce a valuation formula that results in incorrect investment decisions. A more recent paper by Harris and Nehring considers the impact of farm size on the bidding potential for agricultural land. Like Rodewald and Devino, they adjust the income stream for taxes but do not incorporate individual income tax rates in the discount rate used for computing present values. Consequently, they conclude that the progressivity of individual income tax rates puts high tax bracket individuals at a competitive disadvantage in bidding for the perpetual income stream produced by agricultural land.

The purpose of this note is to clarify the effect of income tax rates upon the present value of income streams subject to normal income taxes and to describe how income tax effects may be incorporated into general valuation formulas. The next section discusses the relation between present value analysis and bid-price models and notes some practical limitations of the latter. Subsequent sections describe how risk can be correctly incorporated in present value calculations, how normal income taxes affect present values, and how the availability of tax-exempt municipal bond interest affects the present value of taxable income streams and limits the optimum level of taxable investment income.

Roy D. Adams is an assistant professor of economics at Iowa State University.

The author is grateful to Duane G. Harris for his helpful comments during several stages of the preparation of this paper and to Neil E. Harl for directing him to the appropriate legal references and assisting in the citation of those references. Two anonymous reviewers' comments on a previous draft were also quite helpful. The author accepts the usual responsibility for any remaining errors.

Investment Decision Models

Two different investment decision models are contained in the papers mentioned above. The simpler of the two is that used by Rodewald. In it one computes the present value of the after-tax income stream provided by an asset and purchases it only if that present value is greater than or equal to the cost of the asset.

The bid-price model used by Harris and Nehring provides a considerably broader framework for investment decisions. They also compute a present value (using a risk-free discount rate), but the investment decision is not made solely on the basis of that present value. An investor's bid price also depends on the risk associated with the considered income stream, the investor's preferences regarding risk, the riskiness of the investor's existing portfolio, and the covariance between the return on presently held assets and the return provided by the considered asset. Bid prices equal present values only if the investor is risk neutral or if acquisition of the asset does not change the riskiness of his portfolio holdings. Thus, bid prices are conceptually more general and complete than are decision rules based solely on present value. Whether the bid-price model provides a useful improvement depends critically on the availability and reliability of the additional information required to compute bid prices. That information includes detailed characteristics of investors' utility functions, in addition to estimates of the risks and covariance mentioned above.

Many investors lack at least some of the information needed for bid-price calculations and consequently focus on present values in making investment decisions. The following section presents a method for incorporating risk into present value calculations without recourse to the information about utility functions required for bid-price models. Since Harris and Nehring's bid-price model includes a present value computation, the points made here regarding taxes and present values apply to both decision models. Any tax effects upon present values also apply to bid prices, although the converse is not always true. Since bid-price models incorporate utility functions, taxes may have wealth effects on bid prices that do not appear in present value formulas.

Present Value of Uncertain Income Streams

An important characteristic of many income streams is that they are highly variable over time. This feature is incorporated into bid-price models, but Rodewald does not explicitly consider it in his present value approach to investment decisions. Hirshleifer (1970) discusses two possible methods of accounting for the riskiness of income streams in computing present values. One method (*a*) is to reduce the distribution of possible returns in each future period to a certainty-equivalent value, then discount that series of terms with a riskless discount rate to obtain the "present certainty-equivalent value." The certainty-equivalent value, like bid prices, depends on the investor's utility function. The alternate method (*b*) is to compute the mathematical expectation of the return in each future period, then discount this series with the discount rate appropriate to the "risk class" of the investment.[1] Hirshleifer notes that, although both approaches "lead in principle to the same correct result, the information gaps that are the source of the difficulty require in practice the employment of method (*b*) above" (p. 262).

In its simplest form, the recommended procedure requires only two pieces of information. One is an estimate of the expected value of the net income produced by the asset in each future year π_t; the other is the prevailing rate of return r^o on other assets in the same risk class. The principle underlying estimation of π_t is that it is returns to invested capital. Therefore, one subtracts from each year's expected receipts all costs of inputs other than capital. Property taxes are subtracted because other assets not subject to the property tax are available.[2] Debt interest should not be subtracted because it is part of the return to capital invested in the asset.

The choice of the appropriate risky discount rate is guided by the principle that it should indicate the rate of return available on assets containing the same degree of risk as the considered investment. Since the variance of net income from farmland depends on such factors as the chosen cropping pattern and the amount of insurance purchased, the appropriate risky discount rate may vary among investors planning different uses of the land. The appropriate rate may be difficult to estimate precisely, but as Hirschleifer (1961, p. 118) has noted, the risky discount rate "is at least more of an observable magnitude than the abstract riskless rate of interest." Since the general level of prices is unstable, riskfree investments would exist only if some assets were both free of default risk and were effectively indexed against purchasing power risk. Currently, the riskless interest rate cannot be observed, but a wide range of risky rates are visible.

[1] The concept of risk-equivalent classes of assets is discussed by Modigliani and Miller in their 1958 and 1963 papers. Income streams in a risk class differ only by a factor of porportionality.

[2] If property taxes are expected to grow over time, this expectation should be incorporated.

Income Taxes and Present Values

The above procedure recommended by Hirshleifer abstracts completely from income taxes; the expected income stream and the discount rate he discusses are both in gross-of-tax terms. This section shows that taxes may be safely ignored only when valuing an income stream that is both perpetual and is subject to only normal income taxes. If the income stream is finite in time or if special income tax features such as accelerated depreciation, capital gains, tax credits, etc., apply to it, the individual's tax rate does affect present values and must be applied to both the income stream and the discount rate.

As Modigliani and Miller (1963) note in their analysis of the effect of corporate income taxes upon costs of capital and valuation formulas, there are two equally good methods for valuing perpetual income streams subject only to normal taxes. One can either discount gross-of-tax returns with the gross-of-tax cost of capital or one can discount net-of-tax income with the net-of-tax cost of capital. Their footnote 16 (1963, pp. 441–42) states:

> "Although the before-tax and the net-of-tax approaches to the cost of capital provide equally good criteria for investment decisions when assets are assumed to generate perpetual (i.e., nondepreciating) streams, such is not the case when assets are assumed to have finite lives. . . . In the latter event, the correct method for determining the desirability of an investment would be, in principle, to discount the net-of-tax stream at the net-of-tax cost of capital. Only under this net-of-tax approach would it be possible to take into account the deductibility of depreciation. . . ."

The expressions for the after-tax costs of capital developed by Modigliani and Miller (1958, 1963) for corporations are not applicable to individual proprietors because individuals are not subject to the corporate income tax. The appropriate discount rate for individual (unincorporated) investors to use in computing present values is the rate of return available on other assets in the same risk class; this is the opportunity cost of alternate uses of invested funds, regardless of whether the source of those funds is equity, debt, or any combination of the two.[3] Therefore, the gross-of-tax cost of capital

[3] This approach is consistent with Modigliani and Miller's findings. Their 1958 paper shows that, in the absence of corporate income taxes, the cost of capital to a firm is independent of its debt-equity mix and equal to the rate of return to unlevered equity invested in its risk class. Their 1963 paper shows that the corporate income tax does create an advantage to corporate debt finance and that the correct discount rate for corporate investment decisions does depend on leverage. However, the tax effect is the only permanent advantage to corporate debt, and this advantage does not apply to individual unincorporated investors. It can be shown that the debt-equity mix of individual investors strongly affects the expected value and variance of returns to invested equity. However, the debt-equity mix is irrelevant to present values because the effects of leverage apply to all investments and should not be

invested by an individual is simply r^o, the prevailing rate-of-return in the asset's risk class, and the net-of-tax cost of capital is $r^o(1 - t)$, where t is the investor's marginal income tax rate. The net-of-tax expression recognizes that foregone returns would be subject to taxation (unless it is municipal interest discussed below).[4]

The simple formula for the present value of a perpetuity illustrates Modigliani and Miller's point about the equivalence of the gross-of-tax and net-of-tax approaches. The present value V of the net-of-tax perpetual income stream $\pi(1 - t)$, discounted with the net-of-tax cost of capital $r^o(1 - t)$, is identical to the present value of the gross-of-tax perpetual stream π, discounted at the gross-of-tax cost of capital r^o:

$$V = \frac{\pi(1 - t)}{r^o(1 - t)} = \frac{\pi}{r^o}. \tag{1}$$

This also demonstrates that the present value of a perpetual stream does not depend on the tax bracket of the individual.[5]

The problem with Harris and Nehring, Rodewald, and Devino's present value formulas is that Harris and Nehring explicitly, and Rodewald and Devino apparently, use a gross-of-tax interest rate to discount net-of-tax income streams. Harris and Nehring note that their present value formula (equation (6), p. 162) implies that individual valuations decrease as the marginal income tax rate rises and high income persons *ceteris paribus* bid less for farmland than do persons in lower tax brackets. Since neither Devino nor Rodewald mentioned any adjustment of the discount rate for income tax rates, they presumably would also use a gross-of-tax rate in discounting. If so, Harris and Nehring's conclusion is also implied by Rodewald's and Devino's analyses.

Although income taxes may be safely ignored in valuing perpetuities subject only to normal income taxes, this is not true in general. If the income stream is subject to only normal taxes, and if it terminates after n periods, its present value is

$$V^* = \sum_{i=1}^{n} \frac{\pi(1 - t)}{[1 + r^o(1 - t)]^i} = \frac{\pi}{r^o}\left[1 - \frac{1}{[1 + r^o(1 - t)]^n}\right]. \tag{2}$$

Since

$$\frac{\partial V^*}{\partial t} < 0, \tag{3}$$

the present value of the income stream is less to high tax bracket individuals than to those with lower marginal tax rates. Samuelson derives this relation and also shows that the effect may be offset by the effect of the deductions for depreciation, which commonly apply to assets with finite lives. As Samuelson shows, the net effect of the tax rate vanishes only when tax deductible depreciation exactly equals true economic depreciation.

If the considered income stream qualifies for any special tax considerations, such as accelerated depreciation deductions or the investment tax credit, then (as Modigliani and Miller argue) the net-of-tax approach is required. In this case, one needs to adjust the expected income stream for the tax factors considered by Rodewald and by Devino, but two corrections to Rodewald's method are required. One, recognized by Devino, is that those finance charges that represent interest on debt should not be subtracted because the discount rate accounts for the required return on all capital invested. Second, the discount rate must be adjusted for the individual's marginal tax rate to obtain the net-of-tax opportunity cost of capital he invests. The present value of finite income streams that qualify for special tax treatment generally does depend on the individual's tax rate. Normally taxed perpetuities (such as indefinitely held farmland) are a special case in which the tax rate has no effect on present value.

The Effect of Municipal Bonds

Although the progressivity of the income tax per se does not reduce high income persons' valuations of normally taxed, perpetual income streams, the availability of tax-exempt interest from municipal bonds does put an upper limit on the optimum level of taxable investment income and does thereby deter some high tax bracket individuals from acquiring taxable income streams.

Figure 1 illustrates the optimal investment strategy for high income individuals, where Y_1 is the individual's wage and salary income minus exemptions and deductions, Y_o is equal to Y_1 minus taxes on Y_1, Y_m is the level of taxable income above which municipals provide the greatest after-tax return, and $Y_2 = Y_m - Y_1$ is the optimal level of taxable investment income. Maximum after-tax income from invested equity is obtained by investing $\$Y_2/r^o$ in assets paying a taxable return of r^o and investing the remainder of equity in municipals paying rate r^m. Line 1 shows gross-of-tax income from this strategy, and line 2 shows net-of-tax income. The initial segments of line 2 have slopes equal to $r^o(1 - t)$, and the kinks corresponds to movements between tax brackets. Line 3 shows the inferior

attributed to any particular investment. If a considered asset is to provide as large a return to levered equity as do other assets in its risk class, it must provide $\$r^o$ of gross-of-tax returns to each (equity and debt) dollar invested.

[4] The net-of-tax expression is less simple if part of the return is growth. Since allowing for income growth over time complicates the exposition of this section without charging the results, I assume henceforth that the income stream considered is not expected to grow over time.

[5] The omission of the special treatment of capital gains in this formula is justified by the assumption that the investor expects to retain the asset (in his family) indefinitely.

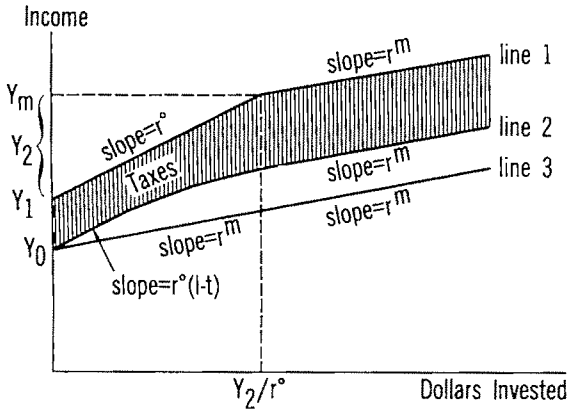

Figure 1. Gross and net-of-tax income with taxable and tax-exempt investment returns

net-of-tax return that results from a portfolio comprised entirely of municipal bonds. The optimum level of taxable investment income to acquire before moving into municipals is determined by Y_1, the individual's taxable wage and salary income; Y_m is determined by the structure of interest rates and tax rates.

Municipal bond holders' valuations of the taxable income stream π depend on the value of π relative to the investor's optimum level of taxable investment income, Y_2. If $\pi \leq Y_2$, then the appropriate net-of-tax discount rate for valuing the net-of-tax returns $\pi(1-t)$ is $r^o(1-t)$, despite the fact that the investor holds some municipals. Since the optimum portfolio contains $Y_2 \geq \pi$ of taxable investment income, the asset producing π is substituted for previously held assets producing taxable income at the rate r^o. Therefore, municipal bond holders whose optimum taxable investment income level is as large as π value π as highly as do lower tax bracket individuals.

However, those investors for whom $\pi > Y_2$ attach a lower present value to π than do lower bracket individuals. Consider first those individuals for whom $Y_2 = 0$ because their wage and salary income alone puts them in the tax bracket where the highest after-tax return on invested equity is obtained from municipal bonds paying rate r^m. This rate is the after-tax opportunity cost of capital for them and is the appropriate discount rate for valuing after-tax returns. Since in this tax bracket $r^m > r^o(1-t)$, using r^m as the discount rate causes their valuation of π to be less than that of lower tax bracket individuals. To match their valuations, the after-tax opportunity cost of capital has to be the lower rate $r^o(1-t)$.

If the municipal bond holder's optimal level of taxable investment income is positive but less than π, his valuation of π lies between the two cases just considered. The excess of $\pi(1-t)$ over $Y_2(1-t)$ is discounted at rate r^m, and these investors' valuations also fall below those of persons in lower tax brackets.

Municipal bond holders' valuations of taxable income streams are less than other individuals' valuations if acquisition of the taxable income stream raises their taxable investment income above the optimum. Whether this is the case depends largely on the municipal bond holder's level of taxable wage and salary income. If this is high, then optimal taxable investment income is low, and large taxable income streams are valued less by them than by others.

The existence of an upper bound on the optimum level of taxable income an investor wants to receive (before investing in municipals) was previously recognized by Dean and Carter. In their analysis of the effect of income taxes upon the optimum size of unincorporated firms operating in an industry where economies of scale exist, they recognize that, because of progressive tax rates and the availability of tax-exempt interest, individuals find that beyond a limit the after-tax return from expanded farm size is less than the municipal rate.

However, Dean and Carter (p. 762, note 12) also argue that this limit may be circumvented by the use of debt. In their scenario, a high bracket individual limits his equity investment in the farm operation and expands with debt while investing his residual equity in municipals. The tax deductions from debt interest keep down the level of taxable income from the enterprise, while scale expands with invested debt capital. Carman implicitly accepted the validity of Dean and Carter's analysis when he examined the effects of the Tax Reform Act of 1969 on optimum farm size. However, Dean and Carter's analysis ignores a provision of the income tax law that prohibits the scenario they describe.

Section 265(2) of the Internal Revenue Code of 1954 stipulates, "No deduction shall be allowed for interest on indebtedness incurred or continued to purchase or carry obligations . . . the interest on which is wholly exempt from the taxes imposed by this subtitle" (*U.S. Code*).[6] The Revenue Procedures (72-18 and 74-8) issued by the IRS to set guidelines concerning 265(2) and the court cases interpreting this provision indicate that it does not automatically disallow all interest deductions by municipal bond holders (Internal Revenue Cumulative Bull. 1972-1, pp. 740–43, 1974-1, pp. 419–20). Among other allowances, the courts have permitted interest deductions on loans taken for nonrecurrent business needs. In the case of *Wisconsin Cheeseman, Inc. v. United States*, the courts permitted the deduction of interest on a loan, the proceeds of which were used to pay for the construction of a new plant, although Cheeseman held municipals (*U.S. Tax Cases* 1968, para. 9145, pp. 86, 153–56). Similarly, in the case of *Ball v. Commissioner*, Ball,

[6] If this prohibition did not exist, individuals in high tax brackets could earn arbitrage profits by borrowing money, deducting the interest from taxable income, and investing the loan proceeds in tax-exempt municipal bonds.

who held tax-exempt bonds throughout the relevant years, was permitted interest deductions on a variety of loans, including two that were used to acquire ranches (*Rep. of the U.S. Tax Court*, pp. 1200–1209).

However, the courts have also ruled that interest deductions on such loans become disallowed if the loans are continued beyond some reasonable retirement period. In the case of *Illinois Terminal Railroad Co. v. United States*, the court disallowed the deduction of interest on a loan originally incurred in connection with the acquisition of a bridge because the court's opinion was that the railroad's dominant purpose in continuing the loan was to maintain its holdings of tax-exempt bonds (U.S. Tax Cases 1967, para. 9374, pp. 83, 968–73). I infer from these and related cases that the municipal bond holder who uses debt in purchasing land is permitted to deduct the interest only if the debt is retired within some "reasonable" interval.[7] Therefore, investors cannot indefinitely use debt to circumvent the upper bound on optimum taxable income identified in figure 1. Consequently, some municipal bond holders will find taxable income streams unattractive because of this limit.

Conclusions

One of the principal conclusions of this analysis is that the progressivity of the income tax per se does not affect different investors' valuations of normally taxed perpetual income streams. Since farmland does not qualify for special tax factors unless it is resold, investors planning indefinite holding of land are not differentially affected by progressive income tax considerations. However, the availability of tax-exempt municipal interest limits the optimum level of taxable investment income, and section 265(2) of the IRS Code prohibits circumventing this limit with the use of debt. Therefore, municipal bond holders are deterred from acquiring taxable income streams if the acquisition moves them above the optimum level of taxable income. A previous study by Dean and Carter ignores section 265(2) and consequently overestimates optimum farm size.

Although my results, like those of Harris and Nehring, imply that high income investors may value farmland less highly than lower income individuals, the source and extent of the valuation disadvantage differ. Harris and Nehring's attribution of the valuation disadvantage to the progressivity of the income tax implies that the effect operates throughout all levels of taxable income. My conclusion is that the progressivity of the income tax deters only some high income municipal bond holders from acquiring farmland. Further, this effect is attributable to the existence of municipal interest rather than to the progressive income tax itself.

Although most investors may safely ignore income tax rates in the significant special case of farmland valuation, this analysis indicates that asset valuation should generally be conducted in net-of-tax terms. To correctly value nonperpetual income streams and assets qualifying for special tax consideration, it is necessary to adjust both the income stream and the discount rate for the effect of individual income tax rates.

[*Received June 1976; revision accepted January 1977.*]

[7] Neither the IRS nor the courts have specified how quickly debt must be retired to avoid invoking 265(2), but the Illinois Terminal Railroad Co. case demonstrates that indefinite continuance of debt is not permitted.

Long-Run Productivity of Insecticides

Gerald A. Carlson

Public concern over the hazards to wildlife and human health associated with insecticides has prompted research on the private costs and returns from the use of these chemicals. Headley uses 1963 state data to estimate a $4 return for each dollar of pesticide materials of all types (fungicides, herbicides, insecticides, etc.) used on U.S. farms. He indicates that this result helped explain the rapid increase in sales volume of pesticides. But during the 1960s producers were giving additional attention to pest control as more insect species became resistant to more chemical types. Many policy questions on the limitation of use and registration of insecticides require more detailed knowledge of the demand for specific compounds. Regulatory officials are concerned about the substitutability of other chemical and nonchemical pest controls (Davis et al.). Yet, no statistical estimates of insecticide demand are presently available.

The importance of insecticide resistance in affecting demand for specific compounds and the long-run productivity of insecticides are investigated in this paper. Individual farm data from several cotton production regions and aggregate insecticide use data are used to test hypotheses of falling productivity of insecticides and substitutability between chemical types.

Long-Run Insect Management

Insect management decisions involve the use of insect density, specie, crop tolerance, and weather information to regulate pest suppression resources to maximize profits. Several authors have used a kill function to refer to the efficacy or productivity of pesticides (Hueth and Regev). Genetic composition of the pest population and weather can influence the percentage kill obtained by a given insecticide dosage. Langham and Mara use data from weather-controlled experiments to illustrate how percentage kill is determined by number of pest generations exposed to a given insecticide dosage. Economists and entomologists have also hypothesized that rate of insecticide resistance development is determined by insecticide dosage or amount of selective pressure (Adkisson, Hueth and Regev).

Hueth and Regev have presented a model to show that in the presence of increasing insecticide resistance both current and future efficacy of an insecticide must be considered in determining optimal use rates of a single insecticide through time. Their model is helpful in understanding that dosages per acre might be increased to maintain current yields, or they might be decreased to preserve survival of susceptible insects and, thereby, lower future control costs. To make the theoretical model of Hueth and Regev operational, one must have observations on pest numbers and insecticide resistance. If pest numbers are available and all other factors affecting crop yield are accounted for, changes in the marginal productivity of insecticides will indicate a change in the level of insecticide resistance. One of the main objectives of the next section is to estimate expenditure functions to determine if insecticide productivity has decreased with time in various cotton production areas.[1]

A second resource allocation problem is the selection of the mix of insecticides given relative prices and productivities of specific compounds in a given period. If physical effectiveness of specific insecticides is falling through time due to resistance development, what responses have growers made? Insecticide type might be substituted at a slightly higher price per unit of material to maintain or increase percentage kill. Similarly, resistance might lead to increased use of land and other inputs per unit of final product. These adjustments can be examined by deriving and estimating a demand equation for individual insecticide products.[2]

Insecticide Productivity in U.S. Cotton Production

Assume that the cotton production process can be described by expenditures for insecticides (X_1), fer-

Gerald A. Carlson is an associate professor in the Department of Economics and Business, North Carolina State University, on leave at the University of Washington.

Paper Number 3884 of the journal series of the North Carolina Agricultural Experiment Station. Without implicating them, the assistance of Richard Boisvert, two *Journal* reviewers, Loren Ihnen, and Jim Seagraves is gratefully acknowledged.

[1] Admittedly, this stops short of calculating optimal insecticide productivity and insecticide use rates. Such an analysis depends upon unknown rates of chemical discovery, rates of decline in resistance when insecticide use is reduced, and the factors mentioned in the text.

[2] A dynamic model such as one similar to Hueth and Regev would also have interest rates, product price, and the rate of change in interest rates and insecticide prices in the factor demand equations. In this static approximation, changes in insecticide prices and interest rates have been omitted. Product price variables were deleted because of lack of statistical significance.

tilizer and lime (X_2), other materials (X_3), land (X_4), labor (X_5), power and equipment (X_6), custom work (X_7), and pest abundance (P). The output resulting from these inputs is given by value of cotton produced (Y). If these inputs (X_i) are combined in multiplicative fashion, then an estimation model with unknown parameters (β_0, β_i, β_8) and error term u can be specified as:

$$(1) \quad Y = \beta_0 \Pi X_i^{\beta_i} P^{\beta_8} u \text{ for } i = 1, 2, \ldots, 7.$$

It is assumed that the function is linear-homogeneous and input prices are constant for all cotton farms of a given size in a region.[3]

Equation (1) has pest abundance as a biological input. The productivity of insecticide materials is likely to be closed linked to pest numbers. In this case, pest abundance is measured as an index of uncontrolled pests as indicated by weeks of greater than 5% bollworm-damaged squares. Where infestation measures are not available, insecticide expenditure (X_1) alone is used in the model.

The sample data used to test for the existence of changes in insecticide productivity were collected by personal interviews of cotton growers across the U.S. cotton production regions for 1964, 1966, and 1969 (USDA 1966, 1969, 1972). Table 1 gives ordinary least-square estimates of expenditure elasticities (β_i) for southeastern and Rio Grande Valley cotton farms utilizing equation (1). A high proportion of total variation in the value of cotton produced is accounted for by these seven groups of expenditures. The finding of interest is that the expenditure elasticity for insecticides declines during both the 1964–66 and 1966–69 intervals for both regions.

The model was also estimated using sample data from other cotton production regions for each of the three years. The marginal physical products (MPP's) for the insecticide variable (X_1) for four of the regions are given in table 2. The Delta-P entries were derived from estimates of equation (1) with inclusion of a measure of pest density (P). The effect of accounting for pest density is to increase the MPP of insecticides about 20% (estimate of all three years combined) and increase its t-values (compare standard errors of IV and V).

The marginal physical products of insecticides are an estimate of the productivity of insecticides for mean dosages if all other factors affecting yield are held constant. Since mean expenditure shares for insecticides are relatively constant for the 1964–69 period for each region (USDA 1966, 1969, 1972), one cannot attribute changes in the MPP's to shifts along the kill function.[4] The changes in the insecticide MPP's are due to shifts in the kill function itself. The distinctive feature of the MPP estimates is the decreases with time for the Southeast and the Delta regions, with small declines in the Rio Grande Valley. There seems to be no evidence of falling productivity in California.

The data support the hypothesis of falling physical productivity of insecticides. The annual rates of decline are higher for later periods (1966–69) for the Southeast and the Delta (table 2). One might question the statistical significance of the shift from 1966 to 1969 because of the high standard error on the insecticide variable in 1969 for all regions except California. However, the 95% confidence interval of marginal physical products for 1964 does not include the 1969 value for the Southeast and the Delta region (adjusted for infestation—Delta-P).

[3] This permits expenditures on insecticides to be a proxy for insecticide quantity. As one reviewer noted, this also requires that the mix of insecticides across farms must be the same, since different compounds have different prices per pound. Examination of individual farm data indicates that this assumption is not too extreme for the homogeneous cotton areas chosen by USDA and used for this study (USDA 1966, 1969, 1972).

[4] The expenditure shares for the 1964, 1966, and 1969 periods are: Southeast—6.9, 8.7, and 8.6; Rio Grande—8.9, 11.0, and 5.0; California—1.4, 1.2, and 1.9; and Delta—3.0, 3.4, and 5.1 (USDA 1966, 1969, 1972).

Table 1. Cotton Production Expenditure Functions

	Southeast[a]			Rio Grande Valley		
	1964	1966	1969	1964	1966	1969
Constant (X_0)	1.84	1.80	2.05	1.45	2.49	3.08
Insecticides (X_1)	0.031	0.027	0.007	0.062	0.041	0.007
Fertilizer and lime (X_2)	0.384	0.368	0.570	0.020	0.022	0.011
Other materials (X_3)	0.107	0.133	0.097	0.230	0.231	0.202
Land (X_4)	0.094	0.101	0.086	0.259	0.249	0.450
Labor (X_5)	0.285	0.185	0.228	0.258	0.090	0.149
Power (X_6)	0.120	0.197	0.004	0.201	0.310	0.058
Custom (X_7)	0.022	0.034	0.037	0.076	0.060	0.037
R^2	0.901	0.863	0.859	0.938	0.958	0.961
N	863	535	399	369	239	177

Note: t-values for all but four coefficients are greater than 2.0. t-values for the others are 0.39 and 0.64 for variable X_1 in 1969 for the Southeast and Rio Grande Valley, respectively, 1.4 for X_2 in the Rio Grande Valley in 1969, and 0.9 for X_6 in 1969 in the Southeast.

[a] Includes production in North Carolina, South Carolina, Georgia, and part of Alabama. See Economic Research Service reports for area delineations, sampling procedures, and other characteristics of the USDA cotton surveys (USDA 1966, 1969, 1972).

Table 2. Marginal Physical Products of Cotton Insecticides

Region	1964	1966	1969
I Southeast	1.85	1.07	0.24
	(0.50)	(0.58)	(0.63)
II Rio Grande Valley	2.88	2.47	1.54
	(0.93)	(1.14)	(1.40)
III California[a]	48.30	16.67	26.47
	(13.45)	(11.66)	(7.06)
IV Delta[b]	20.97	13.20	0.91
	(10.13)	(3.95)	(5.35)
V Delta-P[c]	31.79	16.17	2.55
	(12.18)	(4.04)	(5.67)

Note: MPP's are computed as $(\beta_1 \cdot \bar{Y}/\bar{X}_1)$ (regional cotton insecticide price per pound/regional cotton lint price for each year) (Eichers et al. 1970; USDA 1966, 1969, 1972); standard errors are given in parentheses.

[a] Includes some production in southwestern Arizona. See ERS reports for delineation of subregions (USDA 1966, 1969, 1972).

[b] Includes production in twenty-five counties and adjacent counties in Arkansas, Mississippi, Tennessee, and Missouri for which infestation records were available (Lincoln and Boyer).

[c] Same cotton farms as equation (IV), except a measure of bollworm infestation has been included in the estimation of equation (1).

Demand for Selected Insecticides

There appear to be reductions in the technical efficiency of cotton insecticides during the 1960s as shown above. To determine how insecticide users respond to resistance, one must examine their purchases of various insecticides. The demand model briefly outlined above can be estimated if insecticide prices, quantities, and a measure of insecticide resistance are available.

Resistance measures applicable to U.S. insecticide use are difficult to obtain because of lack of comparability between pest species, crops, and areas. Dosages required to kill 50% of a pest population (LD-50) are a common measure for laboratory and small field-plot studies of degree of genetic change (resistance) in a population (Adkisson, Brown 1971). For more aggregate analysis, a measure is needed that emphasizes the geographical and insecticide use intensity dimensions of resistance. One of the most extensive tabulations of insecticide resistance is given by Brown (1971). He has compiled dates of first reportings of resistance, by major pest by state. An index of organochlorine insecticide resistance for various years was computed from his list of references. Table 3 shows the insect species, host crops, states, and dates of resistance occurrence for major insect species.[5] The pounds of organochlorine insecticides to which resistant pests apply was estimated by using host crop acreage times the average pounds of organochlorines applied per acre as given in the first U.S. Department of Agriculture pesticide survey (Eichers et al. 1968). Host crop acreages are assumed to be the state acreage in the specified year unless the pest is only found in part of the state

[5] Only agricultural pests are included in the index computation. Most of the public health pest resistance to organochlorines occurred prior to 1951 in the United States (Brown 1971). However, this omission may account for the reduced magnitude of the coefficient on the resistant variable when the years prior to 1953 are included in the DDT model, equation (D), table 4.

Table 3. Organochlorine Insecticide Resistance by Major Insect Species

Year	Insect Species[a]	Major Host Crop	States[a]	Estimated Pounds O.C. (A_i)[b]
1951	Coddling moth	apples	Ohio	0.5
1952	Coddling moth	apples	New York	2.1
1953	Coddling moth	apples	Washington	1.2
1955	Boll weevil	cotton	Ark., La.	10.5
1956	Boll weevil	cotton	Tex., Miss., S.C.	30.3
1959	Boll weevil	cotton	Ala., Okla., N.C.	8.7
	Coddling moth	apples	6 minor apple states	0.4
1961	Tomato hornworm	tobacco	N.C., S.C.	5.2
1962	Corn earworm	cotton	La., Ark., Tex.	33.5
	N. corn rootworm	corn	S.D., Ohio, Ill.	0.3
1963	Tobacco budworm	cotton	Tex., Miss.	3.2
	W. corn rootworm	corn	Nebr., Kansas, S.D.	0.2
1964	W. corn rootworm	corn	Iowa, Mo., Minn.	4.2
	N. corn rootworm	corn	Iowa, Minn., Wisc.	5.0
1965	Tobacco budworm	cotton	Louisiana	1.5
	Corn earworm	cotton	Miss., Ala.	18.3
1966	Cabbage looper	cotton, soybeans	Calif., La., N.C., S.C.	6.2
	S. corn rootworm	corn	Vir., N.C.	3.2

[a] From a check of first reported resistant insects as reported in the references in Brown 1971.

[b] Estimated host acreage times pounds of organochlorine (O.C.) insecticides per acre for the particular specie (Brown 1971, Eichers et al. 1968).

(such as boll weevil in Texas). Because of time delays between first reports of resistance and widespread geographical distribution of resistant populations, a two-year lag is selected.[6] The resistance index values (e_t) are cumulated for year t as

$$e_t = e_{t-1} + A_{t-2}, \tag{2}$$

where A_t is the estimated pounds of organochlorine insecticides used for control of the resistant species as given in table 3.[7]

The resistance index (table 3) is dominated by the cotton pests because of the large proportion of insecticides used for these species. The index is only an approximation for the large number of insect species that have various degrees of resistance to the organochlorine insecticides in any year. However coarse it may be, it is the most complete index compiled to date. It may be refined enough to help explain wide swings in pesticide use over the past two decades.

Annual U.S. insecticide use data for the period 1945 to 1970 (1969 for DDT) are used for analysis. This excludes the effects of registration removals, since most were after 1970. Price and quantity data for several classes of organochlorine and organophosphorous insecticides were compiled from tariff commission sales data (USDA 1953–71, U.S. Tariff Commission) and export information (USDA 1953–71, U.S. Dep. Commerce). The estimation model is

$$Q_t = c_0 + c_1R_{1t} + c_2R_{2t} + c_3e_t + c_4C_t + E_t, \tag{3}$$

where Q_t is the quantity (in pounds of actual material) of a given insecticide purchased in year t, R_1 is the insecticide price deflated by an index of all agricultural input prices, R_2 is the substitute insecticide price, e_t is the resistance index, C_t is the agricultural product price index, and E_t is the error term. The model was estimated in linear-log form. The agricultural product price variable was not statistically significant and was deleted from the model.[8] A lagged dependent variable (R_3) is added to account for the assumed effects of delayed adjustments to price changes.[9]

Table 4 presents parameter estimates for equation (3) for several of the largest selling groups of insecticides. Insecticide price (R_1) has the expected negative effect on insecticide purchases for all three groups of compounds examined. Since the model is estimated in log-log form, the coefficients on R_1 and R_2 are direct and cross price elasticities, respectively. The sales of these compounds are quite re-

[6] This was based on the detailed studies of the geographical and chemical spectrum of resistance that have been conducted for tobacco budworm on cotton and the western corn rootworm (Adkisson, Brown 1970).

[7] Because of the lag, resistance index values are needed for the 1953–68 period. Data for the 1967–68 period are incomplete. It is assumed that the rate of increase in e_t is the same as for the 1962–66 period. This linear extrapolation to obtain a small part of the index (12%) is not expected to alter the results very much. The starting point ($t = 0$) is assumed equal to 1.0.

[8] Since insecticide expenditures constitute a small share of total farm production costs (usually less than 5%) and the sales include nonagricultural and agricultural use of insecticides, it is not surprising to find no discernible product price effect. This model change does not change the estimated coefficients for the other variables.

[9] The justification of the delayed adjustment to achieve desired levels of use is the same as Griliches gives for fertilizer use. The lagged dependent variable did not prove to be statistically significant and was deleted for insecticides other than DDT.

Table 4. Demand Equations for Selected Insecticides

Chemicals	Constant	Own Deflated Price[a] (R_1)	Substitute Price[b] (R_2)	Resistance[c] (e_t)	Lagged Dependent[d] (R_3)	R^2
(A)	−2.578	−1.461	0.830	1.51	—	0.941
		(0.796)	(0.683)	(0.158)		
(B)	−4.218	−1.552	0.886	1.85	—	0.960
		(0.780)	(0.670)	(0.155)		
(C)	−1.244	−1.06	0.261	0.958	—	0.968
		(0.273)	(0.43)	(0.167)		
(D)	−2.261	−0.667	—	−0.340	0.759	0.585
		(0.397)		(0.179)	(0.153)	
(E)	−4.522	−1.091	−0.118	−0.747	0.797	0.815
		(0.625)	(0.526)	(0.319)	(0.200)	

Note: Dependent variables in the equations are: (A) domestic and foreign quantity of cyclic organophosphate insecticides (1953–70); (B) same as (A) except dependent variable is divided by domestic cotton acreage planted; (C) total quantity of parathion and methyl parathion (1953–70); (D) domestic quantity of DDT (1945–69); and (E) domestic quantity of DDT (1953–69). Standard errors are in parentheses.

[a] Annual weighted average prices deflated by index of all farm input prices.

[b] In the cases of equations (A), (B), and (C), this is organochlorine weighted average price; for DDT this is average price of cyclic organophosphates.

[c] Cumulative pounds of organochlorines with resistant insects as given in table 3 in 10 million pounds, lagged two years.

[d] All Durbin-Watson statistics are nonsignificant or inconclusive. Durbin's two-sided test for first-order serial correlation in the presence of a lagged dependent variable is nonsignificant with X^2 equal to 3.06 and 34.3 for equations (D) and (E), respectively.

sponsive to price. All direct price elasticities except for the one in equation (D) are greater than |1|. This indicates that there are many substitute pest controls in the long run. Costs of restricting the use of particular insecticides may not be as high as implied by studies such as Davis et al., which allow limited factor and product substitution.[10]

Organochlorine resistance (e_t) explains a high proportion of the variation in annual insecticide purchases for each of the chemicals examined. Resistance to organochlorine increases the demand for organophosphates—the major replacement insecticide. Resistance tends to increase the use of substitute chemicals and decrease the use of the resistant chemical. Resistance is not as important in equation (D) because it includes data from the earlier period (1945–51) for which agricultural resistance was reported to be at the zero level. Resistance has a larger effect on organophosphate sales per acre of cotton than on total sales (compare the coefficient of e_t for equations (A) and (B)).

With one exception other variables have the anticipated effects. Substitute insecticide prices (R_2) (organophosphate prices in DDT equations, organochlorine prices in organophosphate equations) have the expected positive sign in the organophosphorous equations (A), (B), and (C). In the case of DDT (equation (E)), which has many petroleum substitutes for health-related pests, substitute price shows no effect. The predictability of the demand for DDT is enhanced by inclusion of a lagged dependent variable, R_3. The inclusion of delayed adjustments to relative prices does not weaken the association between resistance and insecticide demand. Thus, the overall effect of resistance to specific compounds is to encourage chemical substitution and reduce dosages per acre.

Insecticide Productivity Policy

The recognition of the dynamic nature of pests has led to a description of the pest control process with pesticide productivity or presence of resistance as an important dimension. Analysis of individual farm data from several cotton production regions indicates that the marginal productivity of insecticides in some areas has fallen substantially between 1964 and 1969. If insecticides are similar to other productive inputs (noninferior), one can expect lower use as effectiveness falls. In addition, if the rate of use influences the rate of decline in effectiveness, then insecticide users will decrease use to delay resistance development. The time-series model results are direct evidence that farmers and others are shifting between insecticide types and adjusting use to avoid the development of resistance for the major insecticides.[11]

The decline in insecticide productivity seems to have been encouraged by several economic and institutional forces. The common-property nature of a genetic pool of nonresistant pests suggests that private producers acting in their own interests may underinvest in preserving this resource. Collective efforts for entire regions, in the form of restraints on insecticide use, may be in order if their net benefits exceed those of individual action.

Another public activity that probably influences resistance development is removal of federal insecticide registrations. Reducing the number of chemical types used on an insect specie increases selective pressure from the compounds remaining. It is ironic that deliberations on the social benefits and costs of restricting use of specific compounds have given little weight to effects on future productivity of substitute compounds.

This paper has not attempted to evaluate the costs of activities to delay resistance development. Mixing insecticides, rotating insecticides, avoiding early season insecticide treatments by the use of field scouts, or spatially or temporarily altering cropping patterns are possibilities that come to mind. Likewise, no attempt has been made to answer the question of the effect of resistance development on rates of discovery of new chemical controls. Investigation of the costs of these and other attempts to preserve our ability to control insects should be undertaken by biological scientists and economists.

During the 1950s and 1960s as resistance intensified for one chemical, replacements were available at small price increases. There was little private incentive to preserve productivity. However, the costs of discovering compounds that are both environmentally safe and profitable has increased the breakeven life of a chemical greatly. Few new insecticides are forthcoming. However, the sales potential of an effective new compound is rising. Policy makers should be encouraged to consider the effects of resistance on the relative productivities of restricted and unrestricted insecticides in their deliberations on use regulations and investments.

Factors Affecting the Supply of Off-Farm Labor Among Small Farmers in Taiwan

Donald W. Larson and Hung Yu Hu

Many low-income countries have achieved rapid economic growth in recent years, but the benefits of this growth often have been concentrated in the hands of few individuals. Poverty among small farmers is still one of the most serious problems confronting these countries.

Two main strategies have been used to deal with the small farmer problem. The first strategy has stressed development of new technology and production services to increase the productivity and profitability of the resources used in agriculture. This approach often benefits large farmers more than small farmers because the limited land holdings and other resources of the latter prevent efficient use of much technology; in addition, they are often denied access to production services. A second strategy is migration from rural to urban areas. High rates of rural-urban migration in developing and developed countries have only transferred the human resource problem from one area to another. The migrants who tend to be poor, unskilled, and underemployed increase the burden on overcrowded urban areas that already suffer from high unemployment rates and large numbers of "marginalized" families. For these reasons, some new approaches to this problem should be considered, although they conflict slightly with traditional concepts of agricultural economics.

Off-farm work, a third strategy to deal with the small farmer problem, offers much potential for alleviating low farm incomes, yet it has been generally overlooked in the development literature. Few studies of off-farm work have been completed in either high- or low-income countries. Furthermore, few countries or aid agencies have adopted policies designed to let members of rural households remain on farms while encouraging them to do part-time off-farm work to increase labor productivity and household income. The principal objective of this study is to explore the main microeconomic factors that affect the supply of off-farm work among rural Taiwanese households.

Traditionally, agricultural economists have considered off-farm income as a "by-product" of farms; their attention generally has focused on the problems of how to increase farm income and how to encourage full-time farming. Following recent economic development in many countries, however, off-farm income has increased at a much more rapid rate than farm income, and its changes have deeply affected rural household incomes, farmers' savings, and consumption. In Taiwan, for example, rural households unable to increase their income through increasing farm size have substantially boosted their purchasing power through off-farm work. Farmers' welfare has often been assumed to be directly related to the size of farm business. But a recent study by Larson has shown that size of farm and farm income are no longer precise indicators of farmers' welfare in the United States.

Off-farm income in many countries has become an increasingly important part of rural household income. As can be noted in table 1, off-farm incomes in the United States and Japan are relatively high percentages of rural household incomes and have increased at fairly rapid rates in both countries.[1] Off-farm income in Taiwan was a relatively unimportant source of household income until 1960; since then it has increased at a very rapid rate, so that it now represents nearly 40% of rural household income. In Korea, off-farm income makes up a significant part of household income, but the percentage has not changed noticeably since 1960. These data indicate that the share of household income earned off the farm has increased rapidly in the 1960 to 1974 period and that it will likely continue to increase in the foreseeable future. Because little is known about off-farm income, research is needed to identify the causes for this rapid growth and the implications for agricultural development. Strategies and policies to affect this process can then be developed.

This study focuses on the rural household in an effort to understand the economic factors that affect off-farm work and attempts to measure the effects of these factors from farm level cross-section data. The main data used in this study were

Note: Off-farm income includes wage and salary incomes received from off-farm employment, net income from nonfarm self-employment, and other incomes.

obtained from the 1973 records of 329 farm families distributed in the eight agricultural regions of Taiwan. The data were collected by the Taiwan Provincial Department of Agriculture and Forestry as part of a farm record-keeping project. The data collected by this project are very reliable because households voluntarily recorded their economic activities daily, and supervisors checked this information regularly.

Taiwan was selected for this study because the agricultural sector and the general economy have experienced rapid development. The gross national product has increased at an 8% to 10% real annual rate since the early 1950s, and agricultural production has increased in excess of 5% annually during the same period (Hu). In addition, the government since 1953 has successively launched six four-year development plans to achieve the simultaneous growth of agriculture and industry. Rapid growth of the nonfarm sector, whose industrial output has increased at more than a 12% annual rate, has led to a significant transformation of the economic structure in Taiwan. Agricultural employment as a percentage of total employment has dropped from 61% in 1952 to 37% in 1973, and agricultural net domestic production as a percentage of total net domestic production dropped from 38% to 16% in the same period. The benefits of this rapid growth have also been relatively equitably distributed, thereby creating new opportunities for a large proportion of the population (Oshima).

The Economic Model

A major concern of the study is to determine how Taiwanese farmers distribute their labor between on and off-farm work. Polzin and MacDonald's study for the United States presents a theory useful in explaining the equilibrium between on and off-farm work. Assuming that the individual farmer is a price taker in the nonfarm labor market, the optimal division of time is that point where the marginal revenue product of farm work equals the net wage rate of the nonfarm sector. An increase in the off-farm wage rate causes the farmer to increase the supply of off-farm work. Similarly, an increase in net farm income causes the farmer to reduce his off-farm labor supply.

Commuting costs of the farm family are also expected to affect the off-farm labor supply. Commuting cost, an increasing function of distance in most cases, lowers the net off-farm wage rate and consequently the amount of off-farm work. Since data on commuting costs were unavailable, the ratio of agricultural population to total population in the township was used to represent these costs (Polzin and MacDonald).

Educational levels and size of family are expected to be directly related to the off-farm labor supply. Higher educational levels increase labor skills and, therefore, the opportunity for off-farm work (Hanson and Spitze). Households with many adults have a bigger pool of labor available for both on and off-farm work. The rural household labor pool increases if the wives and older family members assume the farm work when other family members obtain off-farm employment (Mizoguchi).

Changes in the consumption pattern of rural households as they adjust upward their desired standard of living may also affect the off-farm labor supply. As consumption changes, rural households are induced to earn more income in order to achieve a higher standard of living. Although Adams, Canh, and Chin argue that the consumption bundle has changed dramatically in Taiwan during the study period, the lack of data precludes use of this variable in the model proposed here.

Lastly, farming type may affect the off-farm labor supply, since some types of farming, such as vegetable and tobacco, are more labor intensive than others such as rice.

In summary, equation (1) presents the formal specification of the basic Taiwanese model as follows:

$$(1) \quad L_n = f(W_n/I,\ C,\ S,\ A,\ M_h,\ N_f,\ D_l,\ U),$$

where $\partial L_n/\partial(W_n/I) > 0$, $\partial L_n/\partial C < 0$, $\partial L_n/\partial S > 0$, $\partial L_n/\partial A > 0$, $\partial L_n/\partial M_h > 0$, $\partial L_n/\partial N_f < 0$, and $\partial L_n/\partial D_l \gtrless 0$. The off-farm labor supply L_n, measured in man-days, is a function of the ratio of daily wages of off-farm work to net farm income (W_n/I), the percentage of agricultural population to total population in the township (C), average schooling years of

adults (S), number of adults in family (A), stock of farm machinery per hectare in New Taiwan dollars (M_h), farm land in hectares (N_f), farming types (D_i)—a dummy variable used to represent the five farming types of rice (D_0), vegetable and tobacco (D_1), fruit (D_2), other crops (D_3), and livestock (D_4)—and the error term (U).

Linear and double logarithmic functional forms were estimated in the analysis; however, only the results from the linear model are reported here because it provides a better statistical goodness of fit. (See Hu for further details concerning the different functional forms that were tested.)

The Results

The average off-farm labor per rural household was 308 man-days in 1973. The coefficient on W_n/I, the ratio of daily nonfarm wages to net farm income, is significant at the 1% level and has the expected sign; that is, an increase in nonfarm wages or a decrease in net farm income is associated with more off-farm work (table 2). However, the supply elasticity of off-farm labor with respect to W_n/I at the mean of the observations is small, which implies that a change of 10% in the ratio of nonfarm wages to net farm income causes a change of about 0.5% in off-farm labor supply.[2]

The coefficient of C, the percentage of agricultural population to total population in the township, is not significant but does have the expected sign. This suggests that commuting cost has little influence on the labor supply. A possible reason for this is that the commuting distance to off-farm employment is relatively small in Taiwan because the country is geographically small and because both agricultural and industrial centers are located in a narrow seashore plain and upland. There does not seem to have been enough variance to measure in Taiwan on this issue. Commuting cost might be an important factor in other countries that are less confined geographically.

The coefficient of S, average schooling years of adults in a family, is significant at the 1% level and has the expected sign. In addition, the elasticity of labor supply with respect to this variable is elastic, suggesting that an increase of 10% in average schooling years for farmers is associated with a more than 10% increase in the supply of off-farm labor.[3] As shown in table 2, an increase of one year in the average schooling years of adults in a family is associated with forty-seven more off-farm labor days annually.

The number of adults in a family is significant at the 1% level and has the expected sign. It shows that an increase of one adult in a family provides about fifty-nine additional man-days of off-farm labor per year.

The positive sign and statistically significant coefficient of M_h, stock of farm machinery per hectare, means that the supply of off-farm labor is increased if more farm machinery is used on farms. The elasticity of labor supply with respect to M_h is about 0.18.

The variable farmland (N_f) has a negative coefficient, significant at the 1% level, which means that a 10% increase in farm size is associated with a 0.27% decrease in the supply of off-farm labor.[4]

Among the four farming types, the coefficients on vegetable and tobacco farms (D_1) and fruit farms (D_2) are significant at the 5% level and have the expected sign. The negative sign means that vegetable and tobacco and fruit farms provide less off-farm labor than rice farms. As these farm types increase in number, the supply of off-farm labor decreases.

[2] Sample farms were divided into "comparatively large" and "comparatively small" farms to estimate the off-farm labor supply function for the two groups. The dummy variables method was used to test the equality of each pair of coefficients between the two regressions. The off-farm labor supply elasticity with respect to W_n/I was larger (0.129) for small farmers than for large farmers (0.027).

Table 2. Regression Results and Elasticities of the Supply of Off-Farm Labor Among Taiwanese Farmers (Total Sample)

Independent Variable	Regression Coefficient	t-Value	Elasticity at Mean Value
Constant	−241.708	4.010	—

Conclusions and Policy Implications

The findings of this study suggest that the rural household level variables that significantly affect the off-farm labor supply are (*a*) the ratio of daily nonfarm wages to net farm income (W_n/I), (*b*) the

[3] This labor supply elasticity, estimated from cross-sectional data at one point in time, fails to include members of the household who may have been educated in rural areas and then moved to the city. A time-series analysis might result in an even higher elasticity for education.

[4] An additional variable, land use intensity, was included in a second equation not reported here. This variable had a coefficient that was significant and with a negative sign, which suggests that as land use intensity increases, off-farm labor decreases.

educational level of the members of the rural household (S), (c) the number of adults in the household (A), (d) the degree of mechanization on farms (M_h), and (e) the farm size (N_f).

The results indicate that the off-farm labor supply is inelastic with respect to W_n/I (0.05). Therefore, the extent to which rural households seek off-farm work depends upon nonfarm wage and agricultural price relationships. Off-farm wage rates are sufficiently high relative to farm incomes in Taiwan so that rural households have the incentive to seek off-farm work. In other words, the gap between urban incomes and rural incomes makes off-farm work attractive. A government policy of low food prices (common in many less developed countries) in combination with high urban wage rates due to rapid economic growth or minimum wage policy induces rural households to seek off-farm work or to migrate. Taiwanese policy seems to have achieved the former without triggering massive increases in rural-urban migration.

The off-farm labor supply is elastic with respect to the average educational level of rural household members. A 1% increase in the educational level of the rural household results in a more than 1% increase in the quantity of off-farm work. Off-farm work is, therefore, quite sensitive to the skill level of the rural household members. Efforts to improve education in rural areas are expected to increase the off-farm labor supply as well as to accelerate the farm modernization process.

The off-farm labor supply elasticity with respect to the stock of farm machinery per hectare is 0.18. This means that a 10% increase in machinery investment increases the off-farm labor supply by about 2%. As labor-saving technology continues to reduce farm labor requirements, more farmers and especially small farmers are likely to find higher returns to their excess labor resources in off-farm work as opposed to intensifying their farming operations on a limited land base. Government subsidies for capital inputs such as machinery accelerate the rate at which this substitution occurs, creating both the opportunity and need for off-farm work.

Although this study examined several factors that were hypothesized as determinants of off-farm labor supply, further study is necessary to identify other factors such as personal and off-farm employment characteristics that may affect the labor supply. In addition, community and national level conditions such as unemployment rates also need to be examined to assess their impact on off-farm work.

Taiwan's recent experience along with that of other countries such as Japan strongly suggests that off-farm employment has contributed greatly to higher farm incomes among small farmers during the economic development process. Rural Taiwanese households unable to increase their income via larger farm size have substantially increased their incomes by utilizing their excess labor in the nonfarm sector.

The Taiwanese experience of increasing rural purchasing power through off-farm work challenges the conventional technology approach to solving the small farmer problem and the agricultural economists' traditional view of off-farm income as a "by-product" of farms. Development planners and researchers should place higher priority upon understanding this process and developing plans that deal specifically with it. The central issue is to decide what strategy should be adopted for rural households that have found that off-farm work is an optimal way to use household labor resources. Traditionally, a goal of agricultural policies has been to achieve an efficient agricultural sector that rewards farmers equitably in terms of aggregate income and household income. Policy approaches to part-time farming must consider the gains and losses in terms of equity and efficiency for the part-time farmers, the full-time farmers, and rural areas. This research has demonstrated that a substantial payoff exists for the part-time farmers. We feel that off-farm work alternatives for small farmers will permit governments to do more about low incomes and poverty in rural areas.

The Validity of the Cobb-Douglas Specification in Taiwan's Developing Agriculture

J. T. Shih, L. J. Hushak, and N. Rask

This paper tests the specification of production functions within the context of Taiwan's developing agriculture. The Cobb-Douglas and the translog function that contain the Cobb-Douglas as a special case are the alternatives selected for the test. The translog function relaxes many restrictive properties of the Cobb-Douglas function without causing computational difficulties.[1] Statistical and economic considerations are used as criteria of empirical performance.

The translog function has been used as a second-order approximation to a general production function to measure technical change biases with many factors of production (Binswanger) and to test the existence of a consistent aggregate index of labor inputs (Berndt and Christensen 1974). Kmenta has considered it as an approximation to the constant elasticity of substitution. Griliches and Ringstad and Sargan are the only studies found that estimate the translog as a production function in its own right. Properties of the translog function are discussed in Berndt and Christensen (1973) and Christensen, Jorgensen, and Lau.

Data, Variables, and Models

The farm records kept by fifty-three Taiwanese farm families during the 1964–70 period provide the data for this study. The distinctive feature of combined cross-section time-series data is that they permit use of past histories of individual farms to isolate the effects of persistent interfarm differences in behavior. These data, which were generated from a farm-record-keeping project in Taiwan, include rather comprehensive information on land use, labor supplied, farm and nonfarm receipts, farm operating expenses, household living expenses, farm assets, liabilities, and net worth, but the absence of price information on farm outputs and inputs makes it impossible to consider simultaneous equations production models.[2] The nonrandomness of the sample and the small number of farms reduce the value of the estimated production functions for policy issues. The implications of the results from this study are limited primarily to methodological aspects.

Gross farm income is expressed as a function of a set of inputs. The factors that have been observed and that are hypothesized to be arguments in the production function are land, labor, capital services, and management as represented by farm dummy variables. Gross farm income (Y) is defined as the gross income from operation of farm enterprises, including receipts from crop, livestock, and poultry, processed farm products, and others. It is measured in New Taiwan dollars (NT$) of 1960–63 prices (Bureau of Accounting and Statistics, Taiwan).

Area cropped (X_1), measured in hectares, is defined as the total area cropped for first paddy plus second paddy plus other crops in a year. In Taiwan, a parcel of good land is usually cultivated two or three times a year, while land of low quality can be cultivated only once. In this case, the use of area cropped instead of area of farm land may to some extent increase the homogeneity of land input.[3]

Total labor (X_2), including family and hired labor, is measured in adult-man-days worked on farm enterprises. The weights used for conversion to adult-man-days are male aged 15 to 60 years is 1.0, male aged under 15 or over 60 years is 0.5, female aged 15 to 60 years is 0.8, and female aged under 15

J. T. Shih is at the Institute of Economics, Academia Sinica, Taiwan, and L. J. Hushak is an associate professor and N. Rask is a professor at the Ohio State University and the Ohio Agricultural Research and Development Center.

The Agency for International Development, The Joint Commission on Rural Reconstruction, and The Provincial Department of Agriculture and Forestry (PDAF) in Taiwan provided support (financial and other) for the development and processing of the data base of this study. The authors acknowledge the comments of D. Adams, F. E. Walker, and two *Journal* reviewers.

[1] The constant-elasticity-of-substitution function (Arrow et al.), Mukerji's CRES (constant-ratio-of-elasticity-of-substitution) function, Clemhout's class of homothetic functions, and Revankar's VES (variable-elasticity-of-substitution) function are other alternatives. These functions, however, complicate statistical estimation. A modified Cobb-Douglas function (Ulveling and Fletcher) was tested and gave results closer to the translog function than the Cobb-Douglas.

[2] The Taiwan farm-record-keeping project is conducted by the Provincial Department of Agriculture and Forestry (PDAF). The project began coverage of the entire island in 1964. Farmers are free to enter or drop from the program at any time. There were only fifty-three farm families remaining in the project throughout the 1964–70 period. The total number of participating farm families ranged from 402 to 535 during this period. In 1971, only forty of the fifty-three farms were still in the project, and in 1972 only two. For a detailed description of the data, see Ong (pp. 40–61) and Shih (pp. 41–46).

[3] Three land variable alternatives were considered: total area of farm land, total area cropped, and the area of farm land in irrigated equivalents. To choose among these alternatives, their simple correlations with gross farm income were calculated. Crop area was chosen since it had the highest simple correlation.

or over 60 years is 0.4. The assumption implied by this specification of labor input is that the productivity of family workers is the same as that of comparable hired workers.

Capital services (X_3) is measured in NT$ of 1960–63 prices. Included are current expenses for seed and seedlings, fertilizers, wages to hired animal labor, insect and pest control, farm equipment, feed, and others. Also included are the imputed interest expenses and depreciation charges for farm buildings and farm machinery.[4]

In addition to land, labor, and capital, management is expected to play an important role in the process of farm production. No measure of management exists in the data. Following Hoch and Mundlak, the farm-specific index of technical efficiency measured by the residual from the estimated production function is used to estimate managerial and other differences across farms. The farm specific residuals are obtained from the coefficients of a set of farm dummy variables (D_n, $n = 1, 2, \ldots, 53$), where $D_n = 1$ for the nth farm and $D_n = 0$ otherwise.

This covariance model is selected over an error components model because the farm specific residuals are correlated with measured inputs. Although error components models are considered to be more efficient than fixed effects covariance models (Maddala), violation of a basic assumption of error components models (because managerial variations are included in the farm specific residuals) led to the choice of a fixed effects model.

The Cobb-Douglas model of Taiwan's production is

$$(1)\quad \ln Y_{nt} = \ln A + \sum_{i=1}^{3} a_i \ln X_{int} + \sum_{n=2}^{53} F_n D_n + u_{nt},$$

where n ($n = 1, 2, \ldots, 53$) stands for the individual farm, t ($t = 1, 2, \ldots, 7$) for the individual year, and i ($i = 1, 2, 3$) for the input, and u is the disturbance term. The intercept term $\ln A$ stands for the first ($n = 1$) farm whose dummy variable is suppressed. The F_n's are the farm dummy coefficients that, along with $\ln A$ and the a_i's, are to be estimated.

The translog model is

$$\begin{aligned}(2)\quad \ln y_{nt} &= \ln B + b_1 \ln Z_{1nt} + b_2 \ln Z_{2nt} \\ &\quad + b_3 \ln Z_{3nt} + 1/2 c_{11} (\ln Z_{1nt})^2 \\ &\quad + c_{12} \ln Z_{1nt} \ln Z_{2nt} + c_{13} \ln Z_{1nt} \ln Z_{3nt} \\ &\quad + 1/2 c_{22} (\ln Z_{2nt})^2 + c_{23} \ln Z_{2nt} \ln Z_{3nt} \\ &\quad + 1/2 c_{33} (\ln Z_{3nt})^2 + \sum_{n=2}^{53} G_n D_n + v_{nt},\end{aligned}$$

where $y_{nt} = Y_{nt}/Y^*$, $Z_{int} = X_{int}/X_i^*$, Y^* and X_i^* are the geometric means of Y and X_i, G_n are the farm dummy coefficients, and v is the disturbance term. All other terms are as previously defined. As these equations are all linear in the parameters, ordinary least squares can be applied.[5]

Testing of Functional Forms

Only the "best" estimate of the translog is tested against the Cobb-Douglas. The alternative equations are displayed in table 1. The farm dummy variables (D_n) are statistically significant at the 0.01 level in all equations, but the coefficients are not presented.

Selection of the "Best" Translog Model

The translog function (2a) includes all six squared and cross product terms. Only ($\ln X_1 \ln X_2$) and ($\ln X_2$)^2 have significant coefficients. The four vari-

[4] Since the concern in this study is with the specification of functional forms, all capital services were aggregated into a single capital service variable.

[5] A set of time dummy variables was also included as variants to models (1) and (2). The coefficients of the time variables were never significant, either individually or as a group, and are excluded from the models in this paper.

Table 1. Selected Fitted Regressions

	(1)	(2a)	(2b)	(2c)

		(0.393)		
SEE	0.179	0.176	0.176	0.177
R^2	0.934	0.937	0.936	0.935
F-ratio	80.616	75.141	80.895	79.514
D.F.	55;315	61;309	57;313	57;313

Note: All equations include $\ln A$ and the D_n's. The variables are defined in the text. t-ratios are in parentheses. SEE is the standard error of estimate. D.F. is degrees of freedom.

ables with small t-ratios are dropped, and the coefficients of the retained variables in (2b) are similar to those in (2a).

Generally, the use of labor in farm production in a labor-surplus economy is greater than needed relative to other inputs. This implies diminishing marginal returns to increasing quantities of labor input (other input quantities being the same). The positive coefficients of the squared labor variable in models (2a) and (2b) are sufficiently large to make the second-order condition for labor positive when evaluated at the mean, implying increasing returns to labor. Although economic logic does not rule out this possibility, the estimated increasing marginal returns to labor in a developing economy characterized by labor-intensive agriculture is not expected.

The translog function is potentially subject to serious multicollinearity problems. Several alternative estimates were examined. Model (2c), where the labor-capital cross product ($\ln X_2 \ln X_3$) is substituted for the squared labor variable $(\ln X_2)^2$, is the only alternative estimate that yields significant coefficients of second-order variables. The simple correlation between $\ln X_2^2$ and $\ln X_2 \ln X_3$ is 0.89, the largest between any pair of explanatory variables. Since model (2c) is consistent with economic expectations, it is considered as the "best" model on statistical and economic grounds for comparison with the Cobb-Douglas function.

Comparison of Models (1) and (2)

For purposes of comparison, equation (1) is compared with (2c). In equation (1), all the estimated coefficients of the input variables have large t-ratios, but model (2c) has two additional terms whose coefficients have t-ratios greater than 2. Compared with model (1), model (2c) has a reduction in residual variance that is statistically significant at the 0.05 level. This is evidence that the Cobb-Douglas function is not appropriate.

The marginal productivity equations of input X_i for the Cobb-Douglas and translog functions, respectively, are

$$f_i = b_i \frac{Y}{X_i}, \text{ and } f_i = (b_i + \sum_{j=1}^{m} c_{ij} \ln Z_j) \frac{Y}{X_i}.$$

Following conventional procedures, the geometric mean of observed output and inputs in the sample is used as one computational point (table 2). The marginal product of each input at its mean level and at ±10% of its mean level is computed, holding other inputs constant at their mean levels. Then the sample farms are split into two groups based on mean outputs to obtain two additional points: one point above and one below the total sample mean. The value of production per farm, the amount of inputs used per farm, and the average value products of various inputs are reported in table 3 for the sample and the above and below the mean groups.

Because of the diminishing returns nature of the elasticity coefficients, the returns for the quantities of inputs used are the lowest at the 10% above the mean point and highest at the 10% below the mean point (table 2). For model (1), the marginal product of cropped area is NT$7,515 per hectare at the geometric mean of variables. It decreases to NT$7,049 per hectare when the cropped area is 10% above the mean level and increases to NT$8,085 per hectare when cropped area is 10% below the mean. The productivity change of cropped area at alternative levels for model (2c) can be seen across the second row of table 2.

The estimated marginal returns to labor from the two models are similar. Compared with model (2c), model (1) shows a higher return to cropped area and a lower return to capital services. Because of the constant-elasticity-of-production restriction of model (1), the computed marginal product of any input appears to be the "average" of varying production techniques. The constant-production-elasticity function tends to overstate the marginal returns to cropped area and understate returns to capital services for more capital-intensive techniques. The opposite is true for less capital-intensive techniques.

The marginal products of various inputs at three different combinations of input and output levels are presented in table 4. The marginal returns to land input are NT$7,110, NT$7,515, and NT$7,927 per hectare in model (1) at the geometric means for the below the mean, all, and above the mean groups of farms. In evaluating estimates of marginal returns, the emerging pattern is more in agreement with logic for model (2c) than for model (1). The two models show similar marginal products of

Table 2. Marginal Products with Varying Input Levels, All Farms

		Marginal Production at Input Level		
	Model	10%	Mean	−10%
Cropped area (NT$/ha.)	1	7,049.38	7,515.47	8,085.13

[a] The observed inputs and computed output are at the geometric means of the respective groups.

labor. Model (2c) shows a monotonic decrease in land productivity when moving from the lower to the higher combinations of input and output levels, while model (1) shows an increase. Conversely, model (2c) shows a monotonic increase in capital productivity from the smaller to the larger size levels, while model (1) shows a decrease. These results for model (2c) are attributable to the negative effect of the joint variable $\ln X_1 \ln X_2$ and the positive effect of the joint variable $\ln X_2 \ln X_3$.

Under the hypothesis that constant returns to scale prevail in farm production, the introduction of farm-specific dummies into the production models, if there are omitted variables such as management, results in a drop in the sum of output elasticities. The two models under comparison show such an elasticity drop. The scale elasticity of model (1) is 0.82. The scale elasticity in model (2c) is 0.84 at the small size group mean, 0.82 at the all farm mean, and 0.81 at the large size group mean.[6] The corresponding geometric means (antilogs of mean coefficients) of the farm specific residuals are 0.89, 1.0, and 1.12 from model (2c). This indicates that there may be a decrease in returns to scale from the included variables as size or scale increases because the excluded variables become relatively more important on larger farms.

In the translog model (2c), the Allen (p. 504) partial elasticities of substitution, computed at the

[6] The comparable scale elasticities for all farms when the farm dummy variables are deleted are 0.938 for model (1) and 0.983 for model (2c) at the sample geometric mean.

Table 4. Marginal Products at Varying Size Levels

			Farm Groups		
		Model	Below Mean	All Farms	Above Mean
Cropped area (NT$/ha.)	f_1	1	7,110.20	7,515.47	7,927.54
		2c	7,226.88	6,858.65	6.611.48
Labor (NT$/man-day)	f_2	1	10.94	13.11	15.61
		2c	11.76	13.44	15.63
Capital services (NT$/NT$)	f_3	1	0.91	0.89	0.86
		2c	0.92	0.95	0.99

sample geometric mean, are 6.23 for land-labor, 1.67 for land-capital, and −0.89 for labor-capital. The computed partial elasticities at the above and below the mean sample points are of similar sign and magnitude. These elasticities indicate a production technology that is relatively flexible with respect to land and labor use but very inflexible with respect to labor-capital use.

Conclusions

The translog model has two significant variables not in the Cobb-Douglas relation. Although these two models gave similar degrees of fit, the significance of two more variables in the alternative model can be accepted as evidence to reject the Cobb-Douglas specification.

When evaluated on economic grounds, the major difference is in the allocation of output to land and capital. The Cobb-Douglas shows a higher return to land and a lower return to capital services as compared with the translog. With respect to scale changes, the Cobb-Douglas shows increasing returns to land and decreasing returns to capital, while the translog shows the opposite. The restriction of constant-elasticity-of-production makes it impossible for the Cobb-Douglas to distinguish between land and capital productivity on farms with more capital-intensive techniques and farms with less capital-intensive techniques.

Further examination of productivity behavior from scale changes and changes in input proportions indicates that the translog model has advantages over the Cobb-Douglas model in two respects. First, the pattern of input productivity estimates for three different size groupings of farms appears to be more in agreement with expectations for the translog model than for the Cobb-Douglas. Second, in the translog model the output elasticity of various inputs is allowed to vary with size levels and to be determined by the data.

The "best" model emerging on economic and statistical grounds is a simplified form of the translog function. Specified in this manner, the chosen model of production is more similar in appearance to Vinod's multiplicative nonhomogeneous production function than to the original translog specification. Although nonhomogeneity is required by theory, the empirical fitting of nonhomogeneous production functions is uncommon. The results in this paper support the nonhomogeneous production laws.

Land Utilization and Productivity in Prewar Chinese Agriculture: Preconditions for Collectivization

Dennis L. Chinn

The distinguishing feature of the strategy for agricultural development adopted in China after the Communist takeover was the rapid series of organizational changes that occurred. Following the land reform, mutual aid terms were organized, followed in rapid succession by elementary producer cooperatives, advanced producer cooperatives, and finally the rural communes.[1] Although estimates of grain output prior to the Great Leap Forward differ widely, it is generally agreed that China's agricultural performance during this early period was much better than that of many other developing countries.[2] The interesting and as yet unresolved question regarding that experience is the role that the organizational changes themselves played in raising output.

It is useful to conceptually distinguish several aspects of the causal relationship between the organizational changes and agricultural productivity. The official Chinese literature places primary emphasis on the labor mobilization aspect as the key to increased productivity through investments in land reclamation, irrigation, and agricultural infrastructure. The collectivization process was the mechanism by which increasingly large amounts of rural labor could be mobilized. A second closely related aspect of the relationship is the whole question of peasant incentives.[3] There is little doubt that the land reform raised the incomes of poor farmers by effectively eliminating the landlord class and allowing the peasants to capture the returns to the land and other assets, but the extent to which widespread increases in productivity directly resulted in China is unclear. Private land ownership was eliminated with the formation of the advanced producer cooperatives, so it would seem that those arguments that attribute substantial benefits to the incentives created by the establishment of individual property rights by land reform are not applicable to the present case. (For a survey of the literature on land reform and its effects, see Raup.) To the extent that landlord control was simply replaced after a few years by state control, one could hardly argue that elimination of the former significantly improved production incentives in the long run.

The present paper concerns a third aspect of the relationship between changes in organization and productivity, the extent to which static efficiency gains result from the induced reallocation of resources. The land reform consolidated fragmented holdings and effectively eliminated tenancy, transferring ownership from landlords to former tenants and poor peasant farm households; the formation of mutual aid teams formalized and extended cooperation between farm households in the use of labor, work animals, and capital implements; and the formation of the cooperatives increased the effective size of operational units substantially. Using data on prewar China, a simple regression analysis is used to relate tenancy, fragmentation of landholdings, and farm size to agricultural output in order to assess the potential for efficiency gains that existed prior to the Communist takeover and reorganization of agriculture. The existence of such potential would seem to be a necessary condition for significant static efficiency gains to result from organizational changes.

The organization of the paper is as follows. After a brief discussion of some characteristics of land utilization in prewar China, the method of analysis is described, the variables defined, and the statistical results presented. The final section of the paper relates the results to results of a previous complementary study and offers some tentative conclusions.

Land Utilization in Prewar China

Summary data on the pattern of land utilization for eight agricultural areas of China are presented in

Ramon Myers provided helpful comments on an earlier draft of this paper.

[1] For a concise description and chronology of the stages in the collectivization process in China during this period, see Walker. The analysis of this paper focuses on the general cumulative effects of all stages together rather than chronological details or effects specific to each stage in isolation.

[2] All western observers seem to agree that the official figure for total grain output in China for 1957 of 185 million tons is accurate. However, estimates for 1952 range from 175 million tons to acceptance of the official Chinese estimate of 154 million tons. Thus, depending upon which base figure one takes, during 1952–57 grain output in China increased by anywhere between 5.7% and 20.1%. For a summary of the available estimates, see Sinha.

[3] The development of various wage payment schemes with the objective of maintaining production incentives through payment according to work while reducing income differentials is quite fascinating. See Hoffman for a description of these mechanisms.

table 1. The area averages summarize detailed survey data for 16,786 Chinese farm households collected by Buck (1937) and his associates during 1929–33. Several points warrant mention. First, due to high population pressure, the average size of farm is extremely small, especially in the rice areas. The average farm size for the wheat area as a whole is 2.28 hectares, while that for the rice area is only 1.25 hectares. In each area over 90% of the total land area is in productive use. The difference in total area sown is somewhat less than the difference in farm size, as multiple cropping is more prevalent in the rice area.

Second, fragmentation of landholdings is an extremely severe problem in both the rice and wheat areas. The average farm in each area consists of more than five separate parcels of land separated by the average distance of 0.8 kilometer in the wheat area and 0.5 kilometer in the rice area. Third, tenancy is much more extensive in the rice area than in the wheat area. In the former, 40% of all land is rented as compared with only 13% in the wheat area. For the households surveyed by Buck, 6% of farmers in the wheat area and 25% in the rice area are tenants. These figures are considerably lower than the corresponding figures from National Agricultural Research Bureau (NARB) data of 17% and 46%, respectively, as shown in table 1. This discrepancy suggests that tenant farmers may be underrepresented in Buck's samples, so the estimated relationships that follow cannot be interpreted as being necessarily representative of all farms in each crop area.

Finally, there is substantial variation in the pattern of land utilization within the wheat and rice areas as well as between the two. For example, the average farm size in the spring wheat area is almost twice that in the winter wheat-millet area, while the percentage of land rented in the latter is twice that in the former. Variation in the pattern of land utilization within the rice area is also significant, suggesting that attempts to generalize about Chinese agriculture as a whole should be taken with a somewhat larger than average grain of salt.

Method of Analysis

For present purposes traditional Chinese agriculture is represented by the simple Cobb-Douglas production function

$$(1) \qquad Q = AM^aN^bL^cZ^d,$$

where Q is total output, A is a constant term, M is the index of multiple cropping, N is total land area in productive use, L is family labor input into farming, and Z is organic fertilizer.[4] The lower case letters represent the constant elasticities of output with respect to the individual inputs. The index of multiple cropping is interpreted as an index of technical progress and is closely related to the availability of controlled water supplies in areas climatically suitable for double cropping. The rationale for including M as a separate variable rather than simply using total sown area (MN) in place of N as the land variable is that my interest is in changes in the

[4] Other traditional inputs in Chinese agriculture are animal labor and tools of various kinds. However, since suitable data are not available for the sample households, these inputs are not included in the analysis. In any case, the available ownership figures for productive animals are highly correlated with the fertilizer input variable.

Table 1. Characteristics of Land Utilization for Sample Households in Prewar China by Crop Areas

Crop Areas of China	Average Size of Farm (Ha.)	Percentage of Farm Land in Productive Use[a]	Multiple Cropping Index[b]	Fragmentation		Tenancy		
				Number of Parcels per Farm	Average Distance Between Parcels (Km.)	Percentage of Land Rented	Percentage of Farmers Who Are Tenants	
							Buck[c]	NARB[d]
Wheat area	2.28	93.1	127	5.7	0.8	12.7	6.3	17.2
Spring wheat	3.25	90.7	107	4.8	1.0	8.4	5.7	38.9
Winter wheat-millet	1.71	93.1	118	5.5	0.9	17.3	8.9	16.4
Winter wheat-kaoliang	2.25	93.8	139	6.2	0.6	11.8	5.1	12.1
Rice area	1.25	92.4	166	5.5	0.5	40.3	24.6	46.3
Yangtze rice-wheat	1.56	92.8	165	5.3	0.3	39.4	25.1	48.9
Rice-tea	1.00	94.0	169	5.4	0.6	42.1	18.5	48.9
Szechwan rice	1.43	91.3	167	9.7	0.3	49.1	43.1	51.4
Double-cropping rice	0.96	92.5	176	5.4	0.7	46.8	28.2	46.2
Southwestern rice	1.03	88.4	152	3.7	0.6	26.8	21.0	36.4

Note: Data from Buck (1937, tables 15, 21, 22, chapter II, and table 5, chapter VII).

[a] Includes crop land, pasture, forest, productive water area, and land in brush and grass used for fuel. Excludes the farmstead, land taken by roads, ponds, graves, etc., and arable uncultivated land.

[b] Calculated as the total area that would be required to produce the actual output levels for all crops at the most frequent yields in China divided by the area actually required to produce the crops in the locality multiplied by 100.

[c] Farmers who own their farmstead but rent all their crop land are included as tenants.

[d] Source: National Agricultural Research Board.

pattern of utilization of land area rather than area sown to crops.

Assessing the effects of fragmentation of landholdings and tenancy on agricultural output involves two hypotheses. First, fragmentation and tenancy are negatively correlated with family labor input per hectare of land. The greater is land fragmentation and the higher the proportion of land rented, the lower will be the relative rewards to farming, and the farm household's response will be to increase labor allocated to off-farm activities and/or leisure. Second, fragmentation and tenancy are negatively correlated with total factor productivity. Increasing fragmentation and tenancy will tend to shift the production function downward.

The test of these two hypotheses in the present context is straightforward, involving the estimation of two sets of log-linear regression equations:

$$(2)\quad \log (L/N) = \log B + \alpha \log M + \beta \log F + \gamma \log T,$$

and

$$(3)\quad \log Q = \log A + a \log M + (b + c + d) \log N + c \log (L/N) + d \log (Z/N) + e \log F + f \log T.$$

In the first set, equation (2), family labor input per hectare of land is related to a constant term B, the index of multiple cropping M, an index of land fragmentation F, and an index of tenancy T. Based on the first hypothesis, both β and γ are expected to be negative. In the production function (3), the fragmentation F and tenancy T variables simply enter as additional terms. Whether they are entered multiplicatively (additively in logs) or additively turns out to make little difference to the empirical results, but the form used embodies the implicit assumption that a given percentage change in either the tenancy or fragmentation indices has the same effect on output over all values of the indices.[5] Based on the second hypothesis, the expectation is that e and f be negative. The traditional inputs labor L and organic fertilizer Z are measured in per hectare terms, so the coefficient of log N in the production function $b + c + d$ can be interpreted as the returns to scale parameter.

Number of Observations and Variable Definitions

In the statistical volume of Buck's study (1937), averages of individual farm survey data are given for relative farm size classes by individual localities for each of the eight agricultural areas of China listed in table 1. For the spring wheat area, for example, average data are given for surveyed farms in thirteen localities (in six provinces) for eight farm size classes, giving potentially 104 observations for cross-section analysis. However, some localities have to be omitted due to omissions in the data, and the smallest and two largest farm size classes are simply not represented for most localities. As a result, the total number of observations for the spring wheat area is only seventy-one. The sample size for each area is given in table 2.

The variables used in the analysis are defined as follows. Total output Q is total output per farm in grain-equivalent units, the land variable N is hectares of land in productive use, excluding the farmstead, land taken by roads, ponds and graves, and arable uncultivated land, and the index of multiple cropping M is calculated as the total area that would be required to produce the actual output levels for all crops at the most frequent yields divided by the area actually required to produce the crops in the locality (times 100).

Suitable data on farm household labor allocation are not available, so the labor variable L is constructed as the following product: (number of male adult equivalent units) × (12 − number of idle months per able-bodied man) × (the proportion of total income earned from farm sources). The second term adjusts for idleness by choice or due to lack of alternative opportunities, and the last term reflects the allocation of labor between farm and off-farm activities. The implicit assumption is that an equilibrium position is reached by farm households in which the per unit returns to labor in farm and off-farm activities are roughly equivalent, so the proportions in total income reflect the allocation of family labor. This is somewhat arbitrary, but given the available data this assumption cannot be avoided.

The fertilizer variable Z is the total amount of animal manure and night soil applied per farm. Since traditional fertilizer application is little more than embodied labor, the two input variables are highly correlated, so at most one of the two is entered in each estimated production function. The fragmentation index F reflects both the number of parcels per farm and the average distance between parcels and is defined as the product of the two, and the index of tenancy T is simply the proportion of farm land rented.

Statistical Results

The first set of estimated equations, equation (2), is presented in table 2 with t-statistics in parentheses.[6] The most striking result is that the index of fragmentation F is a significant and negative explanatory variable for each equation, except that for the Szechwan rice area for which the statistical results are totally unsatisfactory due to the small number

[5] The formulation of the production function used here is the same as that used in a recent analysis of Indian data. For a discussion of the difficulties involved in estimating such a function, see Bardhan.

[6] A set of dummy variables was included in each equation in order to reflect any systematic differences between provinces, but since they had little effect on the regression results their coefficients are not reported.

Table 2. Estimated Regression Equation with Labor Input per Hectare (L/N) as Dependent Variable for Prewar China by Crop Areas

Crop Areas of China	Constant (A)	Multiple Cropping Index (M)	Fragmentation Index (F)	Tenancy Index (T)	R^2	Number of Observations
Spring wheat	2.741	—	−0.464	—	0.519	71
			(−6.62)			
Winter wheat-millet	−7.301	2.033	−0.154	—	0.398	97
		(5.27)	(−2.27)			
Winter wheat-kaoliang	3.110	—	−0.442	—	0.388	168
			(−8.97)			
Yangtze rice-wheat	−2.278	1.041	−0.170	−0.116	0.288	132
		(4.88)	(−3.52)	(−2.61)		
Rice-tea	−0.210	0.623	−0.209	—	0.373	107
		(4.78)	(−4.84)			
Szechwan rice	3.065	—	—	—	0.019	35
Double-cropping rice	3.580	—	−0.286	—	0.343	60
			(−4.15)			
Southwestern rice	−1.216	0.917	−0.473	—	0.599	55
		(3.34)	(−4.92)			

Note: All variables are measured in natural logarithms.

of observations. Thus, the widespread severe fragmentation of landholdings was clearly an important determinant of household labor allocation behavior in prewar China. On the other hand, for all but one area the tenancy variable T is not significant, suggesting that renting land did not strongly inhibit households from allocating labor to farming.

The estimated production functions are presented in table 3. The coefficient of the index of multiple cropping M is positive and significant for five of the eight areas, and the coefficient of the land variable N is positive and significant for all. The coefficient for either labor L or fertilizer Z is positive and significant for each equation, with the exception of that for the Yangtze rice-wheat area for which neither is significant. The coefficient of the land variable N exceeds unity for all areas except the Yangtze rice-wheat area, suggesting that in some areas increasing the size of farm units through reorganization would indeed result in increased output through scale effects.

Entering the fragmentation index F and the tenancy variable T as independent variables in the production function yields somewhat inconclusive results. The fragmentation index is significant and negative for four of the areas, suggesting that the

Note: All variables are measured in natural logarithms.
[a] Coefficient is returns to scale parameter.

excessive fragmentation did inhibit total factor productivity in at least some areas. However, as in the first set of estimated equations, the tenancy variable is significant for only one of the areas, suggesting that the percentage of land rented was not a severe limitation on productivity.

The lack of statistical significance of the tenancy variable in both sets of equations presented above may in part reflect the fact that the percentage of land rented does not reflect the degree of exploitation involved in the tenancy arrangement or the conditions under which tenant farm families were forced to live and also the possibility that tenant farms were underrepresented in the sample data on which those equations are based. Nonetheless, the lack of significance of the tenancy index is not inconsistent with the results of prewar studies on farm tenancy in China. In a study that summarizes the results of numerous prewar surveys, Buck (1944) compares tenant farms and owner-operated farms of similar size and concludes that yield per unit of land area did not differ systematically between the two, that although total incomes of owner-operators were higher, tenant farmers earned substantially more labor returns per man-equivalent unit through more intensive application of labor, and that the landlord's share of total receipts did not systematically exceed the proportion of inputs he supplied. The samples on which he bases those conclusions were by no means comprehensive, but there is little one can do about that now.

Complementary Results and Some Tentative Conclusions

A recent study by Dittrich and Myers provides evidence on a different aspect of potential static efficiency gains from resource reallocation that is complementary to the above results. Their study uses detailed farm family budget data for three villages in the grain-producing area of north China between 1937 and 1940 to estimate the potential gain in crop revenue by reallocating factors of production between individual crops. Their procedure is to estimate marginal products of labor and land by estimating production functions for individual crops and then to simulate resource reallocation in order to equalize marginal products across crops. The difference between the actual total crop revenues per farm and the potential revenues that would obtain if factors were optimally allocated then represents the potential gain in crop revenue from resource reallocation between crops. As a percentage of actual average farm income, with the exception of one village in 1939, the potential income gain was quite small, ranging from 1.4% to 9.6%.[7] On the basis of their evidence, they conclude that peasant farmers in the region studied were fairly efficient in allocating their labor and land resources between alternative crops.

A second result that stems from their production function estimates is that in two of the three villages considered cotton, corn, sorghum, wheat, and millet production were generally characterized by increasing returns to scale. In the third village, cotton, wheat, and millet were found to be characterized by decreasing returns to scale, so this evidence is by no means conclusive. Nonetheless, even though individual farms do not appear to have suffered much loss of potential income due to resource misallocation between crops, for two of the three villages studied it does appear that productivity gains would have resulted from increased specialization.

The evidence presented by Dittrich and Myers and the statistical results of the present paper suggest that agricultural productivity in prewar China was constrained by excessive fragmentation and small farm size. Following the Communist takeover, these constraints were released by the land reform and the formation of agricultural cooperatives. Whether or not the elimination of tenancy resulted in significant static productivity gains is less clear. The results of the present paper, while highly tentative, do suggest that in most areas of China the potential static efficiency gains from eliminating tenancy per se were small.

The analysis of this paper is relevant to only one aspect of the relationship between productivity and organizational structure in Chinese agriculture. Land reform and the changes that followed restructured Chinese rural society and set in motion powerful dynamic forces that undoubtedly had strong effects on peasant incentives. Whether on balance agricultural productivity increased as a result of the organizational changes depends upon the responses of peasant households to changes in the incentive structure facing them. Unfortunately, due to the rudimentary state of our knowledge in this area, whether one holds that agricultural productivity increased in China during 1949–57 as a direct result of, or in spite of, the organizational changes seems to turn on ideological conviction rather than historical evidence. While ideological conviction is the stuff by which mountains are moved in China as elsewhere, it would seem wise to keep it and economic analysis separate to the extent possible, even if that means substantive conclusions cannot be drawn.

[*Received October 1976; revision accepted January 1977.*]

[7] The exception is a loss of potential income in one village for 1939 of 17.5% of actual income due to rapid price inflation. This result presumably reflects the fact that production adjustments are not instantaneous.

Social Return to U.S. Technical Assistance in Bolivian Agriculture: The Case of Sheep and Wheat

E. Boyd Wennergren and Morris D. Whitaker

Official U.S. technical assistance to the developing world has been a relatively important social investment in the post-World War II era. Approximately $4.7 billion was spent between 1949–72 in agriculture, health, and education by the U.S. Agency for International Development (USAID) and predecessor agencies (USAID, p. 47). In 1972, USAID allocated $103 million to programs in food and agriculture (p. 28), more than 20% of the amount spent on public research programs in U.S. agriculture for the same year (Boyce and Evenson, p. 152). Yet, despite the relative importance of technical assistance and the close involvement of agricultural economists, there has been extremely limited evaluation of the efficiency of society's investment in these relatively costly aid programs.[1]

This note reports estimates of the return to U.S. investment of $4.6 million in a technical assistance program in Bolivia's agricultural sector between 1965 and 1974. A brief history and the principal features of the program are presented in the next section. The efficiency of public U.S. investment in the two principal program components, the sheep and wheat projects, is then analyzed using a conventional benefit-cost model. Conclusions and the implications of the findings are considered in the final section.

The Technical Assistance Program

In July 1965, USAID contracted with Utah State University to provide technical assistance to MACA (Bolivia's Ministry of Agriculture) and related government agencies. (The material in this section is abstracted from a bulletin on the technical assistance program [Utah State University].) The general objective was to assist with economic development of the highland areas, where sheep, llama, and alpaca were the principal agricultural enterprises.

Several interrelated programs, jointly known as the sheep project and designed to increase production and marketing of livestock products, were initiated in 1965 through MACA and continued with varying degrees of emphasis throughout the life of the contract. Included were (*a*) introducing improved management practices in native herds, (*b*) upgrading the genetic base in livestock, (*c*) increasing forage production, and (*d*) improving and developing product markets. Principal components of each program included applied research and extension, institution building in the public and private sector, training of counterparts, and importations of requisite equipment and materials.

During the first year, two principal areas were emphasized. First, an extensive training-demonstration program was mounted to teach campesinos (farmers) to regularly shear their animals with hand clippers. Second, a semigovernmental buying system for wool, alpaca, and llama hair was organized, and quality grading and differential pricing of raw wool were instituted for the first time in Bolivia.

Between 1967 and 1969, the shearing and wool-marketing programs were relatively successful, and emphasis of the sheep project shifted toward introducing other improved management practices (besides shearing), improving the genetic base, and increasing forage production. By 1975, several improved management practices had been demonstrated and introduced with varying degrees of success, including ram and ewe selection for breeding, culling, record keeping, dipping and parasite control, diagnosis and treatment of common diseases, flushing, and fattening with supplemental feeds.

The program for improvement of the genetic base concentrated on importation of pure-blooded rams and ewes and the development of "ram-raiser" flocks. As domestic production of pure-blooded and improved rams increased, these rams were placed in native herds in a complementary exchange and improved management program. Demand for improved rams increased rapidly, and, toward the end of the contract, placement was almost completely through weekly village markets.

The program to increase forage production included introduction of selected crop and pasture varieties and improvement of management practices on native rangelands. Until 1973, emphasis

E. Boyd Wennergren is a professor of resource economics and Morris D. Whitaker is an associate professor of economics at Utah State University.

This note is based on two reports by Wennergren (1974, 1975), which were financially supported under USAID/Bolivia Contracts 511-64T and 511-65T. The authors express appreciation to Harry W. Ayer for review of an earlier draft without implicating him in any errors. The analysis and conclusions are the authors' and not necessarily those of U.S. Agency for International Development or Utah State University.

[1] For example, in chapter 3 of their monograph, Boyce and Evenson consider "International Aid and National and International Research Programs" but devote only two pages to international aid to national systems.

was on selection of adaptable forage species through variety trials and importation and distribution of seeds (especially alfalfa) for commercial use. In 1973, efforts to improve range and watershed management were greatly increased and became the most important aspect of the forage production program until contract termination in 1975.

In mid-1966, the contract was amended to include a cereals project that concentrated on wheat production and marketing in the temperate valleys and later the lowlands. The initial focus of the wheat project was on variety and fertilizer response trials and extension of results. Also, the problems inherent in initiating a seed certification program were studied and recommendations made.

In 1969, the contract was amended to increase staffing from five to eight advisors, and the magnitude of the wheat project greatly expanded relative to the sheep project. Advisory personnel assigned to the wheat project increased from one and one-half to six, and a seed certification program was implemented. In 1971, one of the advisory positions on the wheat project was shifted back to sheep, and five advisors in wheat and three in sheep were maintained until contract termination in 1975.

Benefits and Costs

Conventional benefit-cost procedures are used to estimate the rate of return to U.S. investment in the sheep and wheat projects. Benefits are defined as the marginal net return accruing directly to individual farmers adopting new technologies under the program and do not include secondary benefits. Marginal net returns are calculated by subtracting the gross returns that would prevail without the program and the increased costs of production associated with adopting the new technology from the gross returns realized with the program. The opportunity cost of family labor is assumed to be zero in calculating increased costs of production, so marginal net returns are to management and family labor.

Program costs are the direct costs of the sheep and wheat projects paid by USAID for the contractor's services and do not include costs of the Government of Bolivia. Thus, the rate of return is to marginal U.S. investment in the technical assistance program rather than to total U.S.-Government of Bolivia costs, and increases in net returns experienced by farmers are assumed to be completely due to the marginal U.S. investment. This assumption is based on two observations. (*a*) MACA's total budget declined in real terms during the life of the contract with no evidence of significant internal shifts in favor of efforts in sheep and wheat with the advent of the technical assistance program. (*b*) Previous MACA efforts to increase factor productivity and production of sheep and wheat were relatively ineffective (Wennergren and Whitaker 1975a, p. 210, pp. 253–55).

Data used to calculate benefits and costs are taken from the extensive publications and reports produced under the technical assistance program (more than 233 titles exist),[2] the USAID contracts and their amendments, and unpublished data from MACA and are reported in Wennergren (1974, 1975). All benefits and costs are valued at 1974 prices.

The internal rate of return is used to measure social returns to investment in the technical assistance program and is calculated for the sheep, wheat, and combined projects. In each case, an *ex post facto* analysis is made for the period 1966–75 (fiscal years starting 1 August 1965) based on estimated benefits already realized. The technical assistance program is also analyzed assuming a twenty-year project life (1966–85) under two sets of conditions: (*a*) conservative, with benefits yet to be realized during 1976–85 assumed constant in each year at the level observed for 1975; and (*b*) more liberal, with benefits in 1976–85 extrapolated from the 1966–75 experience. These twenty-year "mid-project" analyses are made to determine the sensitivity of the internal rate of return to benefits yet to be realized.

Benefits from investment in the technical assistance program could be quantified for four distinct phases of the sheep project—wool shearing, production of pure-blooded sires, upgrading the genetic base and management practices in native flocks, and alfalfa production—and for one phase of the wheat project—introduction of improved wheat varieties. In each phase, increases in net returns to farmers due to program investment are estimated for 1966–75 and projected for 1976–85.

Benefits included in the wool-shearing phase are from the increased production of wool from unimproved sheep not accounted for in other phases of the sheep project. More than 200 sheep-shearing courses and demonstrations were conducted by contract technicians principally for training village leaders, extension agents, and Peace Corps volunteers. Unfortunately, no accurate record exists of the total number of campesinos trained by these people. However, records of the contractor indicate that 1,912 pairs of hand clippers were distributed by December 1967, 4,200 pairs by 1975, and that an average of 200 head of sheep were shorn per year per pair of clippers. Production of wool per sheep was increased from 1.1 to 4.0 kilos per five years because sheep were shorn every year rather than once in their lifetime. Costs of shearing were increased by $0.20 per kilo.[3]

To calculate gross returns with the project, it is assumed that the 4,200 clippers were distributed at the rate of 420 per year starting in fiscal year 1966 and that 150 head of sheep were shorn per year with

[2] A complete list of such publications can be obtained from the authors.

[3] In calculating increased private costs of adopting new techniques in each phase, all capital items are amortized at 12%, the bank rate of interest in Bolivia for agricultural credit.

each pair. For the period 1976–85, it is assumed the number of clippers in use remained constant at 4,200 with only replacement. Finally, it is assumed that all sheep in the other phases of the project were sheared, thus restricting the number of clippers available for shearing other unimproved flocks. The wool clipped from such unimproved sheep with the project minus the amount that would have been clipped without the project estimates increased production of wool due to the project. This, minus the increased costs due to the new technology, is the marginal net return to the wool-shearing phase of the sheep project.

The production of pure-blooded sires generated project benefits principally from the sale of seven-eighths to pure-blooded rams to be placed in native flocks and also from increased production of wool (both from annual shearing and improved genetics) and meat. Gross returns with the project are estimated by developing an animal and product inventory for each year of the analysis based on the total number of improved and pure-blooded sheep (1,500 ewes and 60 rams) in the limited number of flocks producing breeding stock in the initial year 1967, the lambing and death rates in such flocks with improved management, and yields of marketable rams, cullable rams and ewes, and wool.[4] Then, the animal and product inventory in native herds producing wool and slaughter animals is calculated starting with the same number of animals in 1967 as with the project to estimate gross returns without the project. Finally, the increased costs associated with producing breeding stock under improved management are calculated. Included are costs of pure-blooded rams and ewes, dipping, disease and parasite control, shearing, supplemental feeding, and the opportunity cost on capital.

Placement of seven-eighths to pure-blooded rams in native flocks and implementation of improved management practices (including shearing) resulted in increased production of wool and meat. Gross returns with and without this phase of the project are calculated in a similar manner to those for the pure-blooded sires phase through development of animal and product inventories. The number of pure-blooded rams initially available (283 in 1968) establishes the number of selected native ewes that could be bred and the subsequent inventory with the project. Increased costs of production for flock improvement include the pure-blooded rams, dipping, disease control, shearing, and the opportunity cost of capital. There is no increased cost for feed, since it is assumed that animals were pastured on native rangelands and that every improved blood ewe incorporated into the flock resulted in the sale of 1.5 native ewes (the crosses required more feed).

The alfalfa-production phase of the sheep project produced benefits from production of alfalfa on land that had previously been used to graze sheep on natural pastures. Gross returns to the project are from the sale of alfalfa produced on dry and irrigated land. The actual level of production in each year is based on the number of hectares and yields as reported in unpublished data of MACA. Gross returns without the project are from production of wool and slaughter animals under traditional conditions that are the same as those for the flock improvement phase but expressed on a per hectare basis. Increased costs of production include land clearing, land preparation, seed, hired labor, the opportunity cost of capital, and the cost of irrigation where applicable.

The only phase of the wheat project that permits quantification of benefits is the introduction of improved wheat varieties and cultural practices. Seed from selected improved varieties were multiplied and distributed to farmers through the seed certification program. Benefits are calculated as follows. Gross revenue per hectare with the project is based on average yields (1,000 kilos per hectare) realized on farms using improved varieties and management. Gross revenue per hectare without the project is based on average yields (750 kilos per hectare) on farms using traditional management and native varieties. Increased costs per hectare with the project include improved seed, hired labor, pesticides and herbicides, harvesting, sacks, transportation, and the opportunity cost of capital. Total benefits to the wheat project are the marginal net returns per hectare times the number of hectares actually planted to improved seed each year, which is obtained from bulletins and reports of the contractor.

Project costs are reported only for the combined sheep and wheat projects until 1971 and by uneven budget periods during the entire technical assistance program. The expenditures for each project during 1 August 1965 through 30 November 1969 are estimated based on the share of technical personnel in each project, since only total expenditures are reported. There are budgets for each project during 1 December 1969 through 28 February 1971, but only total expenditures are reported. Expenditures for each project in this period are estimated by the share of each project in the total budget. Expenditures by budget period for each project are converted to average annual expenditures for each fiscal year and deflated by the U.S. wholesale price index on a 1974 base. It is assumed that contract expenditures and program benefits are realized at the end of each fiscal year.

Rate of Return

The internal rate of return for the sheep project after ten years is 44.1% (table 1). When projected benefits for 1976–85 are held constant at 1975 level,

[4] This procedure was followed because of discontinuities in data on animals in flocks producing breeding stock. The projected 1974 inventory was 4,598 lambs. This is corroborated by a MACA estimate of 4,000 pure-blooded lambs produced in 1974.

Table 1. Internal Rates of Return to Sheep and Wheat Projects

Project Life	Sheep	Wheat	Total
		-----%-----	
1966–75	44.1	−47.5	31.7
1966–85[a]	49.7	14.1	41.2
1966–85[b]	51.5	[c]	43.2

[a] Benefits during 1976–85 held constant at 1975 levels.
[b] Benefits during 1976–85 increasing based on extrapolation from the 1966–75 experience.
[c] Not estimated as yields and area planted to improved wheat are not expected to increase significantly during 1976–85 because of project investment.

the return increased to 49.7% annually and is only 51.5% with benefits projected to increase during 1976–85. Thus, the rate of return is relatively insensitive to projected benefits in the twenty-year "midproject" analyses.

In contrast, the *ex post facto* return to public investment in the wheat project is negative at −47.5%. However, the rate of return is very sensitive to benefits yet to be realized. In the "midproject" analysis with benefits held constant at 1975 levels for 1976–85, the rate of return increased to 14.1%. Thus, the social profitability of the wheat project depends on future benefits being generated.

The combined projects generate a rate of return of 31.7% in the ten-year analysis, reflecting the relative importance of benefits of the sheep project. With benefits held constant at 1975 levels for 1976–85, the rate increased to 41.2% and is 43.2% when benefits increased according to projected trends during 1976–85.

Conclusions and Implications

One conclusion is that returns to U.S. investment in the sheep project are relatively high, although no directly comparable studies are at hand. However, the rates of return are in the range of returns to investment in research and extension programs, which have been previously reported (21% to 96%—see Arndt and Ruttan).

Furthermore, a number of activities were carried out under the sheep and wheat projects that generated social benefits that, for lack of data, could not be quantified in the above analysis. Perhaps the more important were a formal local training program; assistance in marketing wool, artisan products, and wheat; and assistance in developing a viable data base, carrying out economic and social policy studies, and developing agricultural plans. For example, under the training program, thirteen people were trained to the M.S. and Ph.D. level, two to the B.S. level, and fifty-one attended intensive courses all in the United States. Thus, the benefits from project investment are likely understated.

A second conclusion is that programming of U.S. investment in technical assistance for Bolivia's agriculture has resulted in a serious misallocation of resources. Investment in technical assistance programs generates benefits that are captured by citizens of developing countries—relatively poor campesinos in Bolivia's Altiplano and valleys in the case of the sheep and wheat projects. While U.S. technical assistance may be viewed as essentially a transfer program, the relatively large sums spent to develop and monitor programs in each recipient country suggests concern for efficient use of technical assistance resources, although political motivations may be very strong.

In any case, Bolivian society suffered real losses due to the initial decision to invest in the wheat project, especially because of greatly increased emphasis on this program in preference to the much more successful sheep project. In essence, the return to total U.S. investment was reduced by investment in the wheat project.

Early in 1966, contract consultants thoroughly studied the economic and agronomic potential for a wheat program. They concluded such a program would encounter serious difficulties because production of wheat was clearly uneconomic compared with other crops (Gardner 1966, Dewey and McAllister). In 1968, Gardner argued that a significant reduction in Bolivia's relatively large imports of wheat is possible within a ten-year period if improved varieties, which have produced relatively high yields under experimental conditions in Bolivia, could be generally extended to farmers. His analysis indicates that, for wheat to become competitive with other crops, yields at the farm level have to double. Also, land area in wheat would have to double, and more than 80% of all land in wheat would have to be planted to improved varieties in order for imports to be reduced by 50% in ten years.

Despite the pessimistic 1966 report of the consultants, the wheat project was added to the technical assistance program late in the same year. Then, in 1969, the USAID mission director and rural development officer were changed; shortly thereafter, the wheat project was significantly expanded without adequate testing of campesino acceptance of improved varieties or the probability of their widespread diffusion. We have argued elsewhere that rotation of USAID personnel tends to promote changes in program emphasis (Wennergren and Whitaker 1975b). Bolivia is a case in point. The contract focus on wheat was precipitately increased relative to sheep, and $1.8 million was spent on the wheat project between 1970–73 compared with $0.4 million in the previous four years.[5]

[5] In 1973, mission leadership again changed, the sheep and wheat projects were subsequently phased out, and a new technical assistance and loan program was implemented for improved sector management and research and extension in the valleys and lowlands, despite contrary advice from contract advisors.

The implications of this study are two-fold. First, investment in technical assistance can yield relatively high rates of return and can be an important instrument for increasing agricultural production and productivity and ultimately incomes and well-being for the relatively large number of rural poor in developing countries. Second, when programming decisions do not adhere to acceptable economic criteria, recipient nations fail to receive the potential benefit of U.S. investment in technical assistance. It is even doubtful that political objectives can be realized by technical assistance programming that disregards the fundamental importance of such criteria. Certainly, the experience with the wheat project in Bolivia suggests that reliance on the subjective system of programming has imposed relative losses on that society. Furthermore, there is no evidence that U.S. political objectives were met by ignoring the economic criteria.

An Approach to Specifying and Estimating Nonreversible Functions

James P. Houck

This note concerns the specification and estimation of nonreversible linear functions in economic research. Commonly suggested applications involve short- or long-run supply curves that, because of asset fixity or other rigidities, are more output responsive for price increases than for price decreases. The theoretical reasoning behind such functions is not at issue here, only the empirical testing of the nonreversibility hypothesis.

In 1971, Wolffram proposed an ingenious method of dealing with nonreversibilities through partitioning (or segmenting) the variables involved. Tweeten and Quance further discussed the idea but generally endorsed the Wolffram method. Interested readers are referred to those papers, since their essentials are not repeated. In what follows, a rather simple alternative approach for specifying linear nonreversibilities is suggested. This method is consistent with the Wolffram technique but is operationally clearer. In addition, some results applying this technique in two empirical supply studies are discussed briefly to provide insight into some of the issues likely to arise.

Specification

Since nonreversibilities are most commonly expressed in terms of asymmetrical changes from a previous position in time (or possibly space), identification of the starting point or initial observation is central to the analysis. Yet this first observation has no independent explanatory power, since the differential effects to be measured hinge on changes from the previous position, not its level. This key point was not emphasized by either Wolffram or Tweeten and Quance.

Imagine that the variable Y depends upon the values taken by X and that both are time-series variables. The hypothesis to be examined is that one-unit increases in X from period to period have a different absolute impact on Y than do one-unit decreases in X. Such a relationship can be written

$$\Delta Y_t = a_o + a_1 \Delta X_t' + a_2 \Delta X_t'' \tag{1}$$

for $i = 1, 2, \ldots, t$, where $\Delta Y_t = Y_t - Y_{t-1}$; $\Delta X_t' = X_t - X_{t-1}$ if $X_t > X_{t-1}$ and $= 0$ otherwise; $\Delta X''_t = X_t - X_{t-1}$ if $X_t < X_{t-1}$ and $= 0$ otherwise; X_o is the initial value of X; and Y_o is the initial value of Y.

Other variables, segmented or not, could be added to this basic specification, and a_o might be zero, positive, or negative. A nonreversibility occurs in ΔY if $a_1 \neq a_2$. To link equation (1) to the initial position, note that the value of Y at any point t is

$$Y_t = Y_o + \sum_{i=1}^{t} \Delta Y_i, \tag{2}$$

for $i = 1, 2, \ldots, t, t+1, \ldots, T$, where T is the total number of observations beyond the initial value. The difference between the current and the initial value of Y is the sum of the period-to-period changes that have occurred. So,

$$Y_t - Y_o = \sum_{i=1}^{t} \Delta Y_i. \tag{3}$$

Inserting equation (1) into equation (3) and simplifying,

$$Y_t - Y_o = a_o t + a_1(\Sigma \Delta X_t') + a_2(\Sigma \Delta X_t''). \tag{4}$$

Letting Y_t^*, R_t^*, and D_t^* equal $Y_t - Y_o$, $\Sigma \Delta X_t'$, and $\Sigma \Delta X_t''$, respectively,

$$Y_t^* = a_o t + a_1 R_t^* + a_2 D_t^*, \tag{5}$$

where R_t^* is the sum of all period-to-period increases in X from its initial value up to period t, and D_t^* is the similar sum of all period-to-period decreases in X. The variable R^* is always positive, and D^* is always negative. If a_o is not zero, it appears in equation (5) as a trend coefficient. If any other variables affect ΔY in equation (1), they also would be entered in equation (5) as deviations from their initial values.

The computation of R^* and D^* for a hypothetical set of ten observations on a variable X are illustrated in table 1. The hypothetical data are the same as used by Wolffram. Interested readers will note that both methods of segmenting the variable X are basically comparable. However, the method proposed here flows directly from considering period-to-period changes and does not require, as does the Wolffram method, an implicit change in the sign of the a_2 coefficient in order to compare it with a_1. If a positive (negative) net relation exists between Y and X, both a_1 and a_2 are positive (negative) in the formulation proposed here using R^* and D^*. In addition, expressing all variables as deviations from

Minnesota Scientific Journal Series Paper No. 9814.

Table 1. Hypothetical Example of Segmented Variable X_t

Variable (X_t)	X'	X''	R^*	D^*
$X_0 = 10$	—	—	—	—
$X_1 = 13$	3	0	3	0
$X_2 = 11$	0	−2	3	−2
$X_3 = 14$	3	0	6	−2
$X_4 = 17$	3	0	9	−2
$X_5 = 12$	0	−5	9	−7
$X_6 = 9$	0	−3	9	−10
$X_7 = 16$	7	0	16	−10
$X_8 = 20$	4	0	20	−10
$X_9 = 18$	0	−2	20	−12

initial values eliminates the problem of how to deal with the equation intercept, a question of some complexity when actual values of the variables are employed (Wolffram, Tweeten and Quance).

Thus, equation (5) is a simple estimating function for a nonreversibility to which other variables and stochastic properties can be added. Of special interest would be the test for $a_1 = a_2$ to confirm or refute the hypothesis of nonreversibility. By extension, other functional forms that can be linearized for estimation (such as logarithmic, semilogarithmic, etc.) also can be adapted to nonreversibility analysis using this basic framework and this technique of partitioning variables.

Empirical Applications

The hypothesis of nonreversibility in supply response to price change was tested using previously estimated supply equations for two quite different U.S. farm commodities: milk and pinto beans. Only those results that pertain to the nonreversibility question are discussed. A complete presentation of the two supply studies would far exceed the objectives of this note.

A fully reversible milk supply function was estimated by OLS using annual data from the 1947–72 period. The estimated function displays significant (5.0% level or stronger) coefficients with expected signs on lagged milk prices received by farmers, cattle prices, hog prices, average farm real estate prices, percentage unemployment, percentage of total dairy cows bred artificially, and lagged milk output (Hammond). The value of $\bar{R}^2$ is 0.94. The estimated coefficient on lagged milk price has a t-value of 5.96. At the point of means, the price elasticity of supply is 0.23, a result that compares favorably with the elasticities generated under alternative specifications of this basic equation and with other work on milk supply.

When the data are transformed into deviations from initial (1947) values, and the lagged milk price is segmented into rising and declining phases, two significantly different price elasticities emerge. Moreover, the estimated coefficients and standard errors of the other explanatory variables change very little, and the $\bar{R}^2$ increases to 0.96, as is expected.

The price elasticity for price increases is highly significant at 0.25. The elasticity for price decreases also is highly significant but is 0.18. The statistical test for the difference between the coefficients (Johnston, pp. 155–56) permits rejection of the null hypotheses at beyond the 5% level. These results support the hypothesis of a short-run nonreversibility in milk supply response. Such a phenomenon has long been suggested by dairymen.

The second example involves a relatively minor annual crop: pinto beans. Various quantity supply functions for this crop were estimated for other purposes (Ryan). Using 1953–75 data, these OLS supply functions employ explanatory variables such as lagged pinto bean prices received by farmers, lagged sugar beet prices, weather proxies, and a measure of price instability for the previous three years. Reversible equations with various combinations and forms of these variables display R^2 values from 0.90 to 0.94. Individual regression coefficients are significant at beyond the 5% level, and expected signs emerge on all variables. The one-year lagged price response has t-values of 5.79 to 7.41, depending on the particular specification used. At the point of means, the estimated price elasticity is between 0.99 and 1.02.

As with the milk supply analysis, the data are transformed into deviations from initial values (1953), and the lagged pinto bean price is segmented. In none of the various specifications did statistically significant evidence of nonreversibility emerge. The estimated coefficients are very similar to one another for either rising or falling prices, and both have t-values between 4.0 and 6.0. The estimated price elasticities at the means are very close to 1.0 for both rising and falling prices. Moreover, the segmentation does not appreciably alter estimated coefficients on the other variables.

While certainly not conclusive, these two illustrations suggest that hypothesis of nonreversibility is tenable in agricultural supply work. Even in cases where the hypothesis is not supported, the results for other explanatory variables may not be substantially altered when data are segmented and transformed to explore nonreversibility.

In using the techniques suggested here, the investigator should remain aware of a few problems that might emerge. First, the segmentation and data transformation consume two degrees of freedom: one for the added price variable and one for the loss of explanatory power in the initial observation. Second, intercorrelations among explanatory variables might be intensified. When a variable is segmented into increasing and decreasing components, it is possible that the two segments will be highly correlated with each other or with other trend-like variables in the analysis. On the other hand, if the variable to be segmented (a price, for example) is

already highly correlated with other variables (other prices, for example), then segmentation may well reduce the intercorrelation problem. It is impossible to say in advance which tendency, if either, will prevail.

In both the milk and pinto bean supply studies, some intercorrelations were increased between the price segments and other variables as compared with those using actual prices. But because of the high overall $\bar{R}^2$'s, no real estimation problems emerged. Similarly, no estimation problems occurred in these two examples because of strong correlation between the two segments; the correlation coefficients r were -0.78 and -0.87 between the segments of milk and pinto bean prices, respectively. The segmentation process did not alleviate any high intercorrelations between the actual prices and other variables, since none were present initially. On balance, each of these commodities provided a favorable environment for an empirical test of nonreversibility in supply response. Other investigations surely might be less fortunate.

Computer Graphics: An Educational Tool in Production Economics

David L. Debertin, Angelos Pagoulatos and Garnett L. Bradford

Students usually have difficulty in understanding the nature of surfaces generated by two-input production functions. Isoquant maps in two dimensions are easy to draw, and wooden or plastic models have sometimes been used by instructors to help students discover the relationship between an isoquant map and the resultant production surface. However, these models are difficult to build and expensive. Moreover, the exact mathematical specification of the production function underlying the plastic or wooden model is usually ambiguous. But the most serious disadvantage of such a model is that even if a mathematical specification of the production function underlying the model is known, it is impossible with a single model for the instructor to change the underlying function (and hence the isoquant map) so that the student might observe the resulting impacts on the surface of the function.

Computer graphics can be used as an educational tool for helping students better learn production economics concepts. A plotter linked to a computer is used to generate three-dimensional illustrations of two-input agricultural production functions.[1] Moreover, production economics problems often require the maximization or minimization of a function, and computer graphics can be used to develop an understanding of the mathematical conditions necessary and sufficient for a maximum or minimum. This use is particularly important to supplement material in beginning graduate level production economics classes.

Surfaces of Production Functions

Beginning graduate students can usually discern the isoquant map generated by most two-input production functions from the mathematical specification of a production function and draw the map. What is difficult for students to perceive is the importance of the underlying isoquant pattern in determining the shape of the agricultural production function surface.

The Cobb-Douglas is frequently the first production function presented to students in mathematical form. A Cobb-Douglas as represented by[2]

$$y = Ax_1^{\alpha}x_2^{\beta} \tag{1}$$

generates isoquants that are asymptotic to the x_1 and x_2 axes. If $\alpha < 1$, $\beta < 1$, and $\alpha + \beta = 1$, diminishing marginal returns to x_1 and x_2 and constant returns to scale exist. The illustration generated by equation (1) when $\alpha = 0.4$ and $\beta = 0.6$ shows students the exact nature of the surface of the Cobb-Douglas function (figure 1). Computer graphics reveal the shape of the production surface with diminishing marginal returns to x_1 and x_2 and constant returns to scale. With the aid of the computer, students can easily and quickly compare surfaces generated under the alternative assumptions with respect to the parameter values.

The transcendental production function was popularized by Halter, Carter, and Hocking in the 1950s. It became popular since appropriate selection of parameters yields a single function representing the three stages of production comparable with the illustrations contained in undergraduate microeconomics texts. The isoquant map generated by the transcendental

$$y = Ax_1^{\alpha_1}x_2^{\alpha_2}e^{(\gamma_1 x_1 + \gamma_2 x_2)}, \tag{2}$$

when $\alpha_1 = \alpha_2 = 4$, $\gamma_1 = \gamma_2 = -2$, and $A = 1$, consists of a series of concentric rings centered at the global maximum for the function. Ridge lines dividing the stages of production are parallel to the x_1 and x_2 axes and form right angles at the maximum of the function.[3] Figure 2 provides students with an illustration of the production surface resulting from equation (2). The three stages of production are clearly visible. No output is produced if either x_1 or x_2 assumes a value of zero, suggesting that for the transcendental function isoquant rings do not intersect but rather become tangent to the input axes.

All Cobb-Douglas production functions have

David L. Debertin is an associate professor, Angelos Pagoulatos is an assistant professor, and Garnett L. Bradford is a professor in the Department of Agricultural Economics, University of Kentucky.

This paper is an overview of work reported in a research report by the authors. Computer-generated illustrations used in this paper were selected in order to provide evidence of the range of possible uses of computer graphics to supplement production economics courses. Herman E. Collins wrote the PL-1 plotter program.

[1] A copy of the PL-1 plotter program is available in the research report (Debertin, Pagoulatos, and Bradford). Program users select the function to be plotted, function parameters, and values over which the function is to be plotted.

[2] Throughout this article y is used to designate an output, x_1 and x_2 are two inputs or factors of production, e refers to the base of the natural logarithm, A and α, β, γ, and ρ designate production function parameters.

[3] The function $y = Ax_1^{\alpha_1}x_2^{\alpha_2}e^{(\gamma_1 x_1 + \gamma_2 x_2 + \rho_1 x_1 x_2)}$ will generate ridge lines that are not parallel to the axes.

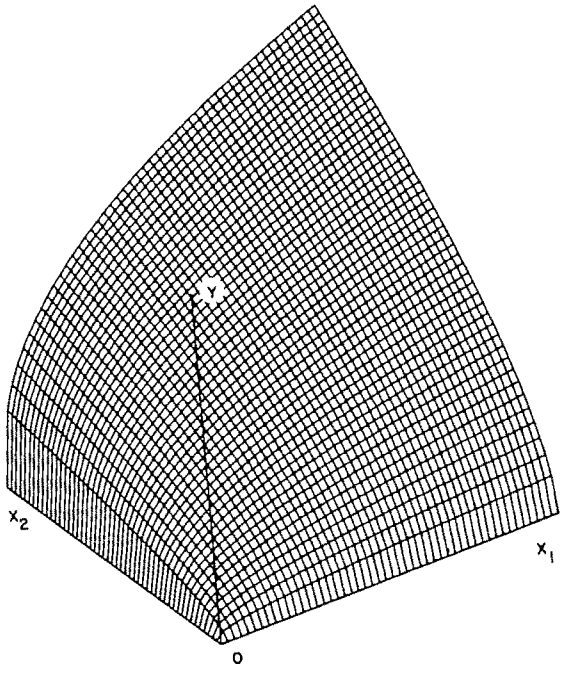

Figure 1. The Cobb-Douglas: $y = x_1^{0.4}x_2^{0.6}$

elasticities of substitution equal to one. The constant elasticity of substitution (CES) function (Arrow et al.) allows for constant elasticities of substitution other than one. The general form of the CES is

$$y = A[\alpha x_1^{-\rho} + (1 - \alpha)x_2^{-\rho}]^{-\frac{1}{\rho}}. \tag{3}$$

The CES can be a valuable pedagogical tool because the single function can be used to generate a wide variety of different isoquant patterns. The elasticity of substitution (σ) is related to the parameter ρ by the identity

$$\sigma = \frac{1}{1 + \rho}; \tag{4}$$

and it is the value of σ (and hence ρ) that determines the shape of the isoquants generated by the CES. Henderson and Quandt outline five cases with alternative assumptions with respect to the value of σ. If $\sigma = 1$, the function becomes the Cobb-Douglas (figure 1). The surface of the CES when $0 < \sigma < 1$ is virtually indistinguishable from the Cobb-Douglas. When $\sigma \to \infty$, the isoquants become diagonal lines of constant slope intersecting the x_1 and x_2 axes. When $\sigma \to 0$, isoquants approach right angles. The resultant surface becomes pyramidal as ρ becomes very large. When $\sigma < 1$ and $-1 < \rho < 0$, isoquants cut both axes. Figure 3 illustrates the surface when $\rho = -0.5$. The surface is similar to the Cobb-Douglas (figure 1), except that because isoquants intersect both axes it is possible to produce a positive output (y) even when one of the inputs is not present. This is clearly evident to students who carefully examine figure 3.

Sufficient Conditions

The problems faced by students who are attempting to understand the meaning of sufficient or second-order conditions required for the maximization of a function are very similar to those faced by students confronted for the first time with the mathematical form of a production function. (See the discussion on sufficient conditions in Chaing and in Intrilligater.) In both cases, a three-dimensional graph is a useful supplement to the mathematical presentation.

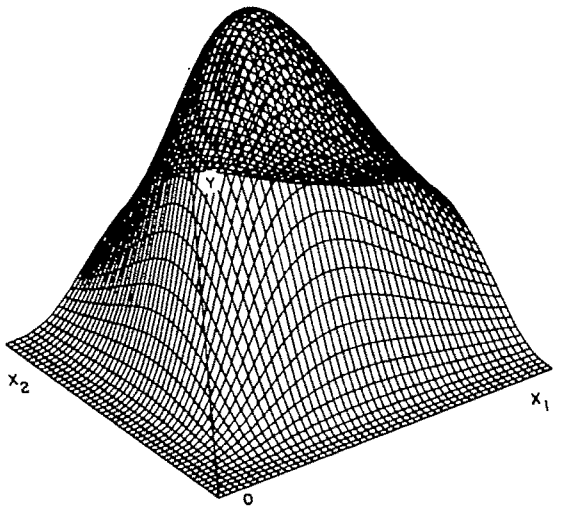

Figure 2. The transcendental: $y = x_1^4x_2^4e^{(-2x_1-2x_2)}$

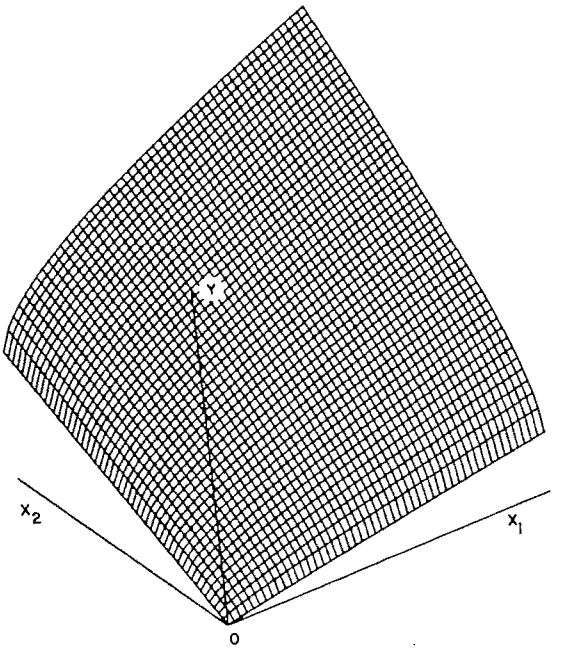

Figure 3. The CES: $y = (0.4x_1^{0.5} + 0.6x_2^{0.5})^{1/0.5}$

For example, a computer-generated graph might be used to illustrate a maximum with an equation such as

$$y = -x_1^2 - x_2^2, \tag{5}$$

or a saddle point with an equation such as

$$y = x_1^2 - x_2^2. \tag{6}$$

The usefulness of computer graphics as a tool for helping beginning graduate students learn about second-order conditions is perhaps best illustrated with the function

$$y = 40x_1 - 12x_1^2 + 1.2x_1^3 - 0.035x_1^4 + 40x_2 - 12x_2^2 + 1.2x_2^3 - 0.035x_2^4. \tag{7}$$

Equation (7) generates nine extreme values (four maxima, one minimum, and four saddle points), occurring over the plotted range (figure 4). Relevant second-order conditions are summarized in table 1. A careful scrutiny of figure 4 reveals the nine extreme values.

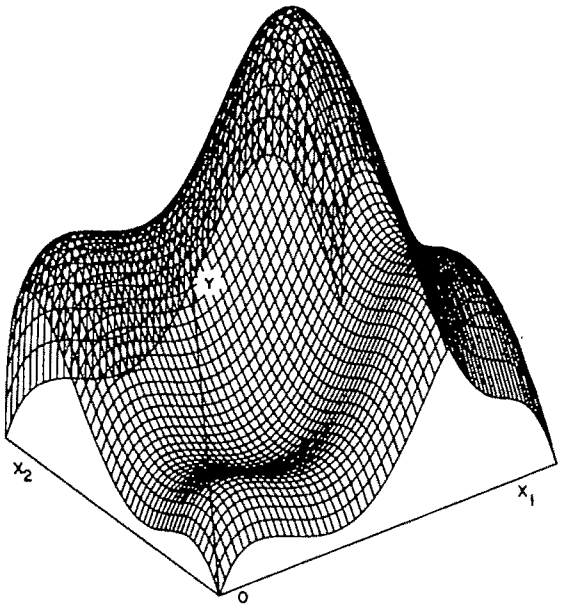

Figure 4. Local and global optima: $y = 40x_1 - 12x_1^2 + 1.2x_1^3 - 0.035x_1^4 + 40x_2 - 12x_2^2 + 1.2x_2^3 - 0.035x_2^4$

Application to Instruction

Computer graphics has been used as an instructional aid in a graduate production economics course that includes a discussion of alternative algebraic forms for production functions. Students are first asked to use mathematics to compare functions such as the Cobb-Douglas, the transcendental, the CES, and the Spillman with respect to characteristics such as the shape of isoquants, the location and shape of ridge lines, and the elasticity of substitution. Each student is then provided with

Table 1. Second-Order Conditions for Figure 4

Value of x_2	Value of x_1: 2.5366	6.9342	16.2434
	Local Maximum	Saddle Point	Global Maximum
16.2434	$y = 232.3$ $\|H_1\| < 0$[a] $\|H_2\| > 0$	$y = 209.5$ $\|H_1\| > 0$ $\|H_2\| < 0$	$y = 379.8$ $\|H_1\| < 0$ $\|H_2\| > 0$
	Saddle Point	Local Minimum	Saddle Point
6.9342	$y = 61.9$ $\|H_1\| < 0$ $\|H_2\| < 0$	$y = 39.1$ $\|H_1\| > 0$ $\|H_2\| > 0$	$y = 209.5$ $\|H_1\| < 0$ $\|H_2\| < 0$
	Local Maximum	Saddle Point	Local Maximum
2.5366	$y = 84.8$ $\|H_1\| < 0$ $\|H_2\| > 0$	$y = 61.9$ $\|H_1\| > 0$ $\|H_2\| < 0$	$y = 232.3$ $\|H_1\| < 0$ $\|H_2\| > 0$

[a] $|H_1| = \left|\frac{\partial^2 y}{\partial x_1^2}\right|$. $|H_2| = \begin{vmatrix} \frac{\partial^2 y}{\partial x_1^2} & \frac{\partial^2 y}{\partial x_1 \partial x_2} \\ \frac{\partial^2 y}{\partial x_2 \partial x_1} & \frac{\partial^2 y}{\partial x_2^2} \end{vmatrix}$

a copy of the twenty-six computer-generated illustrations contained in Debertin et al. Students are asked to determine if the illustrations of production surfaces are consistent with the characteristics of the function that were derived mathematically. Students are then allowed to run the computer graphics program on their own, varying parameters of traditional production functions, and examining properties of functions they develop on their own.

Computer graphics has been particularly useful in supplementing the terse mathematical presentation of the CES contained in Henderson and Quandt. With illustrations of the five CES cases in Henderson and Quandt, students in the class for the first time were able to visualize the interrelationships that exist between the elasticity of substitution, the shape of the isoquant, and the appearance of the resultant production function surface.

Computer graphics has been equally important in supplementing presentations dealing with the mathematics of sufficient conditions. First, the rules with regard to signs on principal minors of Hessians sufficient for maxima or minima are presented by the instructor. Students are asked to determine if each extreme value of equation (7) is a maximum, a minimum, or a saddle point. Students then examine figure 4 to verify the conclusions they reached mathematically. Finally, students are asked to develop a function of their own, find the critical values, and verify the second-order conditions by running the computer graphics program.

Computer graphics enables the student to develop an understanding of the relationship between a two-dimensional drawing of an isoquant map and the resultant production surface. Moreover, with computer graphics it is possible for the student to generate three-dimensional illustrations of surfaces for a host of production functions, not just the usual textbook case. Parameters of the production function can be varied and the resultant impact on the surface be scrutinized by the student. Students can compare surfaces among production functions widely used in agricultural economics research. Students and instructors both discover that even minor changes in the specification of a function and its parameters can have a major impact on the appearance of the computer-generated illustration. Shapes of agricultural production function surfaces can be discerned at least as easily from a computer-generated illustration as from a wood or plastic model, and yet copies of the illustrations can be carried by students in a notebook.

Computer graphics, when used as a tool to supplement instruction dealing with optimization problems, provides students with vivid illustrations of the meaning of mathematical conditions necessary and sufficient for a maximum or minimum. Students can easily grasp the importance of sufficient conditions when a mathematical presentation is supplemented with computer-generated illustrations.

Computer graphics is quite inexpensive and simple for students and instructors use. The only equipment required is a computer linked to a CALCOMP (or other) plotter, which is available at nearly all university computing centers. The computer program developed at Kentucky for using the CALCOMP plotter is simple enough to operate so that students may run their own graphics programs. The cost of each illustration is approximately $1.50 on an IBM 370/165 system. Students in small graduate classes may each run the program several times, and the cost is not excessive. The cost might be excessive if each student in a large undergraduate class were to run the program.

than another and ignore the man of no other property who went hungry when his common law claim on water was denied. They ignore the fisherman or the boater or the saw log floater who lost out with appropriation. In the Anderson and Hill formulation, there are no moral issues; all is a matter of the highest bidder—who can spend the most for law change. In this conception, government is a neutral respondent to market forces that are implied to be a function of technology, resource availability, and consumer taste. They ignore government as a determinant of who has to buy out whom and who has anything with which to make a bid in the first place. In other words, they selectively ignore the existence of some institutions while performing a partial analysis of another. These other institutions are *what influence* marginal costs and benefits to changing a particular property rule.

Anderson and Hill give us a picture of a relatively passive and neutral government as the key to economic growth. After establishing exclusive and transferable private rights, there is no useful or legitimate role for further collective action except for the troublesome equity issue. The following quote embodies one of the most persistent and widespread myths of the American mind. After noting the role of government in eminent domain, police power, and taxation, they say, "Nonetheless, by the time of the Revolution the landowner had basically acquired the right to use his land as he saw fit with few restrictions and controls by the government" (p. 939). This is selective perception guided by a theory with little probative value. The authors begrudgingly notice farmer interest in tariff policy, but they ignore the government's role in roads and canals, the credit and banking system, reclamation and drainage, the development of tort and contract law, and later the interpretations of the commerce clause of the constitution. (Reading Anderson and Hill, one would never guess that the Supreme Court existed or had any creative role.) They ignore such dominant collective actions as supply and price controls for tobacco in the 1630s (Edwards, p. 184). Acting individually, it was in everyone's interest to plant all they could, but a glut developed and farmers used government to establish a price that all enjoyed collectively. Private ownership of land did not protect exchange values, and farmers did not wait until the Great Depression and Roosevelt to develop collective action.

Land use controls did not wait until the modern environmental movement. Building setbacks and roof style were sharply controlled in colonial New England towns. Government was also active in promoting new agricultural crops. England did not like to be dependent on Italy for silk, so the Virginia Assembly in 1619 ordered each man to plant six mulberry trees annually for seven years. In 1740, membership in the Georgia Assembly was made conditional on the planting of 100 mulberry trees (Edwards, p. 187). The role of private property and the later public lands disposal is not to be denied, but neither can other varied expressions of collective action in shaping what opportunities were profitable. These actions did not cease in 1776 and start again in 1875.

Why must Anderson and Hill insist that up until 1875 private rights in inputs were the dominant productive force while ignoring other collective action? It is because this view of history is necessary to the credibility of their theory. As Bartlett explains, once it is acknowledged that resources can be used to produce income via rights change as well as via goods production, there are real questions as to the legitimacy of any market derived income distribution. Anderson and Hill try to solve this problem by distinguishing efficiency and transfers. It is claimed that some resources used to change rules create efficiency and more output, while others are a wasteful use of resources to alter rules that only result in income transfers. By this concept, they assert that the move to the western appropriations doctrine was efficient, but tariffs, regulation of railroads, co-op marketing, and New Deal price-support programs were just transfers. These transfers are seen to serve equity and are rather begrudgingly accepted. These after all may have to be accepted to forestall another revolution, but we were invited in the bicentennial year to be sure to remember that these rights were not what made America great—that accolade is reserved for the efficient destruction of communal property and establishment of the appropriation doctrine, etc. Once exclusive and transferable rights are established, any further use of resources to change the rules is somewhat wasteful, even if some is tolerated in the name of equity.

The role of private property in motivating effort is not to be ignored. However, it would surely be a mistake to regard it as the only way. Ciriacy-Wantrup and Bishop demonstrate that many of the world's communal lands were well managed and preserved and did not suffer what is now mistakenly assumed to be the inevitable "tragedy of the commons." While there are some Pareto-better rule changes, it must not be forgotten that being declared owner of water (and requiring fishermen to make a bid rather than to receive an offer) is no different than having the right to collective bargaining via co-ops, enjoying a tariff, or any of the other things that Anderson and Hill regard as mere transfers. When interests conflict, the government by action or inaction decides whose interests count. The issue is not government or no government, but how government will be used.

What about the Anderson and Hill claim to explain resource allocation? They never address this question is any substantive way. They use theory to argue that exclusivity and transferability are by definition efficient. If the country grew, it must have been due to these rights. There is no need to systematically relate differences in rights to who gets what. There is never a glance at the problem of poverty or backward regions. Even on the example

The Role of Private Property in the History of American Agriculture, 1776–1976: Comment

A. Allan Schmid

After years of relative neglect, there is a growing literature on the economics of property rights. A recent example is provided by Anderson and Hill. They nominally address two questions: how to explain the evolution of particular varieties of property rights, and how these changing rights have affected resource allocation. There is really a third implicit purpose, and that is to justify a particular set of rights. I shall argue that their answer to how rights evolve is severely incomplete, that they never really answer how rules affect the substance of resource allocation, and that their justification of so-called "private property" while pretending to be scientific is value presumptive.

Why do rights change? Anderson and Hill argue that institutions are subject to a productive process like any other commodity. "Efforts to change the rules can be thought of as input into the production of an institutional structure" (p. 938). Seen in this light, changes in rights are a matter of establishing a new equilibrium to marginal benefits and costs of productive efforts devoted to rule change in reaction to changes in relative factor prices.

Anderson and Hill use their theory to explain why people seek property: they seek it when it becomes valuable and scarce. The fact that nobody needs property when there is no interdependence is hardly a new insight. Anderson and Hill go on to use their theory to explain why certain varieties of rights are sought. For example, why did early colonial attempts at a communal agriculture fail? Because some people shirked, say Anderson and Hill. Those that worked found it profitable to spend the effort to change the rules. It is not clear in the paper why the shirkers did not find it equally profitable to retain the old rules. Neither is it clear what happened to the shirkers. Perhaps it is presumed that they reformed themselves. Perhaps there were no sick or lame in the colonies.

What explains the asserted fact that communal property disappeared faster in New England than in the Chesapeake Bay Region? Differences in the supply of shirkers? Wrong. It was due to the relative scarcity of land, say Anderson and Hill. Supposedly where land was better and more plentiful in the Chesapeake, there was less congestion, and it paid no one to work to define new rights. The logic is hard to follow here. If the Chesapeake region began with communal tenure, the availability of land does not solve the shirker problem unless all shirkers can be left behind and a new commune of like-minded workers established.

The Anderson and Hill theory suggests no other possible source of rights change, so it never occurs to them to look for other possible explanations. As an aside, they do note that ideology is a factor. Yet, this does not fit their theory very well, and it is not integrated into it. Could it be that New England and Chesapeake people had different ideologies? Anderson and Hill do not inquire. Neither do they inquire into the interaction of property in civil rights in relation to property in land. Could it be that the rules of popular access to government differed in the two regions? Harris notes differences between the three corporate colonies of Massachusetts, Connecticut, and Rhode Island and the others. "Differences were associated with the religious ideas of the first settlers, their extensive chartered privileges, their corporate form of organization, and the haphazard and uncontrolled pattern of colony location" (p. 98). He further notes that "It would be difficult to overstress the importance of the influence of local autonomy in Massachusetts upon later events" (p. 106). On the other hand, Maryland was a proprietary colony founded by Lord Baltimore with extensive powers that the king did not even have in England. There was no Mayflower Compact formulated by the Maryland settlers. I suspect that we need to look at differences in people and their political institutions, not just differences in land or prices of farm commodities.

The fact that people use economic resources to change institutions is undeniable. To argue that it is the only or the prime factor in change is incredible (and no evidence is offered by Anderson and Hill).

Anderson and Hill next apply their model to water rights. In regions where water was plentiful, there were riparian rights; where scarce, the appropriation doctrine emerged. Unquestionably, the appropriation doctrine does affect investment in consumptive uses of water. But they would have us believe that some rights emerge from a void and create efficiencies implying everyone wins in the new productivity. If resources are scarce, any right is an expansion of opportunity for some and a contraction for others. We are not told what happened to the western riparian who lost out under appropriation. We are only told that water moved to its most efficient use. This begs the issue of what interests become a cost to be considered. Anderson and Hill presume that one person is more worthy

Educational Television as an Extension Delivery System for Teaching Futures Market Concepts

Larry D. Jones, D. Milton Shuffett, Steve Callahan, John C. Gamble, and Charles L. Moore

Television as a medium for delivering extension information has the potential of providing information to more individuals in a single program than most extension personnel reach in one year. Yet, television has been little used as an information delivery system for educating farmers concerning agricultural economics problems. The high cost of commercial air time has meant that few stations are willing to supply time for educational programming on a regular basis. Even if air time is available, it often cannot be obtained at an optimal viewing time. Communicating information via television requires special skills different than those used by extension personnel in a traditional public meeting educational setting. Most extension economists are not as effective in front of a television camera as are professional television commentators.

The purpose of this paper is to explain how educational television is used to teach commodity futures market concepts. The futures market program was designed to educate farmers and other interested persons in the basics of forward pricing and to help them apply that information to their own business situations. Television offers the most direct and cost-effective link with those farmers most in need of information. It is one medium that brings that information to those interested on a regular basis.

Our approach in the use of television as a means to educate farmers is unique in that the educational effort consists of not merely a single show but of thirteen regular, weekly programs on agricultural marketing. The program was aired during prime-time evening television beginning in February 1976.

Educational television stations rather than commercial stations were used because of the availability of air time. The educational television system in Kentucky is one of the largest and most complete in the nation, consisting of fourteen ultrahigh-frequency stations across the state. This is a particular advantage, compared with local, private television stations that can cover only part of the state.

Larry D. Jones and John C. Gamble are associate extension professors, D. Milton Shuffett is a professor, Steve Callahan is an extension specialist, and Charles L. Moore is an assistant extension professor in agricultural economics at the University of Kentucky.

Kentucky Agricultural Experiment Station Journal Article 76-1-76. Gratitude is expressed to David L. Debertin and Joe T. Davis for their helpful comments.

The idea of a marketing program did not evolve solely out of the Department of Agricultural Economics. Rather, members of the agricultural leadership in the state expressed to Kentucky Educational Television (KET) their desire that KET bid on a weekly farm business series. A committee composed primarily of agricultural economists was asked to prepare a program proposal that Educational Television could consider for implementation.

The origination of this program indicates a key factor one must consider in making this type of venture. Agricultural economists acting alone may not convince television producers of the need for a regular show on agricultural marketing or other agriculturally related topics. Our experience suggests that the demand for this kind of educational effort must come from the agricultural leadership in the state.

Why Television?

We sought to educate a large number of farmers about futures market concepts. We faced the following constraints: (*a*) a small extension marketing staff, (*b*) a large geographical area in which to reach farmers, and (*c*) limited travel funds.

Educational television has four unique qualities making it applicable to our objectives and constraints. Television is immediate. Farmers need not wait for an agricultural economist to be available to teach them about marketing and forward pricing.

Television is flexible. The program host transcends the limitations of the classroom or seminar, and through film clips, animation, and live interviews (to name a few examples) presents information in a manner best suited to the nature of that information and most appealing to the farm audience.

In our state, educational television reaches the entire state. The geographic isolation of many rural areas is no longer a barrier to self-improvement. Through television, farmers obtain information in the comfort and privacy of their homes, which they might otherwise have had to travel miles to obtain. Thus, information is obtained without interrupting their workday or losing needed rest time in transit.

Television is familiar. Television, available in the

privacy of the home, is especially appealing to the adult who is often reluctant to admit to educational deficiencies in a group situation. The television host speaks directly to the individual viewer and serves as an authority, with none of the negative connotations that adult learners may ascribe to authority figures.

Television as an extension delivery system also has limitations. First, viewer feedback is usually absent. Second, there are no easy means for handling questions. Third, the feeling of comradeship often found in a public meeting is not achieved. Methods are designed to circumvent and minimize these kinds of limitations.

Methods Employed

In our approach to using television as an extension delivery vehicle, the agricultural economist was used as a resource person. Agricultural economists determine the content and sequence of the subject matter, generate ideas, and develop brief topical outlines for each program. Hence, agricultural economists are responsible for the technical accuracy of the programs. A professional writer takes these ideas and prepares written scripts. Professional announcers are responsible for communicating ideas to the audience. Professional artists are employed to develop visuals.

An outline and sequence of subject matter is prepared several months prior to taping (table 1). Two review and question sessions are scheduled in addition to programs devoted to explaining futures market concepts and illustrations. Questions are submitted by telephone and by mail. These questions are answered on the air by agricultural economists through direct interviews. Submitted questions provide valuable viewer feedback.

The television writer receives written outlines and visual sketches three weeks prior to the taping date. The writer then prepares the script and sends the script back to the agricultural economist for review. The revised scripts are aired five days following taping.

Prepared scripts are read on camera using teleprompters. This delivery mode insures constant eye contact with the audience. Two communications specialists serve as program hosts. These professionals have agricultural training in addition to their communications skills. This approach insures that small talk is kept to a minimum and that the subject matter is covered in a professional manner.

Agricultural economists appear as interviewed guests for highlighting particular facets of the program. For example, an economist made a guest appearance to show how to construct a basis chart. An agricultural economist in another guest appearance showed how to determine an "asking price" when deciding whether to hedge. Commodity brokers and farmers who used the futures market also appeared as guests on the program.

Two months prior to the first program, promotion is begun to enroll farmers and others for the program. Farmers enroll through local county extension staff. Agents are furnished posters and enrollment forms to place in agribusiness establishments. News releases and radio tapes are also used to advertise the program. Enrollees receive by mail special materials (workbook) that complement the television tapes (Callahan, Gamble, and Shuffett). A mailing list is thus provided for use in program evaluation.

Table 1. Program Titles and Sequence of Subject Matter for "Farm Marketplace"

Program	Working Title
1.	Introduction to the various methods of marketing commodities
2.	An introduction to futures marketing
3.	What is basis?
4.	Working with basis
5.	Engaging in futures trading
6.	Review, and questions and answers
7.	Hedging
8.	Brokers and speculators
9.	Using the futures market—grain
10.	Using the futures market—livestock
11.	Using futures in feed
12.	April intentions report
13.	Review, and questions and answers

Evaluation

One week prior to the last program, a postcard questionnaire was mailed to the 5,000 participants who preenrolled through local extension staff. Enrollees were asked to indicate the number of programs watched as well as their general impression of the series. Five percent of those enrolled returned the questionnaires.

Thirty-six percent of the respondents had watched nine or more programs, while an additional 17% had viewed between six and eight programs. Twenty-seven percent had viewed three to five programs, and the remaining 20% had watched fewer than three. Ninety-three percent of the respondents indicated that they felt the series had helped them to understand better the farm marketing system. In addition, 28% indicated that they would use one of the strategies discussed on the program, while 9% said that they might possibly use one of the marketing strategies presented.

Enrollees were asked to indicate whether the television subject matter was clear and easy to understand. Seventy-eight percent of those responding said that the subject matter was clear and easily understood. The remaining 22% indicated that the subject matter was not easily understood. Seventy

percent of the respondents indicated that they would like to view the same program at a later date.

Our experience with television as a tool for delivering extension information suggests the following conclusions.

A professional script writer adds much to the program. Writing style for television is quite unique. This style is different from the methods that extension personnel usually employ. Most script writers find it easier to write a script from a brief outline rather than revising a script prepared by the agricultural economist. In addition, the economist can save valuable time if only an outline has to be initially prepared.

Numerous visuals are essential for television communication. Verbal dialogue without visuals becomes boring to a television audience. Hundreds of visuals are required for a thirteen-week program, and good visuals are difficult to prepare. For these reasons, professional artists are essential to programs of this size.

Communications specialists are better trained to host a regular program series than most agricultural economists. It is helpful if the communicators also have agricultural training.

Viewer feedback after two programs revealed that the material moved at too rapid a pace. One reason cited is the lack of commercials on educational television. Our taping experience suggests that liberal use of visuals, having guest interviews, and film clips makes it easier to follow educational programs on television.

Written materials that complement the television tapes are essential. Ideally, a complete workbook should be distributed to all enrollees prior to the first show. The complementary materials should be liberally referenced on the air as the program progresses.

Large amounts of staff time are required from the agricultural economist. Each program required at least 30 man-hours from the agricultural economist. Agricultural economics departments must be willing to devote many man-hours to similar ventures.

Coordinating such a venture is cumbersome. Scripts have to be prepared, visuals designed, special materials prepared, tapings scheduled, and guests chosen and scheduled. Clearly, an adequate amount of lead time is required to produce a show of this magnitude. We allowed two months of lead time for each show. Four to six months would have been more desirable.

Television facilities and support are essential to ventures such as the program to teach farmers about futures markets. Our state is fortunate in that extensive, modern facilities are available. KET broadcasts in color, has modern equipment, and covers the entire state. In addition, the facilities are less than two blocks from the Department of Agricultural Economics. Clearly, such ventures are impossible unless both the manpower and facility commitment from educational television are available.

Producing a 30-minute program for thirteen consecutive weeks is expensive. KET provided a producer, director, production assistant, script writer, two artists, a facility, camera crews, taping equipment, tapes, and a $2,500 set specially prepared for the program. Educational Television estimates that their total cost in man-hours and facilities came to approximately $52,000, or $4,000 per program. While producing a program of this magnitude is expensive in hours and actual expense, the money expended is small compared with the cost of running a conventional extension program in our state.

Given our state's travel and subsistence budgets, we estimated that a conventional extension program for reaching 5,000 participants would have required three man-years of work at a cost of approximately $120,000. This reported case demonstrates primarily how budgetary constraints may be overcome by shifting the cost burden for an extension educational program to some external agency, in this case the educational television system.

One advantage offered by television ventures is that the tapes are available for subsequent use. Our futures market tapes, for example, were rerun on KET in early 1977. In addition, the video tapes are now available for local meetings.

A Pilot University-Industry Master's Training Program

Gary T. Devino

In a December 1976 open letter to members of the American Agricultural Economics Association (AAEA), the Industry Advisory Committee of the AAEA stated: "In the experience of industry employers, today's graduate student in agricultural economics is well trained in research techniques, but often lacks training needed to relate and communicate the results in the decision-making process" (p. 1). Business games, cases, and other methods may help prepare students for business careers but are not as effective as programs in which the student spends time in a business environment. Many agricultural economics departments have operated trainee programs for undergraduates. The role they can serve in students' programs and the benefits to the parties involved have been documented (Snodgrass). Few similar programs have been operated at the graduate level. Yet the benefits would appear to be at least as great for graduate students as for undergraduates.

To test the applicability of the concept, a pilot master's program has been operated for the last two years by the University of Missouri and Farmland Industries. The objectives of the program are different for Farmland and for the University. Farmland's reasons for becoming involved with the program include "The difficulty in finding college people with an interest or training that would lead to work with cooperatives" and "To get a qualified person to study specific co-op problems and suggest possible solutions" (Farmland Industries 1977, p. 11). The University's objectives are to provide an opportunity for students with a career interest in agribusiness to gain experience in business operations, to improve working relations with industry firms with the University benefiting through identification of curriculum changes needed for better preparation of students for careers in agribusiness, and identification of research proposals that are relevant to industry problems. This note describes and appraises the program.

Student Selection and Program Organization

Student applications for this program are accepted from throughout the Farmland operating area. All applicants are expected to have an undergraduate program that emphasized agribusiness management. Applicants are required to have completed sufficient economics, accounting, and other prerequisites to allow them to take first year master's of business administration work as well as graduate work in agricultural economics. Student selection is joint between the University and Farmland. The first screening is conducted at the University to assure that the applicants are academically qualified for a master's program. Applicants are not required to have a higher minimum grade point level than other students receiving assistantship offers. Farmland invites the several qualified applicants for an interview at its Kansas City Offices. The applicants are interviewed by individuals of both the personnel department and the management staff. Farmland then indicates to the University a suggested ranking of the applicants.

Master's programs in agricultural economics at the University of Missouri call for a minimum of twenty-four hours of coursework and six hours of research. Courses in intermediate price theory, intermediate income theory, and statistics are required. Students who are on an assistantship normally complete their program in seventeen to eighteen months. A student on the Farmland program meets the same minimum department requirements, but because of his or her interim on-location work with Farmland, the total program will usually extend to two years.

The first student on the program spent his first two semesters (summer and fall) on campus. Coursework for this period consisted of intermediate price theory, research methods, corporate capital markets, economics of marketing, advanced price analysis, financial management, and business and society. After spending three semesters (including summer term) on a Farmland assignment, the student finished his coursework by enrolling in two courses: theory of markets and current economic aspects of agriculture. He also completed his thesis. A second student is pursuing a comparable schedule.

Within the Farmland organization, students were assigned to Cooperative Finance Association, Farmland's finance subsidiary. When the first student entered the pilot program, Farmland personnel developed a detailed plan that outlined the type and duration of activities in which he would be engaged. The plan was reviewed and approved by the student's faculty adviser.

Upon shifting from the campus to Farmland, the

Gary T. Devino is an associate professor of agricultural economics, University of Missouri-Columbia.

Helpful comments by Harold Breimyer and *Journal* reviewers are gratefully acknowledged.

student was given a short orientation and then assigned to several projects. The projects were intended to be useful to Farmland. In addition, it was expected that papers developed from these projects would be acceptable to the University in lieu of a thesis. Topics were selected jointly by the student, his Farmland supervisor, and his academic adviser from a list of projects developed by the student and Farmland personnel. Progress on projects was monitored by both Farmland personnel and the student's academic adviser. This was accomplished by requiring reports from the student and by periodically meeting to discuss progress.

The first project was the development of a manual for conducting feasibility projects for investment in local cooperatives. The manual so developed was printed and used throughout the Farmland system (Farmland Industries 1976). In the second project, techniques and potential for leveraged leasing were analyzed. The paper that resulted from this project was used in-house at Farmland. The last project was an analysis of the financial conditions supportive of growth in local cooperatives. This project was used as the basis for a thesis (Mathis).

The time division between the University and Farmland appears to have been satisfactory, both in length and sequence. By spending his first two semesters at the University, the student was able to complete much of his coursework requirements. This added to his maturity and to the course background that he could apply to industry problems. The several months spent at Farmland or on Farmland assignment allowed the student time to become familiar with the organization, personnel, and problems with which he was dealing (table 1). By spending his last semester in campus, the student was able to complete his program in an academic environment. He also was able to interview for jobs without pressure from Farmland. Even though Farmland proved to be interested in employing the student, employment with the cooperative was not a condition for acceptance on the program.

Table 1. Allocation of the Student's Time with Farmland

Orientation—Farmland Industries	1 week
Orientation—Cooperative Finance Association	1 week
Travel with farmland personnel	
Management services fieldmen	1 week
Co-op development specialists	1 week
Business analysts	1 week
Identification and development of research	
Feasibility project manual	15 weeks
Leveraged leasing project	10 weeks
Financial growth in local cooperatives	20 weeks
Visits with other agricultural credit institutions	2 weeks

Program Evaluation

Because a trainee program extends the time required to complete a master's program, students may need more compensation than usually is provided. The first student on this program was paid $1,000 per year above the University of Missouri rate for half-time assistants. The level of compensation appears to be sufficient in that good applicants were attracted to the program both initially and at its renewal.

Organizing and supervising a joint industry-university program requires more faculty time than does a conventional master's program. Arrangements must be made for the student's supervision while on assignment. Time is required to communicate with the student and review his research while he is away from the university.

There are benefits to the university. Improvements in industry relations, research relevancy, and funds forwarded by the industry partner are useful to the university. In this program Farmland advanced funds for the student's salary and expenses. If a firm was interested in this type of program but could not fund it completely, other funding possibilities could include using regular assistantships as a base to which industry funds could be added.

Having the entire Farmland assignment in one block of time appears to be superior to alternating work semesters with academic semesters. The student's involvement in activities of the firm was deeper than probably would have been achieved during shorter time intervals. The student participated in a wide variety of headquarters' and field activities of Farmland. This exposure promoted an understanding of how business operates. It also helped generate project proposals that had the potential for direct benefit for Farmland. A final benefit to the student was the value potential employers placed on the training experience. Several attractive employment opportunities were available to the student at the end of his program.

This type of program appears to be an excellent vehicle for the student who plans a career in agribusiness, either in an operating or a staff capacity. A student interested in further graduate work would not be helped as much. Further graduate work would require more statistics and mathematics than completed by students on this program.

Even though the trainee does not remain as an employee—the firm might not wish to hire him, or he may choose graduate school or another firm—the firm should gain from the work done by the trainee. In Farmland's case, the firm was able to complete several projects that were of interest to it. The experience of the first student was that his ancillary relationship to the Farmland organization actually made it easier for his special projects to be accomplished. He had no operating assignments competing for his time. Since Farmland regularly

recruits the University's graduates, the shared experience of the student trainee should assist other students in evaluating the firm. More efficient recruiting should result.

Enhancing Mutual Benefits from Firm-Level Research Efforts

Lynn W. Robbins, Stephen B. Harsh, and John W. Allen

The food system is usually thought of as having a series of participants that includes consumers, retailers, wholesalers, processors, assemblers, farmers or ranchers, input manufacturers, and input suppliers. Although there are others, the university is one important participant omitted from that list. The omission is made by both food industry executives and university scholars. Excluding the university component from the food system diminishes the opportunities of interaction between agribusiness and the campus. Potential for reciprocal advantage through increased interaction would suggest considering the university as an integral part of the food system, although currently the industrial and scholastic activities have fairly large nonoverlapping parts (figure 1).

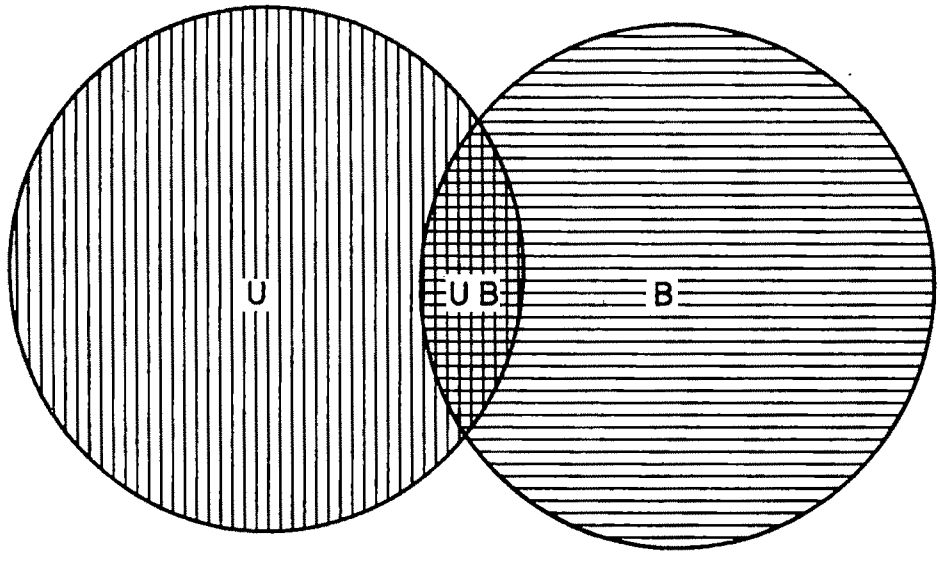
This paper discusses the potential for enlarging the UB intersection in figure 1 by enhancing the mutual benefits from firm-level studies such as those being conducted under existing research approval policies. Barriers blocking potential interaction and suggestions for suppressing them are analyzed with specific illustrations from a case example. Alternative activities for capturing benefits similar to those from firm-level research are also explored briefly.

Cooperation Impediments

Snodgrass, in his paper on off-campus work and study experience programs, concurs with the need for increased industry-campus cooperation: "The establishment of a relationship with cooperators (in intern programs) can reduce 'isolationism' of the college and result in a better rapport with the commercial community, . . ." (p. 20). Similarly, Scroggs believes that "universities must maintain closer touch with industry to maintain their relevancy" (p. 885). Before regular university-agribusiness collaboration can become a reality, existing impediments must be resolved.

Apparently, university agribusiness research has placed primary and possibly singular emphasis on theory development and testing. Over time this approach has nurtured managers' beliefs that university researchers are unable to be practical. This mistrust has yet to be overcome.

Lynn W. Robbins is an assistant professor, University of Kentucky, and Stephen B. Harsh is an associate professor and John W. Allen is a professor, Michigan State University.



Reliance on universities for firm-level research is contrary to normal processes, especially within firms that have developed internal research and service capabilities. Internal services, however, do not always exist in needed areas, especially in smaller firms that have little or no staff support. Universities could potentially provide those abilities that are required to solve problems but that are not attainable within the firm. Where such opportunities exist, often the fear of disclosing operational methods plays a large role in a firm's hesitancy to rely upon university resources. There are, however, many industry-wide, nonspecific needs of the food system where disclosure is not a problem (Bloom).

Another barrier is the university's concern that its coveted neutral position will be violated. Many universities seem to dislike being associated with overt sponsorship of business, but greater interaction with agribusiness might lead to more applicable research and theory without having disproportionate distributional effects within agribusiness industries or between the public and private sectors. Neutrality would at least become less important to all directly involved as the additional university and societal benefits are recognized and captured.

What form should joint research assume? This question is the neutrality argument's central issue. Some argue that only publicly supported joint efforts are justifiable and most firm-specific problems cannot be publicly supported. Firm-level problems are then left to internal staff or external consultants. Accordingly potential benefits from mutual activity can only come from approved professorial consulting. Firms would not be allowed to contract university services in solving firm specific problems.

Shaffer "would restrict studies of efficiency at the firm level or below to the following: (*a*) Where the research is directly tied to an extension program and immediate use of results by competitive firms unable to finance their own research is highly likely. (*b*) Where the research ties to a broader subsector problem or study and thus has a public significance. (*c*) Where new methodology is being developed or tested. (*d*) Where the research is primarily a training exercise" (p. 8).

This policy suggestion for only publicly funded research obviously does not preclude joint research or its benefits. However, the issue in this paper is not that of defining what is proper joint research. The intention is to demonstrate the value of ex-

U = University sector

B = Agribusiness sector

Figure 1. Apparent university-agribusiness consensus on the optimum extent of beneficial mutual activities

panding university-agribusiness interaction within established policies, whatever they are, because historically mutual research benefits have been defined too narrowly.

Multiple facets are added to this "propriety debate," if private funding is allowed, in prescribing the firm's share of the financial support. Here, the prescription is only mutual payment for mutual benefits. Subsidy proportions have to be decided on a case-by-case, private treaty basis. The initial problem is not one of defining financial shares when mutual benefits exist; rather, it is the more basic problem of recognizing mutual benefits.

The Nature of University Research

Joint research efforts can provide increased university-agribusiness interaction. Indeed, university research programs often include studies that use company-specific data, but few are built directly around company-specific problems. Although this process imposes additional restraints upon the researcher, it is possible that research applied to actual business situations can result in an effective means of demonstrating the usefulness and validity of theory.

Dobson and Matthes contend that much university research is inadequate for industry use (pp. 557–64) because it often is either too technical to be readily interpreted or not timely enough to be useful. Results, as well as all other information communicated to managers, must be clear and straightforward. This means keeping mathematical formulae and disciplinary jargon to a minimum. It requires constant surveillance of legal, political, social, and physical feasibility with respect to research and social implementation; otherwise, solutions may be proposed that are theoretically valid but not realistic. For example, it may be politically infeasible to eliminate marginal farm supply cooperative dealerships if the goal is to emphasize member services even though the policy would be economically feasible.

Grayson extends Dobson and Matthes's argument by relating his experience as chairman of the Price Commission. In his opinion, "Managers and management scientists are operating as two separate cultures each with its own goals, languages and methods. Effective cooperation and even communication between the two is just about minimal" (p. 41). He explains that academicians want to help managers produce more explicit decision making through scientific methodology. Managers, on the other hand, "make and implement decisions largely by rough rules of thumb and intuition, . . ." (p. 42).

These positions are incompatible. Grayson discovered what he thought were the reasons for this incompatibility. When "putting together the Price Commission, (he) used absolutely none of the management science tools explicitly, . . ." (p. 43). He could not use them because of shortage of time, inaccessibility of data, resistance to change, long response time, and invalidating simplifications.

Company-specific research could adjust economic, marketing, and management tools to more adequately solve industry problems within industry constraints. Unlike company executives, university researchers are free to contend with technique inadequacies without interference from the firm's day-to-day responsibilities. Once implementation techniques are developed, however, managers should be able to apply them in the face of constraints such as those suggested by Grayson.

An Example

Applied firm-level research is one method for members of the university and agribusiness groups to discover, delineate, and enlarge the UB intersection (figure 1). A recent research effort contracted by the Michigan Farm Bureau's Supply Division is an example (Robbins). Farm Bureau management contracted with Michigan State University to compare projected assembly, distribution, and warehouse costs to those of a one-warehouse system. These comparisons were to provide information needed for deciding whether to invest in a one-warehouse system and to identify the ideal site for such a system.

Outside research was used because management's internal investigation had been too superficial. The major elements of the firm's estimates, managers' knowledge of warehousing technology and their familiarity with Farm Bureau warehouses, were insufficient confidence builders. The dilemma was that the Farm Bureau had neither the time nor the human resources required to internally obtain that information, but they possessed the financial capability to purchase those resources from the university.

Initially, the Farm Bureau was concerned over data confidentiality. Early planning included a disclosure agreement. The foundation for experiment station approval of any research is total data disclosure. The agreement met the full disclosure condition by requiring an initial understanding that all data required for the research effort could and would be provided. The requested data's specific form and detail were left to Farm Bureau's management. The managers' trade-off decision was between data sensitivity and potential solution accuracy. Data needs were presented to management for sensitivity evaluation. None were censored. As new data needs emerged, Farm Bureau screened them according to the agreement. Ultimately, the fear that university research might disclose classified data subsided as the Farm Bureau managers' confidence in university researchers grew. As a result, data disclosure did not hinder the research process.

A review of Farm Bureau's early internal study reinforces the virtue of its decision to ask for outside assistance and confirms the suspicion that the internal research was too perfunctory. For example, preliminary research had correctly identified the central warehouse location using an ordinal ranking approach but did not show that the cost differentials were small.

The research contract provided an opportunity to explore the applicability of research techniques to common agribusiness problems of plant size and location. Techniques used were unique to economies of size and location analyses due in part to limitations imposed by actual agribusiness constraints. For example, an apparent straightforward application of transshipment linear programming was compounded by backhaul requirements until a modification of Schruben and Clifton's lockset model was required (Robbins, pp. 48–49).

The importance of research timeliness was illustrated by Farm Bureau's requests for rough first approximation studies soon after the project started. Schedule adjustments were made to allow concentration on areas that were either previously not scheduled or set for a later time, and interim reports were submitted regularly.

In addition to the benefits of added information the study provided Farm Bureau with an opportunity to improve the return on its investment from the contracted research. The Farm Bureau could realize this return by using computer models specifically designed for the research project, yet applicable to normal operating decisions. The routing algorithm could be utilized as an aid in daily route structuring, and warehouse simulators could be used in ordering and inventory strategy as well as labor force planning.

Conclusions

Joint research benefits from one case study say little about the value of similar additional efforts. Indeed, the marginal return to the university of exactly duplicating the Michigan Farm Bureau research would likely be small. Researching a similar problem with another firm might allow discovery of an even more efficient application of theory and would add university familiarization with another type of agribusiness firm.

The largest marginal return from added firm-level research will most likely come from studying unique firm problems that arise across the entire range of agribusiness types. Apparently, solutions are needed for that set of firm-specific problems for which current university research has been labeled inadequate.

Joint university-agribusiness research conducted under existing policies provides university personnel with insights beyond those gained from less pragmatic efforts. Applied research not only demonstrates theory's usefulness and validity but it also updates the researchers' industry knowledge. University personnel can enhance their teaching by bringing realism into the classroom and can conduct more effective research by obtaining detailed information with respect to how agribusiness firms are organized and managed.

Currently, acceptable firm-level research can provide greater benefits than are generally realized. However, research is not the only source of mutual benefits. Industry and related university departments can do more to achieve the kinds of goals discussed. Together they can establish improved cooperative education programs and other learning-by-doing methods. University staff might become involved with industry issues in other than a consulting or staff role. Such relationships can build understanding and empathy for the food industry that has not previously existed in academia.

Agribusiness firms might provide executive-instructors and finance mutually beneficial research. Executives can also be more specific as to ability areas desired in job applicants.

The goal of determining the full range of effective instruments for achieving cooperation remains largely unfulfilled. Graduate and undergraduate intern programs, faculty consulting, extension programs, executive lectures, and funds for contracted research are among the techniques currently used. Faculty-executive exchange sabbaticals, graduate student apprenticeships, and joint university-agribusiness advisory boards (for coordinating agribusiness research, teaching, and extension efforts at the regional, state, and national level) are other techniques (Scroggs).

Nevertheless, greater recognition of the need for cooperative efforts in more university and agribusiness activities has developed. Recently, an "Open Letter to the Members of the Agricultural Economics Profession" from the AAEA Industry Advisory Committee urged "the profession to review the recommendations that have been placed before it in recent annual meetings and to develop research and training programs that incorporate as many of the recommendations as possible. The committee also invites comments from others in the profession as to how industry could expand its role in narrowing the gap that has developed in our profession." The need is to restructure existing university-agribusiness relationships and obtain greater joint benefits.

of New England and the Chesapeake region, there is never any data on real output and human life in the two regions during the period when their land tenures differed.

Of course, in the Anderson and Hill model any detailed reference to the substance of performance is beside the point because the real purpose is to theoretically legitimatize a particular institution, not to provide information on institutional-performance linkages, so that people could support the institution that serves their particular interests best. It is time to make the economics of property rights analytical rather than value presumptive.

It is also time to remove the artificial wall between distribution and production. If we read our history better and look about today, we may find that, when people feel they are being fairly treated, they make greater effort. The marginal product of labor is not a given but is affected by peoples' view of equity.

The Role of Private Property in the History of American Agriculture, 1776–1976: Reply

Terry L. Anderson and P. J. Hill

Schmid is accurate in his opening statement regarding the "relative neglect" and "growing literature on the economics of property rights," and we would hasten to add that this renewed interest in the subject should contribute significantly to our understanding of individual and collective behavior. While Schmid concedes that our article is an example of the renewed interest, he probably would not consider it a "significant" contribution. His basic criticisms fall into the following four categories: (*a*) the data are too sparse and misrepresent what was actually occurring; (*b*) the analysis ignores losers when in fact distribution is important; (*c*) the theory is at best incomplete; and (*d*) the "real purpose is to theoretically legitimatize a particular institution." We respond to each of these in turn.

The data that can be presented in a short paper covering 200 years of agricultural history must be limited and chosen carefully, and we make no claims that our data series are complete. Nonetheless, those data present a reasonably accurate historical sketch or summary statement. Obviously, not all topics in American agricultural history could be discussed. Schmid raises some issues that he considers more important and implies that our sample of history is biased. However, what he calls "selective perception," we would term "attempts to characterize briefly." In spite of Schmid's examples, we stand by our original statement that the nineteenth century "can be characterized as a period of rapid establishment of individual rights" (p. 940). This characterization does not preclude collective action, and indeed we cite examples. Schmid points out others and emphasizes the importance of collective action with the example of attempts to control tobacco production in the 1630s. Was it "selective perception" that led him to ignore that such collective action failed? On the page after the one quoted by Schmid, Edwards indicates that the attempts at limitation were not successful (p. 185).

Turning to Schmid's second criticism, we do not deny that questions involving distribution of wealth are important, but we also believe that questions involving how institutions affect the absolute level of wealth are at least equally important. The record of private property institutions in promoting efficiency is well documented (Furubotn and Pejovich). The point that Schmid seems not to recognize is that the move from systems of communal rights to private rights is not a zero-sum game. What happened to the colonial shirkers or the man who lost his common law claim on water are interesting questions. But the whole point of Pareto efficiency that comes with private ownership is that all can be made better off. There is nothing a priori to suggest Schmid's emotional conclusion that the man who lost his common law claims "went hungry." By definition, improvements in efficiency are positive-sum games.

Schmid, with his concern for distribution issues, seems to be offering an implicit hypothesis: if there had been less private property in American agriculture, the "problem of poverty or backward regions" would have been reduced. Is it more likely that the problems of poverty will be eliminated if we choose to ignore efficiency and concentrate entirely upon distribution? We think not. Efficiency may not be a sufficient condition for social welfare maximization, but it is necessary.

Third, Schmid is concerned that our "theory suggests no other possible source of rights change, so it never occurs to them to look for other possible explanations" than economic variables. To say the theory suggests "no" other sources of change is false. We do "note" (we thought we did more than note) that ideology is a factor. As is clear in our other work (1975, 1976, 1977), the marginal effectiveness of efforts to alter property rights is a function of "such conditions as cultural and ethical attitudes, the existing rules of the game or the institutional structure, historical precedent, the decision making rule, . . . , to mention a few" (1977, p. 13). This hardly seems to argue that economic factors are solely responsible for institutional change or that government is "passive and neutral." To the contrary, if we are to understand the evolution of the institutional system, we must concentrate more on political, philosophical, and legal conditions. These all influence the willingness of individuals to attempt change and the ability to achieve success. However, we also believe that economic factors cannot be ignored and that differences in relative prices go a long way in explaining differences in behavioral responses. Thus, differences in scarcity of land are a prime explanatory variable in explaining land tenure patterns. Schmid's addition of

Terry L. Anderson is an associate professor in agricultural economics and Peter J. Hill is an associate professor in economics, Montana State University.

"rules of popular access to government" may add to the explanatory power of the model. Further work in this area is encouraged.

Finally, we turn to the comment that "the real purpose is to theoretically legitimatize a particular institution." Our argument that private property promotes efficiency by equating private and social rates of return is straightforward. The first half of U.S. agricultural history can be characterized as a move towards private property. Efficiency resulted. If this legitimatizes an institution, so be it.

Schmid acknowledges this "role of private property in motivating effort" but contends that there are other legitimate means to this end. We agree but do not regard the Ciriacy-Wantrup and Bishop article as evidence "that many of the world's communal lands were well managed and preserved and did not suffer what is now mistakenly assumed to be the inevitable 'tragedy of the commons.'" Ciriacy-Wantrup and Bishop do not demonstrate the efficacy of communal property. They simply offer several ways in which private rights can be partially assigned through quotas, fishing seasons, controls on number of cattle that could be grazed on communal pastures, and other institutional regulations. Rather than being a defense of common property, as Schmid sees it, the article is a strong argument for the necessity of additional institutional arrangements to make common property functional.

Almost half of our paper deals with the twentieth-century movement from efficiency to equity questions as the major focus of institutional change. Schmid does not comment on this. Is this focus an attempt to legitimatize a different institution that Schmid finds more pleasing? Hardly. This focus is a result of our theory and the variables that changed during the last quarter of the nineteenth century. To be sure, additional testing is necessary and revisions in the theory will likely occur. We hope our paper stimulates such work.

Prices and Demands for Input Characteristics: Comment

Randall E. Westgren and Lee F. Schrader

Ladd and Martin have modeled the demand for corn as neoclassical input characteristics (derived) demand. Their theoretical model is a variant of neoclassical firm theory, where the intrinsic characteristics of corn are the arguments in the processor's demand function. Following a discussion of firm theory, two empirical applications cast in linear programming framework are offered.

The second of two blending problems presented, wherein bins or carloads of corn with known characteristics (grade factors) are blended into lots of U.S. grades 1, 2, 3, 4, and 5 yellow corn so as to maximize gross return, is improperly formulated. The empirical formulation offered by Ladd and Martin for this problem is inconsistent with their theory and can be shown to yield a technically infeasible solution. This note provides an alternative formulation that is technically feasible and consistent with their theory.

In the Ladd and Martin paper the profit-maximizing behavior of the firm is stated as

$$\max \sum_j c_j x_j \tag{1}$$

subject to

$$\sum_j a_{ij} x_j \begin{bmatrix} \leq \\ = \\ \geq \end{bmatrix} r_i \quad \text{for} \quad i = 1, \ldots, m \tag{2}$$

and

$$x_j \geq 0 \quad \text{for} \quad j = 1, \ldots, n, \tag{3}$$

where x_j is the quantity of jth output blended, c_j is the gross revenue per unit of jth output, a_{ij} is the amount of ith characteristic per unit of jth output, and r_i is the total stock of ith characteristic (from all bins).

This model fails to recognize that outputs are produced from linear combinations of input characteristic bundles and that an input characteristic cannot be independently drawn from a source without also drawing other characteristics, in fixed proportion, from the source.

Alternatively, the formulation of the problem should appear as

$$\max \sum_j c_j x_j \tag{4}$$

subject to

$$\sum_k b_{ik} z_{kj} - a_{ij} x_j \begin{bmatrix} \leq \\ = \\ \leq \end{bmatrix} 0 \tag{5}$$

$$\text{for} \quad i = 1, \ldots, m \quad \text{and} \quad j = 1, \ldots, n,$$

$$\sum_k z_{kj} - x_j = 0 \quad \text{for} \quad j = 1, \ldots, n, \tag{6}$$

$$\sum_j z_{kj} \leq r_k \quad \text{for} \quad k = 1, \ldots, p, \tag{7}$$

and

$$z_{kj}, x_j \geq 0 \quad \text{for} \quad k = 1, \ldots, p \quad \text{and} \quad j = 1, \ldots, n, \tag{8}$$

where b_{ik} is the quantity of characteristic i per unit of corn in bin k. a_{ij} is the quantity of characteristic i per unit of output j, z_{kj} is the quantity of corn from bin k used in output j, x_j is the quantity of output j produced, c_j is the gross revenue per unit of jth output, and r_k is the stock of corn available in bin k.

This is a larger problem. One constraint exists for each of the i characteristics for each of the j outputs rather than for each of the i characteristics only. Thus, there are mn equations of type (5), n equations of type (6), and p volume control equations describing the problem. The Ladd and Martin formulation includes a constraint for each of the i characteristics and a single volume control equation.

Four carloads of corn with characteristics described in table 1 are blended according to the Ladd and Martin formulation, equations (1) through (3), and the revised formulation, equations (4) through (8). The market prices for the five grades are taken from the Ladd and Martin article and are presented at the bottom of table 2.

The Ladd and Martin formulation has five output grade producing activities with four characteristics rows (test weight, moisture, BCFM, and damage) and a weight control row. (The a_{ij} terms are taken from Ladd and Martin, table 1.) The right-hand side column contains the sum of the characteristics available and weight of the corn in the four carloads.

The alternative problem repeats each of the four characteristic equations (type (5)) and the "adding up" restriction (type (6)) for each of the five output grades and contains a volume control equation (type (7)) for each carload. This formulation has twenty input activities (four carloads by five output possibilities) and five output producing activities.[1]

Randall E. Westgren is a graduate research assistant and Lee F. Schrader is a professor in the Department of Agricultural Economics, Purdue University.

Journal Paper No. 6678 of the Agricultural Experiment Station, Purdue University, West Lafayette, Indiana.

[1] The a_{ij} terms are the same as for the Ladd and Martin formulation, and the b_{ik} terms are taken from Ladd and Martin (table 1).

Table 1. Carload Characteristics

Characteristic	Carload Number 1	2	3	4
Test weight	57	54	52	50
Moisture	0.14	0.16	0.18	0.20
BCFM	0.03	0.04	0.07	0.03
Damage	0.03	0.02	0.10	0.06
Carload volume	3,300	3,300	3,300	3,300

Solution values for the two problems are presented in table 2. The Ladd and Martin formulation produces 11,220 bushels of U.S. no. 2 corn and 1,980 bushels of U.S. no. 4 corn, compared with 9,900 bushels of U.S. no. 3 and 3,300 bushels of U.S. no. 4 corn blended by the alternative formulation. Hence, there is a $1,168 loss in gross revenue associated with the corrected formulation. The Ladd and Martin formulation produces an infeasible solution. The maximum allowance for BCFM in no. 2 corn is 0.03. With carloads 1 and 4 at the limit, and 2 and 3 above the maximum allowance, no more than 6,600 bushels of no. 2 can be produced by ordinary blending procedures. The shadow price generated by the broken corn and foreign material constraints are chosen for illustration and show that the aggregation of the resources by the Ladd and Martin technique results in a zero shadow price for the constraint, while the revised model gives positive shadow prices for all but the U.S. no. 5 BCFM constraint.

The revised formulation of the Ladd and Martin corn blending problem is consistent with their neoclassical input demand model. In the theoretical model they quite properly maintain the identity of inputs into the independent production processes; that is, their production function maintains the identity of inputs into a single production process.[2] Their blending problem formulation ignores this identity and, as originally formulated, is less restrictive than the theoretical model. The revised formulation results in a feasible result, whereas the original problem is likely to result in a technically infeasible solution.

Table 2. Comparison of Results

	Ladd and Martin	Revised
Objective function[a]	$12,784	$11,616
Quantity produced		
U.S. no. 2	11,220 bu.	—
U.S. no. 3	—	9,900 bu.
U.S. no. 4	1,980 bu.	3,300 bu.
Shadow price		
BCFM	0	—
U.S. no. 1 BCFM	—	48.43
U.S. no. 2 BCFM	—	98.22
U.S. no. 3 BCFM	—	12
U.S. no. 4 BCFM	—	12
U.S. no. 5 BCFM	—	0

[a] Given market prices of $1.00, $1.00, $0.91, $0.79, and $0.63 for U.S. grades 1 through 5 yellow corn.

Ladd and Martin draw upon the results of their linear programming analysis to show that the present corn grading system cannot meet a desirable condition of "sign-optimality." The results of revised formulation supports these conclusions. Clearly, the difference in shadow prices for the same characteristic within the firm renders the notion of condensing corn quality to a single number even more questionable. One is tempted to hypothesize that the marginal value of a particular lot of corn is most likely to depend on one or two critical characteristics rather than any given set which may be used for grade determination.

[*Received September 1976; revision accepted April 1977.*]

[2] The production function appears as $q_h = G_h(v_{1h}, v_{2h}, \ldots, v_{mh}, x_{11h}, x_{12h}, \ldots, x_{mnh})$, where v_{ih} is the quantity of the ith input used in the production of the hth product, x_{jih} is the amount of characteristic j provided by one unit of input i that enters into production of product h, and $x_{j \cdot h}$ is the total quantity of characteristic j that enters into production of product h (g_n).

Prices and Demands for Input Characteristics: Reply

George W. Ladd

This reply covers four topics: (*a*) a brief comparison of the Westgren and Schrader (WS) and the Ladd and Martin (LM) formulations of blending processes in multiproduct plants, (*b*) a brief comparison of objective functions in the two models, (*c*) derivation of shadow prices of characteristics from the WS model, and (*d*) reevaluation of evidence on sign-optimality of the present corn-grading system.

The statement of blending processes in the WS formulation of the second blending problem is clearly superior to the formulation in the LM paper. However, the LM model maximizes net revenue. WS maximize gross revenue. For reasons presented later, I believe that maximization of net revenue is more appropriate. The rest of this reply deals with a WS model in which the objective function has been changed to net revenue and which is referred to as the "revised WS model."

The shadow prices for corn yielded by the revised WS model can be used to determine if a grading system satisfies the LM criterion of sign-optimality and for other purposes. The shadow prices for corn characteristics yielded by the WS model, however, are not useful for evaluating grades because they do not measure the effect on cost or on revenue of varying the amount of characteristic in a product or input.

The interpretation of the shadow prices is clarified by looking at the dual to the revised WS program. The revised WS model contains one constraint for each characteristic in each output. These constraints are represented by expression (5) in the WS paper. Assume all these constraints are of the form

$$(5WS) \qquad a_{ij}x_j - \sum_k b_{ik}z_{kj} \leq 0.$$

Then the dual to the revised WS program is

$$(1) \qquad \min G = 0\sum_i \sum_j v_{ij} + 0\sum_j u_j + \sum_k y_k r_k$$

subject to

$$(2) \qquad \sum_i a_{ij} v_{ij} - u_j \geq c_j \text{ for } j = 1, 2, \ldots, n,$$

$$(3) \qquad y_k - \sum_i b_{ik} v_{ij} + u_j \geq 0 \text{ for } j = 1, 2, \ldots, n \text{ and } k = 1, 2, \ldots, p,$$

and

$$(4) \qquad \text{all } v_{ij}, y_k \geq 0, \text{ all } u_j \text{ unrestricted.}$$

The dual variables can be defined as v_{ij} is the shadow price of characteristic i in product j, u_j is the shadow price of WS product balance equation (6), and y_k is the shadow price of corn in bin k.

If the amount of corn in bin k is increased by the amount dr_k, where the added corn has exactly the same combination of characteristics as the corn originally in the bin, then

$$(5) \qquad d(\max \sum_j c_j x_j)/dr_k = d(\min G)/dr_k = y_k,$$

where y_k measures the effect on net revenue of varying by one unit the available amount of corn having the same set of characteristics that the corn in bin k has and where y_k is the maximum price the firm can afford to pay for such a unit of corn. If it pays more than y_k, its net revenue will be reduced.

To interpret the v_{ij}, rewrite expression (5WS) as

$$(5WSa) \qquad a_{ij}x_j - \sum_k b_{ik}z_{kj} \leq -E_{ij}.$$

If $E_{ij} > 0$, equation (5WSa) states that the total amount of characteristic i taken from all bins for use in product j shall exceed the amount actually used in product j by the amount E_{ij}. (What happens to the surplus of characteristic i?) If $E_{ij} < 0$, equation (5WSa) allows the amount of characteristic i actually used in product j to exceed the total amount of characteristic i taken from all bins to use in product j. (Where does the rest of the characteristic i needed for product j come from?) A nonzero value of E_{ij} either forces waste on the firm or has a nonsense meaning. If $-E_{ij}$ is varied by the amount $d(-E_{ij})$, then $d(\max \Sigma c_j x_j)/d(-E_{ij}) = d(\min G)/d(-E_{ij}) = v_{ij}$. The shadow price v_{ij} measures the effect on revenue of varying the artificial waste or deficit requirement by one unit. A characteristic's shadow price having this interpretation does not seem useful to me. It does not measure the value to the firm of having more or less characteristic in an input or output. It only measures the value of varying an artificial requirement of surplus or deficit.

Characteristics' shadow prices that would be useful for evaluation of grades are obtained by answering the question, "What happens to maximum net revenue if the amount of one characteristic in a bin is increased?" Let s_{fg} equal amount of characteristic f in bin $g = b_{fg} r_g$, and suppose s_{fg} increases by the amount ds_{fg}. What happens to maximum net revenue? Duality theorems will not provide an answer to this question because s_{fg} is not an explicit parameter in the linear program. Changing s_{fg}

George W. Ladd is a professor of economics, Iowa State University.

Journal Paper No. J-8763 of the Iowa Agriculture and Home Economics Experiment Station, Ames, Iowa. Projects No. 1906 and 2196.

changes r_g, and it also changes the b_{ig} coefficients; $db_{ig}/ds_{fg} = (r_g ds_{ig}/ds_{fg} - s_{ig} dr_g/ds_{fg})/r_g^2$, where $ds_{ig}/ds_{fg} = 0$ unless $i = f$. The resulting change in max $\Sigma c_j x_j$ can be obtained from a relation in sensitivity analysis (see Gass, pp. 139–40). If the changes in r_g and the b_{ig}'s do not cause a change in the optimal feasible basis, then

$$(6)\quad d(\max \Sigma c_j x_j)/ds_{fg} = \sum_{i=1}^{m}\sum_{j=1}^{n} z_{gj} v_{ij} (db_{ig}/ds_{fg}) + y_g (dr_g/ds_{fg}) \gtreqless 0.$$

Denote the right-hand side of equation (6) by w_{fg}, where w_{fg} is the maximum amount the firm can afford to pay for an increase of one unit in the amount of characteristic f in bin g. The value of w_{fg} can be easily determined from the solution to the primal linear program. After ds_{fg} is specified, the values of the derivatives can be determined. The linear programming solution provides the values of the primal variables z_{gj} and the dual variables v_{ij} and y_g. If the changes in r_g and the b_{ig}'s do cause the optimal feasible basis to change, the value of w_{fg} is obtained from

$$(7)\quad w_{fg} = \max \Sigma c_j x_j' - \max \Sigma c_j x_j,$$

where max $\Sigma c_j x_j$ is the maximum feasible value of the WS objective function for the original linear program and max $\Sigma c_j x_j'$ is the maximum feasible value for the linear program obtained by changing the values of r_g and the b_{ig}'s.

Equation (6) shows that w_{fg} may not equal w_{ft} $(t \neq g)$ even though $ds_{fg} = ds_{ft}$. The contribution to net revenue of increasing the stock of characteristic f by one unit depends upon the characteristics of the corn in the bin to which the addition is made.

As stated earlier, I believe that for purposes of evaluation of grades it is better to use net revenue rather than gross revenue as the objective function. To understand this, assume the objective function is gross revenue. Then $d(\max \Sigma c_j x_j)/dr_k = y_k$ measures the effect on gross revenue of increasing r_k. But y_k exceeds the maximum amount the firm can afford to pay for an additional unit of corn having the same combination of characteristics as the corn in bin k. If the firm pays y_k for the corn, its net revenue is reduced by the amount it costs to blend this additional corn. If the cost of using additional stock of corn is independent of the bin to which it is added (i.e., independent of the combination of characteristics in the addition) and also independent of the product in which it is used, then $y_k - t$ is the maximum price the firm can afford to pay for the corn, where t is the cost of using an additional unit of corn. By a similar argument, w_{fg} overstates the maximum amount the firm can afford to pay for an increase of one unit in the amount of characteristic f in bin g. If the cost of using this additional stock of characteristic is independent of characteristic, bin, and product(s) in which it is used, then $w_{fg} - T$ is the maximum price the firm can afford to pay, where T is cost of using the additional stock of the characteristic.

To write net revenue as $\sum_j c_j x_j$ means that c_j is the net revenue per unit of output $j = p_j - t_j$, where p_j is the selling price and t_j is the variable cost of blending one unit output j. All t_j's may have the same value. The variable cost of blending one unit of output j may depend upon the bin from which the inputs for the product are taken (e.g., upon the combination of characteristics in the bin, or the location of the bin). Then, net revenue can be expressed as

$$(8)\quad \sum_j p_j x_j - \sum_k \sum_j t_{kj} z_{kj} = \pi,$$

where t_{kj} is the average variable cost of using one unit of input from bin k in output j. If the WS objective function is replaced by equation (8), the dual constraints (2) and (3) become

$$(9)\quad \sum_i a_{ij} v_j - u_j \geq p_j$$

and

$$(10)\quad y_k - \sum_i b_{ik} v_{ij} + u_j \geq -t_{kj}.$$

Then $d(\max \pi)/dr_k = y_k$ from equation (5) and $d(\max \pi)/ds_{fg} = w_{fg}$ from equation (6). Replacing the WS objective function by equation (8) does not change the expressions used to obtain y_k and w_{fg} but can change the values of y_k and w_{fg} because changing the objective function can change the solution values of primal and dual variables.

The LM paper relies on three pieces of evidence to support our position that the present corn-grading system is not sign-optimal and our suggestion of the specified-order method of reporting: (*a*) our linear programming results, (*b*) marginal value products (MVP's) that Knapp obtained for some 190 bins of corn in a corn merchandising study, and (*c*) corn users' rankings of importance of various corn characteristics. The WS comment makes it clear that our linear programming results cannot be relied upon. But the other two pieces of evidence support our position. Nothing in WS or in this paper affects the LM interpretation of the ranks assigned by corn users.

Knapp's MVP's are equal to y_k from equation (6) plus the cost of using a bushel of corn from bin k. Let y_k be the MVP of a bushel of corn of grade k (k = 1, 2, 3, 4, 5, and 6; 6 indicates sample grade) and t_k be the cost of using a bushel of corn of grade k. Knapp's results are inconsistent with sign-optimality for every value of k and i that satisfy

$$(11)\quad \max y_k + t_k \geq \min y_{k-i} + t_{k-i}.$$

If the cost of using a bushel of corn is not affected by grade, then $t_k = t_{k-i}$ and all of Knapp's results are inconsistent with sign-optimality because max $y_k >$ min y_{k-1} for all k. Likewise, if $t_k > t_{k-1}$, all Knapp's results are inconsistent with sign-optimality. His results are also inconsistent with

sign-optimality in many cases in which $t_k < t_{k-1}$. For example, if $t_5 - t_6 = 0.08815$, his MVP's are inconsistent with sign-optimality for some bins of U.S. no 5 and U.S. sample grade corn.

A question has been raised (not by WS) about the nature of the inequalities in table 1 of the LM paper as well as the results in table 2. Tables 1 and 2 in the LM paper are consistent. The problem in table 1 is exactly problem 11 whose solution is presented in table 2 and is representative of the other problems whose solutions are presented in table 2. The problems would have been more realistic, however, if all constraints had been of the "less than or equal to" form: $\Sigma a_{ij}x_j \leq a_{i0}$. If all constraints in table 1 were of this form, the only nonzero shadow prices in table 2 would be those for damaged kernels. These shadow prices would all be \$33.33 per bushel.

Books Reviewed

Breimyer, Harold F. *Economics of the Product Markets of Agriculture*. Ames: Iowa State University Press, 1976, x + 208 pp., $11.95.

The theme of this book is set in the preface: "the ideas contained herein are designed to fit traditional courses in agricultural economics yet are also intended to lead the student into explorations that may be distinctive and in instances unconventional" (p. ix). This is a textbook on agricultural product marketing designed for upperclass or beginning graduate instruction and a book in which traditional concepts in agricultural marketing and principles of industrial marketing are drawn upon separately and together. The result is a partial "redesigning of the analytical structure" (p. ix).

Breimyer has utilized his years of experience and broad knowledge as an authority in agricultural marketing to put together an interesting, provocative text. He presents new conceptual frameworks for often old ideas and melds together differing opinions that make for intriguing contemplation. It is a book all students of marketing will want to read. Its style is clear and easy reading, but stimulating.

In most classroom situations, this text will probably not stand alone. First, most of the "[b]asic ideas are presented in summary form and rapid order, without detailed elaboration" (p. ix). However, Breimyer has done an excellent job of citing the literature so the student can easily refer to the underlying arguments and logic of basic notions. Second, this book focuses in a descriptive manner on the economic concepts relating to the market mechanism, and it is not a how-to-do-it marketing book. It is nontechnical, without voluminous tables of data, and contains minimal references to empirical work.

The first four chapters lay out the fundamental concepts in which the author goes beyond conventional wisdom and suggests alternative model formulations. The first chapter points out the diversity of alternatives when examining systems of economic organization, organizational structure of marketing, and definitions of marketing. No stand is taken on the issues presented, although the author presents his version of the evolution of agricultural marketing through four epochs. Chapter II fits least well in the text and examines goals of consumers and firms from the standpoint of how to judge the performance of the economic system towards meeting these goals. Standard utility theory is relied upon, but despite the author's criticism of theoretical economists, the problem of evaluation remains.

The next two chapters present the basic conceptual frameworks. Chapter III rules out traditional neoclassical analysis and presents the economics of the firm in an imperfectly competitive structure. A theory of full cost pricing is described, where costs are divided into three groups, controllable variable, specific overhead, and general overhead. Oversimplifying, full cost pricing is an accounting device whereby a multiple product firm, like a retail food store, prices products with varying markups; that is, the overhead is not apportioned evenly among products but is divided according to the competitive nature of the various products.

Chapter IV discusses the structure of markets in standard terms. Imperfectly competitive markets are emphasized, and rightly so, and the variables examined are those typically used in most structure-conduct-performance analyses. Special attention is given to vertical relationships, an overriding concern throughout the text. One anomaly stands out in these conceptual chapters. Considerable effort is made to reject marginal analysis and substitute descriptive frameworks. Yet, when the subject of price discrimination (market stratification) is discussed, the standard model in which marginal cost is equated to marginal revenue is presented.

The remainder of the book is more empirical or problem specific. Nevertheless, the theories laid out above in addition to notions of limited divisibility and mobility of resources, and the impact of firms operating at less than full capacity, are continually referred to and act as common threads of analysis. Subjects discussed include the standard breakdown of the consumer dollar (appropriate caution is given about the unreliability these data have as a measure of market performance), structure of the farm marketing, processing, and retailing sectors, price discovery systems, and research on the performance of the marketing system. Continual reference is made to the significant findings of the National Commission on Food Marketing, but that in itself, plus reminders through the text, reveals the need for an update. The book points out how much we do not know and that we are lacking critical data for market analysis, especially in vertical coordination arrangements and industry specific information about conglomerates.

Governmental policies affecting marketing, economics of (railroad) transportation, theory of firm location, and marketing in economic development complete the book. Each of these topics is handled briefly, raises some structure-pricing-performance issues, but leaves the resolution to others.

One disappointment of mine is in a topic not covered. On page 9, Breimyer lists the marketing functions found in standard texts and in one fashion or another discusses all of them but one—risk bearing. This topic, or the more broadly construed topic of risk management, ought to be confronted directly

in a marketing text. The importance of this area has increased with the increased price volatility of the 1970s, and recent methodological breakthroughs have led an upsurge of both theoretical and empirical literature. Certainly, one of the underlying impetuses for various vertical coordination arrangements is the firms' attempt to manage risk. Breimyer's well-known underlying preference towards traditional agriculture, especially in pricing, creeps into this book also. In this regard, I have argued before that the most visible forward contracting market, the futures market, helps preserve the traditional markets by providing large firms an alternative for risk management other than vertical production or marketing contracts, or even conglomeration.

The author does an excellent job in referring the reader back and forth through the text to previously stated underlying arguments or subsequent elaborations of a point. Only once is this done excessively when on page 103 an illustrative sketch of food marketing is repeated from page 84, and one still wonders if there is significance to the size of boxes in the sketch. Also, some of the analytical frameworks are rather loosely described, which will leave technicians and theoreticians uneasy. Broad generalities and vague terms like "giant" and "probably" occasionally mar the quality.

Nevertheless, these minor complaints aside, Breimyer is a senior scholar and has provided us with a text that will serve as a basis for discussion for years. He has insight and creative abilities possessed by few people and an ability to communicate these thoughts so as to provoke the profession.

Raymond M. Leuthold
University of Illinois

Fuller, Anthony M., and Julius A. Mage. *Part-Time Farming: Problem or Resource in Rural Development.* Norwich, England: Geo Abstracts Ltd., 1976, 291 pp., price unknown.

The proceedings of a symposium on part-time farming held at the University of Guelph, Canada, are reported in this book. The symposium grew out of the co-editors' long-standing interest in part-time farming and the part-time farming research program of Guelph's Department of Geography. The stated objectives of the symposium are to (*a*) identify who are the part-time farmers, (*b*) assess whether part-time farming represents a problem or resource, (*c*) identify the relationship between newcomers to agriculture and part-time farming, and (*d*) identify some policy implications.

The major papers and discussion of the symposium are in three groups. The first group is conceptual in nature and sets the stage for the remainder of the conference. The second group focuses on problems associated with part-time farming, and the final group concentrates on policy implications.

The two papers in the first group have as their objective the development of a typology of part-time farming and a conceptualization of part-time farming problems. Part-time farming is defined as situations in which farm operators have remunerated nonfarm work. The role of nonfarm employment of farm family members other than the operator is not addressed in defining part-time farming. From the variety of part-time farming situations identified (small-scale hobby, large-scale hobby, aspiring to full-time, persistent part-time, and sporadic part-time), it is apparent that the part-time farming phenomenon is not simply the "opposite" of full-time farming. The problems of part-time farming are conceptualized in terms of two dimensions of time: work-time allocation and adjustment time. Several problems with allocation of time between farm and nonfarm employment are identified. The concept of adjustment time is used to identify problems associated with farm enterprise and rural life style change and personal and occupational mobility. The concepts developed in these papers are helpful and are likely to stimulate additional efforts to refine the concepts presented. They need to be tested in areas other than Ontario, Canada. Especially needed is an analysis of the impacts of cultural differences and specific economic factors such as land use patterns, nonfarm employment opportunities, and life cycles of farm businesses.

The second group of papers falls under the general heading of problems with part-time farming. The seven papers are grouped under four subheadings: economic marginality, physical marginality, newcomers to agriculture, and problem or resource. There is substantial variation in the focus, depth, and polish of these papers. Some are helpful because of their detailed empirical analysis and concentration on carefully defined issues. Economic and physical marginality are not clearly differentiated. The hobby farming discussion is helpful, but the problem of newcomers to agriculture is broader than hobby farmers. This section of the book would have benefited a great deal from introductory sections concentrating on problem definition and reasons for selection of countries and specific issues addressed.

The third group of papers is concerned with policy implications. A general lack of clarification of policy issues related to part-time farming is apparent from the three papers and the four-person panel discussion. Canada, Finland, Sweden, Italy, United States, and Britain are represented in the policy discussion. A common thread running through the papers is the limited attention to part-time farming issues by policy makers in these countries. However, there is a general consensus of no need for special policies to protect or promote part-time farming. The papers suggest that part-time farming may be an important part of the development strategy for some declining rural areas and some developing areas.

This volume also includes a conference summary, a paper presented at a special session on part-time farming in Poland, four papers in absentia, and a transcript of the participant discussion following each group of papers.

There is much in this book that will be helpful to the agricultural economist interested in part-time farming. The complexity of the research and policy issues is made apparent. The conference did not resolve whether part-time farming is a problem or a resource, but many hypotheses relative to this question were suggested. The conference did not accept the myth that all small-scale farmers are part-time and conversely that all part-time farmers are small scale. The need to go beyond a conceptualization of part-time farming as a transition stage for a farmer or an agricultural region is apparent. Data limitations and problems with much of the analysis that has been done to date are clearly identified.

There are some limitations to the book. Most relate to the inherent limitations of a three-day international conference dealing with complex issues. Although some attention was given to the multidisciplinary nature of part-time farming issues, the conference did not address the opportunities for meaningful cooperation among agricultural economists, geographers, and rural sociologists in addressing these issues. Given the objectives of the conference, it is difficult to understand why the experiences of some of the Far Eastern countries were not included. The conference was dominated by papers about Ontario, Canada. One is left with the uneasy feeling that not much has been learned about part-time farming outside Ontario. However, this is probably a telling sign about the current status of part-time farming research in the countries represented rather than an indication of parochialism on the part of the conference planners and hosts.

Thurow, Lester C. *Generating Unequality: Mechanisms of Distribution in the U.S. Economy*. New York: Basic Books, 1975, xiv + 258 pp., $5.95 paper.

How does an economy generate income and wealth distributions? As early as 1848, John Stuart Mill asserted that "it is only in the backward countries of the world that increased production is still an important object; in those most advanced, what is economically needed is a better distribution" (p. 749). Distribution remained central to economic analysis until the twentieth century, when the separation of equity and efficiency focused attention on the latter. In the last decade, the study of distributional issues has once again gained intellectual respectability. *Generating Unequality* is an attempt to explain observed reality by formulating separate theories of the determinants of income and wealth.

Rejecting the marginal productivity theory of distribution as an amorphous body of assumptions embellished by ad hoc hypotheses to explain deviations between theory and reality, Thurow sets out to "construct consistent mechanisms for explaining the observed distributions of earnings and wealth" (p. xi). Since earnings and wealth are generated by different distribution mechanisms, separate distribution theories are constructed. A "job competition" model is advanced to explain the distribution of earnings, while a "random walk" theory serves to explicate the distribution of wealth. Distribution mechanisms are viewed as processes generating different "economic prizes" or outcomes under alternative sets of rules. By comparing and evaluating different sets of rules, an optimal distributional framework can be selected.

The book comprises four parts. Part I surveys the distribution of income and wealth and discusses the equity criteria against which any distribution must be assessed. Part II advances a job competition model to explain the distribution of earnings, while part III describes the determinants of the distribution of wealth. The book concludes with a discussion of the impact of discrimination on the earnings distribution and the policy implications that flow from the analysis. The appendices provide an overview of marginal productivity theory and a listing of persons with fortunes in excess of $50 million.

The book opens with an overview of changes in the distribution of personal incomes since 1947. Between 1947 and 1972, the two poorest quintiles and the richest quintile transferred 4% of their income to the fourth quintile, the upper middle class. Physical wealth is more concentrated; in 1969, the top 7.4% of the population owned about 60% of all wealth. Income and wealth distributions are, of course, meaningless without some criteria against which they can be judged. After noting that economists have neglected equity issues to focus on efficiency mechanisms, four specifications of economic equity are proposed: rely on fair or equitable rules; allow individual preferences to prescribe equity; distribute income and wealth in accordance with "merit"; and utilize distributional criteria that maximize the common good. After examining the four approaches and their shortcomings, Thurow concludes that "equity remains unspecified, . . . since any specification of equity requires substantial amounts of empirical information" (p. 50), which is unavailable.

"Deviant" labor market observations are adduced to illustrate the failure of marginal productivity theory to explain the observed distribution of earnings. The persistence of unemployment and the continued skewness in the earnings distribution despite a trend toward equalization in the distribution of human capital (education) attributes provides the foundation for a "job competition" view of the

labor market. Rather than acting to distribute existent skills, the labor market is viewed as a device for distributing training slots among workers ranked by their costs of training. Job competition finds that "individuals compete against one another for job opportunities based on their relative costs of being trained to fill whatever job is being considered" (p. 75). The distribution of jobs is determined by technology, exogenously determined wages, and the way in which training costs are shared between workers and employers. Since the wage attaches to the job rather than the individual, competition is confined to movement along a labor queue that ranks workers in terms of their relative costs of training for a particular job. Thus, the rules governing access to job slots simultaneously act to dictate the distribution of earnings.

Turning from the earnings distribution to the distribution of wealth, Thurow advances a "random walk" theory of the creation of large fortunes. Those not inheriting wealth take advantage of disequilibrium between rates of return in real and capital markets. Chronic disequilibrium in rates of return within and between industries and the tendency of industry to finance investments from retained earnings result in the divergent returns between real and financial markets (which merely transmit money from one investor to another). Individuals attain "instant wealth" by being lucky participants in the disequilibrium lottery, where equal *ex ante* returns produce unequal *ex post* returns. Since fortunes are generated in a "random walk" or lottery process, there is no inherent justification for taxing capital gains at lower rates than wage earnings. Thurow argues that capital gains should be treated as wage earnings for tax purposes. In conjunction with the abolition of the corporate income tax and the distribution of all corporate earnings to stockholders, such a policy would force firms to sell stocks and bonds to raise capital, thus restoring the "proper" linkage between real and financial markets.

A statistical theory of discrimination is advanced to explain why certain groups are excluded from job-training slots. Employers treat individuals as members of a (race or sex) group and base hiring decisions on the general characteristics ascribed to that group. While the characteristics are true, on average, for the group, "the judgements are incorrect with respect to many individuals within the group" (p. 172), denying qualified individuals entry into jobs. The elimination of statistical discrimination necessitates access to jobs that provide training: "To significantly alter the distribution of earnings, it is necessary to significantly alter the distribution of on-the-job training" (p. 191). Rather than prescribing indirect methods that alter the human capital attributes of those suffering discrimination, this model argues that guaranteed access to jobs is vital to preclude continued exclusion.

In working from the observed distributions to the forces determining the distributions of income and wealth, Thurow has generated thought-provoking models. The theory that short-run labor market adjustments occur through an altering of the required applicant background or human capital attributes helps explain the actual short-run rigidity of wages. Unfortunately, such labor market models hold only in structured labor markets. Although Thurow recognizes that "there is a continuum between wage competition and job competition and that the American economy lies somewhere between those extremes" (p. 76), attention focuses on access to and promotion within a structured labor market. In structureless labor markets, epitomized by the agricultural harvest labor market, little training is necessary, permitting wage adjustments to act as short-run equilibrating devices. Similarly, one must question the import of access to job-training slots across societies. In Europe, where apprenticeship programs are relatively uniform and widespread, do markets equilibrate with applicant qualifications or other factors? Despite reservations as to the theory's generality, Thurow has provided fresh insights into an oft-neglected area of economics.

Mill, John Stuart. *Principles of Political Economy*. London: Longmans, 1900.

Book Review Editor note: In November 1976 the Frederick Wiseman film, *Meat,* was broadcast on National Public Television. Although films have not been previously reviewed in the *Journal,* the topic and content of the film is of interest to the agricultural profession. The following is a review of the film.

Wiseman, Frederick, producer. *Meat.* Boston: Zipporah Films, 1976, 113 minutes. $125 per first screening, $62.50 subsequent screenings, $950, five-year lease.

Meat is an unusual documentary film, the tenth produced by Emmy award-winner Wiseman, whose productions include *Primate,* the 1975 study of scientific experimentation with monkeys and other primates that stirred much public anger and dismay. By stressing the macabre of livestock slaughter, one suspects that Wiseman might be seeking a similar reaction to *Meat*; however, the lack of human resemblance to a steer or lamb makes empathy difficult.

This is the beef and lamb industry, from ranch through feedlot, slaughter, and packing to "ungraded goosenecks in combos," told in a two-hour black-and-white film with no narration. Wiseman

lets the sounds do the talking, including the bawling of cattle, the auctioneer's banter, salesmen making deals in their peculiar jargon, the mechanized sounds of a meat plant, and a fixation on the sounds of diesel truck engines. In a sense it is the story of the assembly line in reverse, beginning with the completed product and ending with the parts. It was not produced as an educational film, yet it is being promoted as one. This review examines that potential.

Filming took place at Monfort's feedlot and packing plant in Greeley, Colorado. Thus, it shows a "typical" feedlot of some 100,000 head capacity and a packing plant handling 10,000 head or so per week—not the average processing or farmlot feeding operation, but nonetheless representative of those 200 or so largest feedlots that currently account for over a third of all cattle feeding. As such, it documents a closely orchestrated production-processing system for meat that most people seldom if ever have the opportunity to observe first hand, yet one that is steadily becoming representative of this industry.

In quick succession, cattle are rounded up on the ranch, put on the auction block, trucked, vaccinated, disinfected, penned, fattened, weighed, trucked, penned, stunned, hoisted by the hooves, and slit at the throat. Poor husbandry practices are realistically portrayed in all livestock handling scenes. Then, in an extensive sequence of slaughter and processing, cattle are beheaded, and the heads are processed in close-up detail. Cattle are eviscerated, skinned, split, sawed into sections, cut into pieces, mechanically tenderized, ground into patties, wrapped, boxed, and shipped. The sequence is repeated for lambs, with shearing thrown in and the auction left out. A disproportionate amount of time is spent in the packing plant on relatively insignificant operations. This makes it difficult to grasp the time dimension involved in total animal and meat production, processing, and distribution. Judging by the time allocation in the film, slaughtering and processing is roughly three times as important as are all livestock enterprises combined. The lack of narration does not help eliminate this misconception.

Some insightful scenes of the management process are included. Wholesale trading in meat, procuring feeder cattle, dealing with a slow-paying customer, and a staff meeting where department heads coordinate related activities such as feeder cattle purchases, feedlot operations, slaughtering and packing, sales, and merchandising are interesting sequences. Particularly well done is a session between labor and management, with management implementing job redefinitions despite the protests of the union representatives. This sequence is particularly notable in that, as is true throughout the film, the people (as well as the animals) appear to be totally unaware that they are being filmed.

Overall, the film captures much of the complexity involved in coordinating livestock feeding, slaughtering, and meat packing. This, combined with the opportunity to see the processes involved on a large scale and to observe labor and management in their normal and unheroic routines, are the points to recommend its use for educational purposes. As such, it could be useful to classroom teachers relative to subjects such as the economics of the livestock/meat industry and meat processing and to extension educators working with livestock producers and perhaps consumers. The lack of narration should prove a benefit to educators, as the missing explanation of what is being seen tends to stimulate questions and thus discussion.

However, it has at least two major limitations for educational purposes: excessive length (involving much of little significance) and high cost. Two hours is both too long for most educational uses and much longer than needed to demonstrate the relevant points. Much of the length is due to excessive overemphasis on aspects of livestock handling that suggest cruelty and on aspects of processing that appear gruesome, such as the five-minute sequence on processing cattle heads, repeated for lamb heads. While such disproportionate coverage may make for some social commentary (unperceived by these reviewers), it adds unnecessarily to length. On cost, we have no benefit-cost ratio to offer. But, it is difficult to imagine an educational situation where the $125 initial screening fee is available, much less justified. We believe the film could benefit from a sharp editing job in terms of its usefulness to educators. It could easily be reduced in length to 30 to 40 minutes total, without losing much but its excesses and gruesomeness. If the cost was reduced proportionately, it could justify consideration by educators.

As it is, if you can catch it on your local television station, it beats watching *The $25,000 Pyramid.*

Announcements

1977 Meeting Allied Social Sciences Association

The American Agricultural Economics Association will meet jointly with the Allied Social Sciences Association in New York City, 28–30 December 1977. A program will be published in the November issue of the *Journal*.

Book Review Editor

Starting with the February 1978 issue, Herbert H. Stoevener will be the book review editor. Communications about books for review and books submitted for announcement in the *Journal* should now be sent to Herbert H. Stoevener, Department of Agricultural Economics, Oregon State University, Corvallis OR 97331. All other manuscripts and editorial correspondence may be sent to the new editor, V. James Rhodes. However, revisions of manuscripts originally submitted to the current editor should be sent to Cornell University so that the entire folder can be forwarded to Professor Rhodes.

Appointments: Barry Edmonston, former assistant professor, Stanford University, is with the International Population Program; **Robert C. Nolan** is an extension associate in the Cornell Home Study Program in food industry management; **Jan Sweeney** is a visiting assistant professor, 1977–78.

University of Florida

Appointments: Jose Alvarez, Timothy D. Hewitt, formerly with the University of Tennessee, and **Bryan E. Melton,** formerly with Iowa State University, are assistant professors.
Leaves: Edna T. Loehman is on academic development leave at the Stanford Food Research Institute and the Department of Economics, University of New Mexico, Sept. 1977–June 1978.

University of Illinois

Appointments: Mack N. Leath is an associate professor; **K. E. Nelson** is an assistant professor.

Kansas State University

Appointment: Gary Vacin is the extension editor for the Kansas Cooperative Extension Service.

Resignations: Parman Green, former area extension economist, Garden City, is with the Farmers and Merchants State Bank of LaCrosse, Kansas; **Dean Parker,** former area extension economist, Concordia, is a county extension agent in Ohio.
Honor: Dale L. Fooshee of Garnett, Kansas, 1951 graduate, was named the 1977 Distinguished Agricultural Economics Alumnus.

University of Manitoba

Appointment: Edward W. Tyrchniewicz succeeds Arthur W. Wood as head, Department of Agricultural Economics.

University of Maryland

Appointment: Barbara J. Redman, Ph.D. Iowa State University, is an assistant professor of consumer economics.

University of Massachusetts

Appointments: N. E. Engel is director, Office of Policy Analysis, College of Food and Natural Resources; **John H. Foster** is chairman, Department of Food and Resource Economics.

Michigan State University

Appointment: Lindon Robison, formerly with the ERS, USDA, is an assistant professor in production economics.
Retirements: Richard Hartwig, after 27 years of service; **Henry Larzelere,** after 35 years of service.
Honor: Lester V. Manderscheid received a 1977 Distinguished Faculty Award, the highest faculty honor within the University.

University of Minnesota

Appointments: Dale W. Nordquist, M.S. University of Minnesota, is an assistant extension specialist, farm management-Farmers Home Administration; **Michael D. Petkovich,** M.S. University of Nevada, is a research specialist in economics of tourism and recreation.

University of Nebraska

Leave: Paul Gessaman, professor, is on a research assignment at the North Central Rural Development Center, Ames, Iowa, April–Sept.

North Carolina State University

Appointments: John D. Hanson, Jeffrey S. Royer, Gary F. Vocke, and **Michael K. Wohlgenant** are assistant professors of economics and business.
Retirement: Henry A. Homme, former extension associate professor.

Pennsylvania State University

Leaves: Robert F. Hutton is with the Cooperative State Research Service, Washington, D.C., through June 1978; **J. Dean Jansma** is the assistant dean for research, College of Agriculture, through June 1978.

Purdue University

Appointments: Janet S. Ayres is a community development analyst; **Peter L. Nuthall** is a visiting assistant professor in farm management; **Thomas L. Vollrath** is a temporary assistant professor on the Agency for International Development African Project.
Honor: David C. Petritz was elected to the Board of Directors of the American Forage and Grassland Council.

Rutgers—The State University

Appointment: A. Robert Koch, chairman, Department of Agricultural Economics and Marketing, is on the State Clean Air Council, New Jersey.

Stanford University

Appointments: Carl H. Gotsch, Ph.D. Harvard University, is an associate professor; **Anne Peck,** Ph.D. Stanford University, is an assistant professor.
Leave: Tetteh A. Kofi, assistant professor, is on leave, Sept. 1976–77.
Honors: Walter P. Falcon, director, Food Research Institute, was awarded the Helen Cherington Farnsworth Professorship in international agricultural policy; **Roger W. Gray,** professor, was awarded the Holbrook Working Professorship in commodity price studies.

Texas A&M University

Appointments: Richard Edwards, formerly at the University of Georgia, is an economist in agribusiness; **Bruce Gardner,** former senior staff economist, President's Council of Economic Advisors, is a professor; **Ray Owensby,** formerly with Texas Transportation Institute, is an extension economist in marketing.

U.S. Department of Agriculture

Appointment: Linley Juers is with the Inputs and Finance Program, National Economic Analysis Division, ERS.
Retirement: Arthur J. Walrath, former adjunct professor and agricultural economist, Economic Development Division, ERS, Virginia Polytechnic Institute and State University.

Washington State University

Appointments: Richard Dunford, formerly with the University of Wisconsin, and **Ronald Mittelhammer** are assistant professors.

University of Wisconsin—Madison

Appointment: Marvin B. Johnson, Ph.D. Syracuse University, is an assistant professor of public finance.
Honor: Frank Groves received the 1976 Cooperative Builder Award from the Wisconsin Federation of Cooperatives.

University of Wyoming

Appointment: Ed Bradley, Ph.D. candidate, Pennsylvania State University, is a research associate in resource economics.

Other Appointments

Mark J. Erlandson, M.S. Oregon State University, is with the Oregon State Department of Economic Development, Portland.
David A. G. Green, University College of Wales, is on sabbatical leave as professor of agricultural economics and head of the Rural Development Department, Bunda College of Agriculture, University of Malawi, Lilongwe.
Edward E. Ives, Ph.D. Oregon State University, is with the Governor's Energy Advisory Council, Austin, Texas.
Marshal Khan, Ph.D. Stanford University, is a research fellow, Economic Development Institute, University of Nigeria, Enugu.
Larry S. Robbins, M.S. University of Arkansas, is self-employed in livestock and other operations in the Northwest Arkansas area.
Thomas E. Snider is vice-president of the Charlotte Branch, Federal Reserve Bank of Richmond, North Carolina.
Harold B. Williams, M.S. University of Arkansas, is a county extension agent—agriculture, Arkansas Cooperative Extension Service, Hamburg.
Lawrence Witt received a Meritorious Honor Award for his work in the U.S. Department of State.

Obituaries

Wendell C. Binkley

Wendell C. Binkley served the University of Kentucky in the Department of Agricultural Economics from 1946 to his death on 4 December 1976.

Binkley received a B.S. in agriculture with "High Distinction" from the University of Kentucky in 1939 and an M.S. in agriculture, with a major in agricultural economics, in 1942. His doctoral work in economics was done at Vanderbilt University, 1952–53. In the areas that his professional interests centered around—cooperative marketing, agribusiness management, and youth education, he received recognition at the state, national, and international levels.

Perhaps the most rewarding to Binkley was his work with the youth of the Commonwealth of Kentucky. He developed the Kentucky Youth Seminar for high school juniors for the purpose of learning about the American private enterprise system. Several hundred Kentucky students participate annually in this nationally recognized program. State winners have made an enviable record in national competition and thus achieved recognition for themselves, Binkley, and the University.

In 1964 and 1968–69, he served as a consultant with the Ford Foundation in India. He helped develop the Vaikunth Mehta National Institute of Cooperative Management at Poona, India, which engages in management research, training, and consulting. As a member of the Delhi-based Ford Foundation's Intensive Agricultural Development Program team, he worked with cooperatives and government officials in utilizing the "package" approach to improve agricultural production and marketing.

Binkley authored numerous publications in agricultural marketing. In addition, he was a member of the Youth Education Consulting Committee of the American Institute of Cooperation and the Social Sciences Advisory Committee of the Cooperative Foundation in Chicago, Illinois, as well as a member of Alpha Zeta and Gamma Sigma Delta—agricultural honorary societies, Block and Bridle, U.K. Agribusiness Clubs, and the Methodist Church.

He is survived by his wife, Byrd Binkley, a daughter, Mrs. Lewis B. Henry, and a son, Thomas K. Binkley.

Members of the Department of Agricultural Economics, as well as a host of coworkers and friends, will miss this enthusiastic, dynamic, and compassionate colleague.

Newton Mack Penny

Newton Mack Penny, professor emeritus, University of Georgia, died on 28 January 1977 at the age of 67. Penny was born at Lakeland, Georgia, in 1909. He received his B.S.A. (1933) in agricultural economics from the University of Georgia and his M.S. (1941) and Ph.D. (1950) in agricultural economics from Cornell University.

In his early career, Penny was active in marketing research, especially in the field of dairy products and peanuts. He also contributed leadership and direction to the establishment and operation of regional research in the South. In 1957 Penny became the head of the Department of Agricultural Economics of the Georgia Experiment Station, holding this position until his retirement in August 1971. Under his guidance and encouragement, the Department grew numerically, but more importantly, it also increased in stature and influence throughout the region and nation.

Penny was a loyal and dedicated friend of agriculture and will be missed by his colleagues and friends. He is survived by his wife Evelyn of Griffin, Georgia, four children, and four grandchildren.

the journal of business

published quarterly by The University of Chicago Press

Since 1928 **The Journal of Business** has presented research and scholarship covering the entire range of business topics. Particularly strong in the areas of finance, security markets, and the application of mathematics to business policy and operations, the **Journal** considers as well work on administration and management, banking, marketing, and related fields.

A SURVEY OF AGRICULTURAL ECONOMICS LITERATURE

Volume 1, Traditional Fields of Agricultural Economics, 1940s to 1970s

edited by Lee R. Martin, Professor of Agricultural and Applied Economics, University of Minnesota

This is the first volume of a comprehensive three-volume survey of agricultural economics literature since World War II. This volume contains surveys of the literature in seven broad areas, prepared by ten outstanding authorities.

Subjects and authors of the reviews in Volume I:

Farm Management and Production Economics, 1946-1970. Harald R. Jensen, University of Minnesota.

The Analysis of Productive Efficiency in Agricultural Marketing: Models, Methods, and Progress. Ben C. French, University of California, Davis.

Policy for Commercial Agriculture, 1945-71. George E. Brandow, Pennsylvania State University.

Postwar Policies Relating to Trade in Agricultural Products. D. Gale Johnson, University of Chicago.

Agricultural Price Analysis and Outlook. William G. Tomek and Kenneth L. Robinson, both of Cornell University.

Agricultural Finance and Capital Markets. John R. Brake, Michigan State University, and Emanuel Melichar, Division of Research and Statistics, Board of Governors of the Federal Reserve System, Washington, D.C.

Technical Change in Agriculture. Willis Peterson, University of Minnesota, and Yujiro Hayami, International Rice Research Institute, Manila, Philippines.

Published for the American Agricultural Economics Association by the University of Minnesota Press.

The regular price of Volume 1 is $25.00. Members of the American Agricultural Economics Association may order copies at a special price of $18.00 ($20.00 outside the U.S.), postpaid. This special price offer is available to AAEA members for this year only. Send your order now, using the order form below.

european review of agricultural economics

Managing editor: Jan de Veer
Landbouw-Economisch Instituut
Conradkade 175 · The Hague · Netherlands

ERAE is a quarterly journal designed to serve as a forum for discussions about the development of theoretical and applied agricultural economy research in Europe and for stimulating ideas regarding the economic problems of agriculture in Europe and other parts of the world.
ERAE also promotes discussion on national research use, protection of the environment, marketing of agricultural products and development of rural areas.
ERAE offers original articles as well as full or abstracted articles which have already appeared in national publications and in other languages and, in addition, shorter features (research notes, book reviews, comments, communications) to supplement the main contents and insure that the most recent information available is covered.

A selection of papers published in Volume 2

H. SCHRADER and W. HENRICHSMEYER *(University of Bonn)*
Structural adjustments in agriculture under different price conditions

M. CSEHI and CS. SZÉKELY *(University of Agricultural Policy, Gödöllö, Hungary)*
A computer-based method of examining students in farm management

G. BARBERO *(University of Siena)*
World food problems: A note on the World Food Conference, Rome, 5-16 November 1974

Q. PARIS *(University of California, Davis and University of Calabria, Cosenza)* and T. P. LIANOS *(Athens School of Economics and Science)*
A neoclassical measure of labor exploitation in American agriculture

F. PETRINI and O. BOLIN *(Agricultural College of Sweden)*
Factors influencing the rationalization of Swedish agriculture

S. MITTER *(University of Cambridge)*
Problems of estimating demand parameters in a complete system of equations: An analysis of the demand for food items in the U.K.

Proceedings of the First European Conference of Agricultural Economists at Uppsala, 25-29 August 1975, on the theme 'Future development in agriculture in Europe – prospects for the 1980s'.

O. ARESVIK *(Agricultural College of Norway)*
The role of the International Research Centres in the strategy for agricultural development in less-developed countries

WAERSA/CAB ABSTRACTS ON-LINE

CAB ABSTRACTS, the world's leading database in agriculture and related fields are now available on-line through Lockheed's DIALOG Retrieval Service.

Features of the service include:

—records taken from 8,500 world serials in 37 languages
—450,000 records on tape for 1972 to 1976, increasing by 10,000 monthly
—searches may encompass the whole database or be limited to one or more journals like WAERSA, or to groups of "animal" or "plant" subfiles.

WORLD AGRICULTURAL ECONOMICS AND RURAL SOCIOLOGY ABSTRACTS (WAERSA) is still available both in its normal form and in microform at the same price. In 1976 it included 7,683 fully indexed abstracts on agricultural economics and policy; development and agrarian reform; land use and conservation; rural development; supply, prices, marketing and trade; farm management and production economics; education, extension and research; co-operation; rural sociology.

1977 Subscription Rates: US$110 (1 year) US$210 (2 years)
£24.88 (1 year) £46.00 (2 years) (members of CAB)

Information on Submitting Manuscripts

1. **Cover letter.** In a cover letter to the editor, the author must state (*a*) that the material has not been published, and is not being published or being considered for publication elsewhere; (*b*) that the material in the manuscript, so far as the author knows, does not infringe upon other published material protected by copyright; and (*c*) that he or she is aware that each issue of the *Journal* is copyrighted, that submission of a manuscript to the *Journal* gives the AAEA the right to publish and to copyright the material, and that republication elsewhere at a later date is contingent upon written approval from the *Journal* editor. If the applicability of point (*a*) is unclear, the author should provide an explanation of the publication status of the manuscript.
2. **Author's identification.** In order to protect their anonymity in the review process, authors should avoid identifying themselves in the manuscript. Attach a separate page including the names of the author(s) and appropriate biographical information, as well as the title of the manuscript. Include only the title on the first page of the text.
3. **Typing.** Double-space all material, including footnotes, tables, quotations, and references, on 8½-by-11-inch standard weight white paper with margins on all sides of at least 1¼ inches.
4. **Style.** Follow *A Manual of Style* by the University of Chicago Press as well as previous issues of this *Journal*.
5. **Mathematical notation.** Use only essential mathematical notation; such notation is costly to typeset and may limit the readership. Avoid using the same character for both superscripts and subscripts, using capital letters as superscripts or subscripts, and using overbars, tildes, carets, and other modifications of standard type. Asterisks, primes, and small English letter superscripts are suitable substitutes.
6. **Footnotes.** Number footnotes consecutively throughout the paper, not page by page. Type the footnotes, double-spaced, on a page following the article. The institutional paper number and acknowledgments, if any, should be placed at the beginning of the list of footnotes. Footnotes should be only explanatory and should not be used for citations or for directing the reader to a particular work. This information can be incorporated into the text itself.
7. **References and citations.** Place all references, alphabetized by author, in a list at the end of the paper entitled "References." Only cited works should be included in the reference list. All citations should appear in the text and contain the author's name and page numbers, when necessary. Citations can be inserted parenthetically, e.g., (Doe) or (Doe, p. 5). Specify the date of publication if the same author appears more than once in the reference list, e.g., (Doe 1971, p. 5). If the author's name appears as part of the sentence, a parenthetical reference is unnecessary unless you need to cite page numbers or a date. A style sheet on references and citations is available upon request.
8. **Tables.** Place each table on a separate page; double-space all material; omit vertical rules.
9. **Figures.** Prepare figures on heavy white paper or acetate sheeting using black India ink or paste-up types suitable for black and white reproduction by a photographic process. Typescript is not suitable.
10. **Three copies.** Send the typed original and two carbon copies or photocopies. All copies should be inspected for completeness and quality of reproduction.
11. **Abstract.** Instructions for the preparation of an abstract will be sent when the manuscript is accepted for publication.
12. **Page charge.** All published contributions, with certain specific exemptions, are subject to a charge of $40 per printed page or fraction thereof. Exemptions are granted for book reviews, papers invited by the editor, the presidential address, the fellow's lecture, and those invited addresses and papers receiving explicit written exemption from the AAEA president. If an author has no financial support from an employer or granting agency to cover the charge, an exemption may be granted. Instructions for making payment and for requesting an exemption are provided with galley proofs. If the charge is honored, 100 reprints are provided. An employer cannot request a financial exemption while agreeing to buy reprints.

American Agricultural Economics Association

Fred A. Mangum, North Carolina State University
Philip M. Raup, University of Minnesota
B. F. Stanton, Cornell University

Objective

The AAEA seeks to further the systematic development of knowledge of agricultural economics in order to improve agriculture and agriculture's contribution to the general economy. The activities of the AAEA include:

—publishing the *American Journal of Agricultural Economics;*
—planning and conducting two annual meetings of the membership;
—sponsoring annual awards for outstanding extension programs, distinguished teaching, and outstanding research;
—recognizing outstanding agricultural economists through a fellows program;
—supporting a literature retrieval system in cooperation with the U.S. Department of Agriculture;
—publishing periodically a biographical directory of the AAEA's members;
—supporting an employment registry for agricultural economists in cooperation with the U.S. Department of Labor.

Membership and Subscriptions

Membership in the AAEA is open to individuals having a professional interest in agricultural economics. Dues, payable at the beginning of each calendar year, are as follows: regular members, $25, senior members, $12.50, and junior members, $12.50. Senior membership is open to persons, upon written request, who are sixty-five years of age or older and have retired from active professional work. Junior membership is for students and is limited to three years; students should use application forms available from and signed by the head of the department in which they are studying. Members receive this *Journal*.

The subscription rate for institutions and nonmembers is $35 per year. Individual issues of this *Journal* are $10.00.

Payment of membership dues, correspondence regarding subscriptions, orders for individual copies of the *Journal*, changes in address, or inquiries about the general affairs of the AAEA should be sent to John C. Redman, Secretary-Treasurer, American Agricultural Economics Association, Department of Agricultural Economics, University of Kentucky, Lexington, Kentucky, 40506.

The *American Journal of Agricultural Economics* is published five times a year (February, May, August, November, December) by the American Agricultural Economics Association. Prior to 1968, this *Journal* was the *Journal of Farm Economics.*

Printed for the AAEA by Heffernan Press, Inc., Worcester, Massachusetts, USA.

Second class postage paid at Lexington, Kentucky, and additional mailing offices, Pub. No. 019500.

Copyright © 1977 by the American Agricultural Economics Association.

An article, note, or other material appearing in the *American Journal of Agricultural Economics* may not be republished in full or in part without the express written permission of the editor.

Editorial Policy

The purpose of the *Journal* is to provide a forum for creative and scholarly work in agricultural economics. Thus, acceptable manuscripts should have a relationship to the economics of agriculture, natural resources, or rural and community development. Contributions, methodological or applied, in the business, extension, research, and teaching phases of agricultural economics are equally encouraged.

Editorial Communications

All manuscripts and editorial correspondence, except as noted below, should be addressed to the editor, V. James Rhodes, Department of Agricultural Economics, Mumford Hall, University of Missouri, Columbia MO 65201.

Communications concerning book reviews and books submitted for announcement in the *Journal* should be sent to the book review editor, Herbert H. Stoevener, Department of Agricultural Economics, Oregon State University, Corvallis OR 97331.

An Equilibrium Analysis of U.S. Sugar Policy

Gordon Gemmill

U.S. sugar policy is examined in an international context by means of a spatial equilibrium model of the world sugar economy in which various trade barriers are imposed. The Sugar Act, which expired in 1974, is found to have had only a minor influence on U.S. price and a small net cost to the nation. International free trade would cause greater adjustment in the European Economic Community than in the United States. Discrimination in trade against Cuba continues to impose large costs on that country. A cartel of cane-sugar exporters would be very unlikely to succeed.

Key words: cartel, international trade, policy, spatial equilibrium, sugar, United States.

This article is concerned with the costs and benefits of alternative U.S. and international sugar policies, particularly from the U.S. viewpoint. Among the policies considered are the Sugar Program as of 1974, international free trade, unilateral free trade by the United States, and an international cartel of cane-sugar exporters. The repercussions of the U.S. embargo on Cuban sugar and the inefficiency of the international pattern of trade in sugar are also examined. The method of analysis is the simulation of the world sugar economy with a spatial-equilibrium model in which various trade barriers are imposed. Prices and quantities are calculated for a series of resulting long-run equilibria, which may be considered as average positions in a fluctuating market. The article concentrates particularly on the U.S. Sugar Program, which ended in 1974, as similar legislation to protect domestic producers continues to be discussed and the results of this research indicate that the program had a smaller impact than had previously been recognized.

The Sugar Act, as amended in 1971, had the following features (see Johnson, p. 10, for a fuller presentation): (*a*) a price objective, related to the parity index of agricultural input prices and the wholesale price index;[1] (*b*) quotas on domestic production and on both raw and refined imports designed to be consistent with the price objective; (*c*) a tariff on imports of 0.625¢ per raw pound; (*d*) a tax at wholesale on all sugar of 0.50¢ per raw pound; (*e*) small payments to producers conditional upon their keeping within their quotas; and (*f*) the setting of minimum wages to be paid to workers in the sugar industry.

From the viewpoint of avoiding low domestic prices, the Act was undoubtedly successful (figure 1). Quotas were adjusted so that the United States was not subject to the price troughs of 1955, 1961, or 1966 that occurred in the largely unregulated world free market. On the other hand, any significant decline in the rate of expansion of world production, such as occurred in 1950–51, 1957, 1963, and 1974, resulted in increased prices in both the world and U.S. markets. Price behavior in the United States was therefore similar to that in the free market but truncated at the lower end.

World sugar production in 1974 was 78.7 million tons of which only 21.7 million tons were traded.[2] The free market accounted for 10.7 million tons, U.S. imports for 5.2 million tons, and other bilateral arrangements for the

Gordon Gemmill is a lecturer in economics, Wye College, London University.

The author is grateful for financial assistance from Michigan State University, the U.S. Department of Agriculture, and the U.S. Department of the Treasury. Helpful comments from two anonymous reviewers are acknowledged.

[1] Stated formally, it is

$$POB_t = \frac{PSUG_o\,(PARINDEX + WPI)_t}{(PARINDEX + WPI)_o},$$

where *POB* is the price objective, *PSUG* is the price of sugar, *PARINDEX* is the parity index of agricultural input prices (1967 = 100), *WPI* is the wholesale price index (1967 = 100), *o* denotes 1 Sept. 1970 to 31 Aug. 1971, and *t* denotes current time period.

[2] All tons are metric and in raw value (92 parts raw equals 100 parts refined). The data came from the International Sugar Organisation.

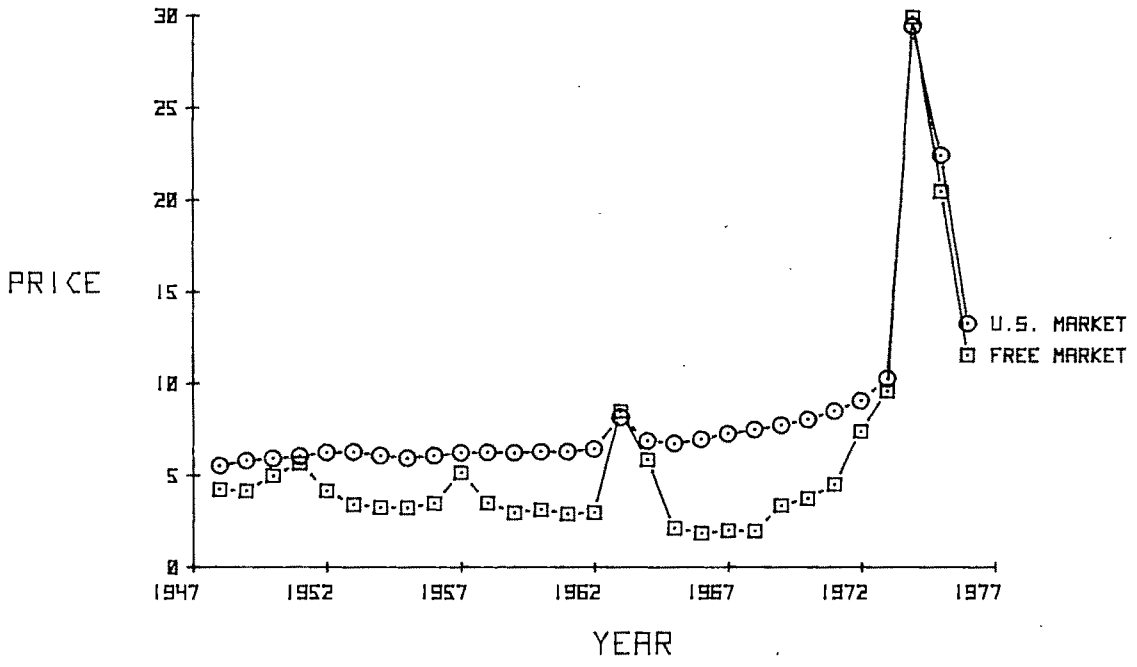

Figure 1. Prices in U.S. and free markets, 1948–76 (U.S. cents per raw pound)

remaining 5.8 million tons. When the Sugar Program ended in January 1975, the United States became the largest importer operating in the free market and, as shall be seen, the long-run price on that market may be expected to be higher as a consequence.

Analytic Framework

This research combines and extends the approaches of Johnson and Bates. Johnson uses a range of premia (that is, the difference between the U.S. protected and estimated unprotected prices) in order to judge the likely cost of the Sugar Program. At premia of 1.5¢, 2.0¢, and 2.5¢ per raw pound in 1972, the cost to consumers and taxpayers is estimated to be $502, $616, and $730 million, respectively. Assuming relatively inelastic domestic supply, the benefit of the program to U.S. farmers is estimated to be $101 million at most. Johnson estimates transfers to quota-holding foreign countries to be about $198 million. He concludes that the apparatus of the program should be removed, as it was clearly inefficient in terms of resource allocation, but suggests that it might possibly be replaced by a system of deficiency payments in order to avoid depressed prices. Earlier work along similar lines by Snape reached similar conclusions concerning the inefficiency of the protection and taxation of sugar for several wealthy nations, including the United States.

The work of Bates (also reported by Bates and Schmitz) is mainly concerned with the inefficiencies created by the special arrangements under which sugar was traded, such as the Sugar Act, and particularly with the additional inefficiency resulting from the cessation of trade by the United States with Cuba in 1960. The approach uses spatial equilibrium for a thirty-three-region world together with linear supply and demand functions. Two equilibria were computed, one with international free trade and the other with free trade except for the exclusion of Cuban sugar from the United States. Compared with actual 1959 prices, competitive free-trade prices were found to be substantially different, that of the United States being 19% lower. However, the cost of excluding Cuba from the U.S. market was an increase of only 2% in the U.S. price.

Both of these studies have distinct limitations that the present work has attempted to overcome. Johnson makes informed guesses concerning supply and demand, whereas great attention is directed in the present research to estimating supply and demand functions. Bates estimates simple linear supply functions, whereas more complicated forms, in some cases implying irreversible responses,

are used in this work. Bates takes no account of the controls on production and trade in the United States and other markets. The current work computes equilibria in which the whole set of existing trade distortions including tariffs, variable levies, and quotas is imbedded. Despite the pioneering work of Bawden, very few models have specifically incorporated the distortions on international trade. An exception is the work of Zusman, Melamed, and Katzir on oranges in Europe. The extreme case of free trade may be of interest, but it has very little relevance to policy making. Beginning with the case of fully distorted trade, the serial relaxation of the distortions in this model allows the costs and benefits of protection to be carefully evaluated.

In the model the world was divided into seventy-five regions, each based on a single port. Sixty-eight of the regions have supply functions, and all seventy-five have demand functions. The United States was divided into five regions based on the ports of New Orleans, New York, San Francisco, Honolulu, and San Juan. Because of the concentration in this article on U.S. policy, the five regions were further disaggregated into eight (four beet-producing, two mainland cane, Hawaii, and Puerto Rico) in presenting the results. The supply and demand equations for the whole model are too numerous to be listed here and may be reviewed in Gemmill (chaps. 3 through 7).

The model is quite simple and may be stated as follows. Let there be m producing and n consuming regions, subscript i always denoting a producing region and subscript j a consuming region, then Q_j^D is the quantity of raw sugar demanded in the jth region, Q_i^S is the quantity of raw sugar supplied by the ith region, P is the wholesale price of raw sugar, q_{ij} is the shipment of raw sugar from region i to region j, and G_{ij} the cost of shipment, including trade barriers, from region i to region j.

Demand relations for each consuming region are

$$(1) \quad Q_j^D = Q_j^D(P_j) \text{ for } j = 1, 2, \ldots, n.$$

Supply relations for each producing region are

$$(2) \quad Q_i^S = Q_i^S(P_i) \text{ for } i = 1, 2, \ldots, m.$$

Total quantity demanded in equilibrium equals the sum of all shipments, or

$$(3) \quad Q_j^D = \sum_i q_{ij} \text{ for } j = 1, 2, \ldots, n.$$

Total quantity supplied in equilibrium equals the sum of all shipments, or

$$(4) \quad Q_i^S = \sum_j q_{ij} \text{ for } i = 1, 2, \ldots, m.$$

Shipments cannot be negative, or

$$(5) \quad q_{ij} \geq 0 \text{ for } i = 1, 2, \ldots, m \text{ and } j = 1, 2, \ldots, n.$$

At equilibrium the prices in any two regions cannot differ by more than the transfer cost per unit, or

$$(6) \quad P_j - G_{ij} - P_i \leq 0 \text{ for } i = 1, 2, \ldots, m \text{ and } j = 1, 2, \ldots, n.$$

At equilibrium the sum of transfer expenditures is exactly balanced by the sum of price differences times quantities shipped for all regions, or

$$(7) \quad \sum_i \sum_j \{(P_j - G_{ij} - P_i)q_{ij}\} = 0.$$

The solution gives quantities produced and consumed in each region as well as intersectoral trade and the domestic price in each region. All prices are converted to the wholesale level for solution, and all known taxes on consumption are incorporated into the G_{ij} term of equations (6) and (7). All prices are in 1974 dollars, and technology, population, and income are fixed at estimated 1974 levels. Solution is by means of an adaptation of the King and Ho reactive programming algorithm.

Five policy experiments of particular interest to the United States were conducted: (*a*) Sugar Act as of 1974 in operation and all other countries having their 1974 policies; (*b*) free (i.e., competitive) trade by all countries, except for the imposition of taxes on consumption; (*c*) unilateral free trade by the United States, including the importation of Cuban sugar, all other countries continuing their previous policies; (*d*) free trade by the United States as in (*c*), but Cuban sugar not allowed entry to the United States (essentially the current situation); and (*e*) cartel of cane-sugar exporters imposes a 10¢ per pound export tax on raw sugar, otherwise policies as in 1974.

duction and prices for 1974 are included on the left-hand side of the table, but valid comparisons may only be made between the computed, long-run equilibria. Comparisons with the actual situation in 1974 are particularly misleading, as in that year the market was far from a long-run equilibrium—production was at its lowest for twelve years and prices were at their highest recorded level.

Policy (*a*) is that which existed in 1974 and is used as a benchmark for comparisons. In the long run a switch to free trade by all nations, as exemplified by policy (*b*), implies a 13% decline in U.S. sugar production. A switch to free trade by the United States alone (policy (*c*)) implies a 24% decline in U.S. production, but if Cuban sugar is excluded (policy (*d*)) the decline is limited to 17%. This 17% decline is what is therefore predicted to occur under current policy. A cartel of cane-sugar exporters imposing a 10¢ export tax (policy (*e*)) would, conversely, result in an expansion of 23% in U.S. production.

These outcomes reflect the price equilibria between domestic import demand and foreign export supply under different policies. The key to understanding them lies in the underlying supply functions. It would be usual to assume that foreign export supply is highly price elastic and that domestic U.S. supply is inelastic. Contrary to this, the weighted average elasticities for the United States, which were estimated in the original research and incorporated here, are 1.74 for beet and 1.57 for cane, while export supply to the United States is less elastic. As a result, when the United States ends protection, the world free market price is raised by more than the U.S. price is lowered. For example, a switch from protection under the Sugar Act (policy (*a*)) to current policy (*d*) raises the free market price by 2.49¢ (32%) and reduces U.S. price by 1.06¢ (9%). With the United States buying there, prices of the order of 2¢ per pound, which occurred in the free market in 1966–68, are unlikely to be repeated.

The geographical distribution of U.S. contraction or expansion depends on the elasticities of supply in the different regions. Most of the adjustment occurs in beet regions III and IV (which include the Pacific Northwest, Utah, and California) and in Florida. For the two beet regions, the contraction of 31% under the most extreme circumstances (i.e., under U.S. unilateral free trade) is less than that which actually occurred in 1974. For Florida, under such circumstances the computed contraction of 48% may seem unrealistically large, but it refers to the long run in which all inputs (including capital in cane and mills) are vari-

able. No attempt is made to adjust for asset fixity in the U.S. cane industry. Under current policy, (*d*), the discrimination against Cuban sugar reduces the contractions in the responsive regions to 21% for beet regions III and IV and 36% for Florida.

The repercussions of alternative policies on the major sugar producers of the world are remarkably muted (table 2). World production is not significantly altered by any policy except a 10¢ tax on exports by all cane-sugar exporters (policy (*e*)), following which a decline of 4% occurs relative to the 1974 set of policies (policy (*a*)). The ease of adjustment of beet-sugar production throughout the world dampens any tendency to greater changes in total output. Supplies from Brazil and Cuba are hardly affected by the liberalization of trade in the model. The USSR is also unresponsive, except under the imposition of a cartel that would lead to a 16% increase in Soviet production. The European Economic Community (EEC) would face an estimated 23% contraction under free trade, as compared with the 13% contraction in the United States under similar circumstances. This reflects the very high degree of current protection in the EEC.

The Direction of U.S. Trade

In 1974 net imports were 50% of U.S. consumption as compared with 45% in 1973. The simulated equilibrium with 1974 policy (see policy (*a*) in table 3) fixes imports by quota at 44% of consumption. International free trade (policy (*b*)) is then estimated to result in Cuba exporting 5.8 million tons to the United States. This figure is inflated by the peculiar equilibrium in which the United States itself exports 1.4 million tons, but undoubtedly Cuba is the natural supplier for the U.S. market. Unilateral free trade by the United States (policy (*c*)) would also be of immense benefit to Cuba, with 3 million tons now coming into the United States from there and another 3.2 million tons being imported from elsewhere. U.S. free trade with discrimination against Cuba, the 1976 situation (policy (*d*)), produces a widely dispersed pattern of trade. Brazil, the Dominican Republic, Mexico, and Peru now become important. Curiously, and perhaps unrealistically since it produces refined sugar, Poland exports 0.4 million tons to the United States in this case. The Philippines, Australia, China-Taiwan, and South Africa are suppliers for which the United States is not a natural market, and hence they do not appear except under the old Sugar Act with its quotas (policy (*a*)). Under the three regimes of freer trade (policies (*b*), (*c*), and (*d*)), imports are 52%, 58%, and 54% of consumption, respectively, as compared with the 44% under the 1974 policy. A 10¢ tax on exports by the cane-sugar exporters (policy (*e*)), equivalent to a sugar cartel, reduces U.S. imports to 32% of consumption. Under this policy Cuba remains an exporter of 1.8 million tons to the United States, but her domestic price is reduced to a mere 2.73¢ per pound (see table 4), and the USSR exports 1.3 million tons to the United States as she is not part of the cartel. U.S. domestic production, as previously noted, is greatly expanded in this case.

The cost to Cuba of the continuing U.S. trade embargo may be assessed from table 4. The value of Cuban sugar production under the Sugar Program of 1974 is estimated in the model to be $924.5 million. Freedom to trade with the United States (policy (*c*)) leads to a gain of $334.5 million or 36% of this value. Given the current policy situation as approximated by policy (*d*), Cuba gains $281.9 million or 29% from renewed access to the U.S. market. At the extreme, universal free trade (policy (*b*)) holds the possibility of a $420.7 million

inefficiency of trade in 1974. Two contributors to this inefficiency are the quotas of the Sugar Act and the embargo on Cuban sugar. The ending of the Sugar Act, but with the embargo continuing as at present, saves $101 million (10%). The ending of the embargo (policy (*c*)) leads to a further saving of $70 million. Transportation costs are important for Cuba because other markets are distant (e.g., USSR and Japan). It is not only necessary to bar Cuban exports to the United States in computing some of the equilibria but also to prevent the "laundering" of Cuban sugar via the Dominican Republic, Mexico, and Colombia.

These results reinforce one's qualitative expectation that the pattern of trade in sugar is economically inefficient. The gains to Cuba from access to the U.S. market are large, mainly stemming from the large transportation costs that she now has to bear. The effect on U.S. price of excluding Cuban sugar is estimated to be an additional 0.5¢ per pound (table 2), equivalent to 5%, whereas in Cuba the effect is a loss of 2.04¢ per pound (table 4), equivalent to 22%. These results may be compared with those of Bates, who estimates a 2% premium in U.S. price for 1959 if Cuban sugar were excluded, but less than a 1% decline in the Cuban price. The present results suggest that the U.S. ability to "hurt" Cuba is much larger than previously recognized.

Welfare and Policy Implications

Domestic and International Repercussions of U.S. Policy

Thus far only production and price effects have been considered. To obtain a more general indication of welfare, changes in economic surplus are measured, assuming the income effect of price changes to be zero. The limitations of such a procedure are well known but are not considered so extreme as to invalidate this exercise entirely (see Currie, Murphy, and Schmitz for a review).

The world was divided into four segments, each of which is affected differently by U.S. policy. There are the United States, countries that held quotas under the Sugar Act, Cuba, and the rest of the world. The single change in policy to be considered is the switch to nondiscriminatory free trade by the United States (policy (*c*)) from the 1974 protection under the Sugar Act (policy (*a*)).

Table 6 summarizes the impact of no U.S. protection on these groups in terms of producers' and consumers' surplus and government revenue. From the viewpoint of the United States, the Sugar Act is estimated to have had a net cost of only $33 million, comprising costs to consumers of $330 million, gains to producers of $230 million, and government tariff revenue of $67 million. Johnson, by contrast, estimates a median consumer cost of $616 million and a transfer to producers of only $100 million, leading to a net domestic cost of $516 million. Johnson's figures include the effect of the 0.50¢ per pound wholesale tax on sugar and conditional payments to producers (of less than 1.5¢ per pound), which are minor additional influences.

The present estimates suggest that Johnson greatly overstates the net cost of U.S. protection, mainly because he assumes a less elastic supply and a more elastic demand than are estimated for the present model. Considering the viewpoint of quota holders, the net value of their premium from quotas for the U.S. market under the Sugar Act is estimated to be $177 million, which they lose under U.S. free trade. The gross premium of $377 million is adjusted by changes in producers' and consumers' surplus due to alterations in the terms of trade to reach the net figure. However, Cuba gains $314 million under the assumption of its sugar entering the United States, mainly due to the saving of transportation costs already discussed. If Cuba's sugar is kept out, as at present, part of the $177 million loss of quota holders will be offset. Finally, the rest of the world loses under U.S. free trade by $191 million relative to the situation under the Sugar Act. This results from the rise in free market price, causing greater losses to con-

Table 6. Welfare Impact of U.S. Free Trade

Total	1,213	−791	−444	−21

[a] Figures in parentheses are the median estimates of Johnson.

sumers than gains to producers. The analysis leads to the conclusion that the "public interest" in the Sugar Act should be judged on the desirability of (*a*) taking $330 million of income from consumers to bolster the income of producers in the United States by $230 million and of government by $67 million, (b) avoiding low prices in the interest of producers, and (*c*) distorting the pattern of trade in favor of "certain friendly countries."

Protection Reconsidered

(This subject is discussed in Jesse et al.) These results may be set in the broader context of a theory of protection. The objectives of protection are really twofold: to maintain a level of self-sufficiency in the long run above the freemarket level, and to avoid extremes of high and low prices that occur in the short run. The effectiveness of alternative instruments in achieving these two objectives is considered.

The first or long-run objective requires the limitation of imports either directly via quotas, tariffs, or variable levies or indirectly via subsidies to domestic producers. Subsidies do not lead to an increase in the price of sugar and hence may be shown to be economically more efficient than other policies. To give protection equivalent to that of the Sugar Act would require a subsidy of 4.13¢ per pound, raising the U.S. price to 11.89¢ and lowering the free market price to 7.76¢. The cost in direct taxation would be $545 million, too large and visible a sum to be easily accepted. Of the other import-limiting policies, variable levies and quotas have the advantage, as compared with tariffs, of achieving a greater smoothing of short-run price. Both perfectly avoid the occurrence of low prices and do not exacerbate high prices. By contrast a tariff, whether specific or *ad valorem*, is less flexible in avoiding low prices (hence its demise as the major instrument for U.S. sugar policy in 1934) and merely increases high prices.

The second or short-run objective of smoothing price has already been introduced with reference to import-limiting policies. Quotas or variable levies, which passed the test of avoiding low prices, do not protect consumers from high prices. Three policies that could achieve such protection are buffer stocks, consumer subsidies, and pooled pricing. All such policies of domestic stabilization also destabilize the international market, limiting their own effectiveness. The first alternative, buffer stocks, requires that the U.S. market be separated from the free market by a quota system so that the release of sugar can have an impact in the United States. Given a price elasticity of the order of −0.03, a 1% change in quantity would induce a change in price of 33%; hence, the stocks need not be very large in relation to total consumption. The second alternative, consumer subsidies, if directly applied are not likely to be politically acceptable. However, such subsidization could be achieved through the imposition of negative variable levies or bonuses to quota suppliers. During the period of high prices from 1974 to 1975, such negative variable levies were used quite effectively by the EEC. The third alternative, pooled pricing, was used prior to 1973 by the United States in relation to oil. The consumer pays the weighted average of a regulated domestic and a fluctuating international price. It could be used in conjunction with quotas. Somewhat similarly, pooled pricing could be effected under a policy of producer subsidies by making such subsidies negative (i.e., taxes) to the amount by which free market prices exceed some price objective.

This inventory of policies indicates that two instruments are needed to achieve two objectives, just as the work of Tinbergen suggests. Producer subsidies, quotas, or variable levies, as long-run instruments, need to be combined with consumer subsidies, buffer stocks, or pooled pricing as short-run instruments. A third objective, that of maximizing U.S. revenue, may now be used to further sort the instruments. Under the Sugar Act, a potential revenue of $377 million passed to quota-holding foreigners rather than to the U.S. Treasury (table 5). Variable levies or auctioned quotas would capture these transfer payments for the United States, thus achieving protection at the level of the Sugar Act with a Pareto-better situation for the United States.

Finally, any review of policy must include the probable impact of a new International Sugar Agreement. The U.S. interest in such an agreement would be directed to the short-run smoothing of price. The interest of the major exporting nations would be in smoothing the short-run and raising the long-run price, while assuring their access to the U.S. market. The limited possibility of raising long-run price by forming a cartel has already been demonstrated, and an international meeting that includes both exporters and importers is not likely to agree to any but the smallest rise in long-run price. Hence, the role of an International Sugar Agreement is limited to the smoothing of short-run price. The only policy that might be mutually agreeable and have an impact is a commitment to free trade by all parties. The exporters would gain assured access to the U.S. market, avoiding low prices. The United States would gain by the avoidance of high prices if such a commitment reduced uncertainty and hence smoothed the cyclical supply of international sugar.

Summary and Conclusions

This article has empirically examined the long-run effects of a number of U.S. and international sugar policies and has discussed the implications for short-run stabilization of some further alternatives. Currently, the United States pursues free trade but with a continuing ban on Cuban sugar.[3] Under these circumstances, price and output are estimated to be in the long run 9% and 17% lower, respectively, than under the protection afforded until 1975 by the Sugar Act. This impact is less than might have been expected due to the large effect of the United States on its terms of trade. The cost to U.S. consumers of not having Cuban sugar is estimated to be 0.5¢ per pound or $97 million, while the repercussion for Cuba is a loss of 2.04¢ per pound or $272 million.

The ease of substitution of beet sugar for cane sugar ensures a remarkably constant world output of sugar under all policies. Even if cane-sugar exporters imposed a 10¢ per pound tax on exports, world production was estimated to decline by only 4%. However, the pattern of trade in sugar is inefficient, and free trade would save an estimated $139 million (16%) in transportation costs relative to current policies.

The net cost to the United States of the Sugar Act, as compared with free trade by the United States, was estimated to be only $33 million per annum. Whether such protection is in the public interest hinges upon the desirability of transferring income from consumers to producers rather than upon the net costs to the United States. It is possible to devise policies based on variable levies or auctioned quotas that give protection equivalent to that of the Act but that capture the $377 million that was previously transferred to foreign suppliers. Assuming the objectives of protection are to raise the long-run and to smooth the short-run prices, two kinds of instruments are needed, one to limit imports and the other to smooth prices. Any short-run stabilization of the U.S. market would tend to destabilize the world free market, thus complicating its own task. The simplest stabilization policy might be international free trade, which could be negotiated under the auspices of a new International Sugar Agreement.

[*Received October 1976; revision accepted April 1977.*]

[3] Except for a small tariff of 0.625¢ per pound, raised to 1.875¢ in September 1976.

Devaluation, Foreign Trade Controls, and Domestic Wheat Prices

Paul R. Johnson, Thomas Grennes, and Marie Thursby

The 1970s have seen sharp fluctuations in grain prices. Several plausible explanations for the unusual severity of these ups and downs have been advanced, including devaluation of the dollar for the upswing in 1972–74. U.S. wheat prices for the year of highest prices, 1973–74, are examined. A trade model that distinguishes wheat by country of origin is used to analyze various events in that year. It is concluded that insulating trade policies by wheat exporters and importers had the largest impact on U.S. wheat prices.

Key words: devaluation, land prices, trade controls, transport costs, wheat prices.

An insightful paper by Schuh called attention to the relationship between currency markets and agricultural product and factor markets.[1] He argues that overvaluation of the dollar prior to 1971 depressed the prices of U.S. agricultural products and advances the hypothesis that the subsequent devaluation of the dollar was responsible for an important part of the increase in agricultural prices in 1973–74.[2] This article is an attempt to test that hypothesis by considering the exchange rate and other explanatory variables that should also affect agricultural prices and compare their relative importance. The variables selected from orthodox trade theory are tariffs, export taxes, and transport costs.

The evidence fails to support the hypothesis that devaluation had a larger effect on prices than any of the other variables taken separately. This conclusion stems largely from looking at a particular market—U.S. wheat exports. In value terms, wheat is the most important agricultural product exported by the United States. Since the export markets for U.S. agricultural products have been highly volatile since 1970, data for this period should be helpful in identifying sources of price changes. We concentrate on the substantial price increase in the crop year 1973–74 when wheat prices exceeded $6 per bushel ($220 per metric ton). Specifically, how much of the observed increase in the domestic price was attributable to dollar devaluation and how much to tariff policy of the European Economic Community (EEC), trade controls by Canada, Australia, and Japan, and policy-distorted ocean freight rates?

Theoretical considerations would lead one to expect that dollar devaluation, tariff reductions by the EEC and Japan, and export restrictions by Canada and Australia would all shift demand toward U.S. wheat and raise its price in the United States. Higher transport costs from the United States to its major markets would lower the U.S. wheat price. In fact, the above is an accurate description of the actual policies that were followed by various nations in 1973–74.

Paul R. Johnson is a professor and Thomas Grennes is an assistant professor, Department of Economics and Business, North Carolina State University, and Marie Thursby is an assistant professor of economics, Syracuse University.

Paper 5189 of the Journal Series of the North Carolina Agricultural Experiment Station, Raleigh. The authors would like to thank Bruce Gardner, D. G. Johnson, and two *Journal* referees for helpful comments.

[1] Interest in this relationship is not new, having been discussed by Adam Smith in his chapters "Of the Rent of Land" and "Of Bounties." He considers the effects of devaluation (pp. 194–99) and export subsidies (book IV, chap. V), although his discussion is marred by emphasizing "the great and essential difference which nature has established between corn and almost every other sort of goods" (p. 482). In addition, the effect of the 1933 devaluation of the dollar on prices of export crops was investigated in a series of papers by Davis, Rowe, and Richards published by the Brookings Institution and by Timoshenko at the Food Research Institute. These studies are summarized by Benedict, who concludes that the price effect of the devaluation "was small or negligible for wheat" (pp. 298–99).

[2] Schuh states: "If this interpretation is correct, an important share of the rise in agricultural prices in mid-1975 is a result of monetary phenomena which induced an export boom in an economy that was already responding to expansive monetary policies, and in the case of agriculture, increased the foreign demand for U.S. output . . ." (p. 12).

Explanatory Variables

Accurate estimation of the degree of overvaluation of a currency is difficult. When rates were fixed in the 1960s, Floyd (1965b) estimated the overvaluation of the dollar at 10%.[3] When the dollar was allowed to float in 1971, the dollar depreciated by approximately 10%, verifying to a large extent the Floyd estimate.[4] In early 1973 the dollar was devalued again by an average of 10%, but there was a partial reversal by the end of the year. This analysis employs a 10% devaluation of the dollar against all other countries.[5]

The EEC applies a variable levy to wheat imports and automatically insulates the domestic price from changes in foreign prices. In 1972–73 world prices, although high by historical standards, were low relative to the EC threshold price, and the levy averaged $50 per ton. In 1973–74 world prices continued to rise, and the levy fell to zero for most of the year. This encouragement to EC wheat imports was supplemented by an EC ban on exports to certain regions of the world and taxing exports to other regions. By the middle of 1977, the levy was approximately 100% of the import price.[6]

Japan engages in state trading, and its Food Agency is the monopoly importer for wheat. Prior to 1973, the Agency bought wheat at the world price and sold to Japanese millers at a higher price, the difference constituting an effective tariff. In 1973–74 the Agency insulated Japanese consumers from the increase in world prices by selling domestically at a loss. They continued this import subsidy until it was phased out in early 1976.

After the United States, Canada and Australia are the most important wheat exporters. They both employ state trading agencies in the foreign sales of their wheat. In 1973–74 both agencies levied effective export taxes by selling to domestic millers at far below the export price. The Canadian Wheat Board's average export price was $6.00 (Canadian) per bushel, while the price to domestic millers was $3.25. The Australian Wheat Board's export price was 53% higher than its domestic price.

The U.S. government has pursued several policies that have raised shipping costs paid by exporters of U.S. wheat (see Bennathan and Walters, Jantscher).[7] These include the promotion of shipping cartels or conferences that collude to set monopoly freight rates and cargo preference laws that require exporters to use higher cost U.S. ships when cheaper transport is available. An increase in shipping cost lowers the price received by U.S. sellers relative to the price paid by foreign importers. In this respect, it acts as an export tax or a currency revaluation. The ongoing high cost shipping policy depressed the U.S. wheat price in the same way as the overvalued dollar did prior to the 1971 devaluation.[8] Shipping policy did not change in 1973–74, but retaining the historical policy depressed wheat prices relative to what they otherwise would have been. This shipping policy effect can be measured to determine whether it depressed wheat prices more than devaluation raised them.

In order to calculate the net impact of increased shipping costs, one needs to know what fraction of those costs are attributable to government policy. Reliable estimates of this effect are not readily available, but one study has attempted to measure the effect (Bennathan and Walters). They observe that freight rates for U.S. exports exceeded those for U.S. imports by 32%, and they attribute this differential to the cartel.[9]

World Trade Model

In some recent work (Johnson et al.) for a somewhat different purpose, a trade model for grains was formulated that allows isolation of

[3] Houthakker invokes the purchasing power parity theory to obtain an alternative estimate of the degree of overvaluation of the dollar.

[4] This depreciation is taken from the *Economic Report of the President* (Council of Economic Advisers, p. 222). It is measured by the Morgan Guaranty trade weighted index.

[5] The actual average annual rates were zero for Canada and Argentina, 5% for Japan, and 13% for Australia (International Monetary Fund). An approximation was used to avoid specifying an index for the EEC exchange rates. The effect of devaluation with respect to the EEC is reduced by an increase in the variable levy.

[6] The weekly *News* of the USDA reported on 11 May 1977 a levy of $128 per ton when the import price for U.S. no. 2 hard winter wheat was $118.

[7] U.S. shipping policy is also held responsible for raising ocean freight rates by President Ford's Task Group on Antitrust Immunities in its January 1977 report (*The News and Observer*).

[8] American colonial farmers protested that English cargo preference laws depressed the prices of their products. The Navigation Acts required the use of British ships for all trade between England and the colonies, and some colonists complained that this increased transport costs and depressed the price of tobacco that they received (see Rothbard).

[9] The shipping portion of the current five-year U.S.-USSR grain agreement also has the effect of depressing the U.S. price. The agreement specifies a range of exports and a negotiable price with the condition that a certain fraction be carried in high-cost U.S. ships. The shipping condition lowers the Soviet demand at a given price, which reduces export volume and price.

the separate effects of the above variables on the U.S. price of wheat. The model distinguishes wheat by its place of origin.[10]

The view of the world that distinguishes goods by place of origin can be contrasted with the view that underlies spatial equilibrium models of trade such as those of Schmitz and Bawden and Rojko, Urban, and Naive. The latter models are concerned with allocating homogeneous wheat among producing and consuming regions. The main difference between spatial models of homogeneous goods and differentiated goods models is that the latter results in more diversified trade flows. This is to be expected on a priori grounds, since spatial models generate a trade pattern that minimizes transport costs. This difference is confirmed in some comparative experiments (Grennes, Johnson, and Thursby). This model, for instance, allows a consuming region to distinguish among U.S., Canadian, and Australian wheat and to simultaneously purchase all, and at different prices. This view is not new, and it underlies other empirical work in international trade that uses market shares or elasticities of substitution (Harberger, Sirhan and Johnson).

Several straightforward observations of real world behavior support the differentiated good view. Japan does, in fact, buy from many sources; Europe simultaneously imports and exports wheat. Wheat differs by quality, for instance, and there may be blending problems that lead buyers to distinguish different wheats. Importers may vary sources because of security or other political considerations. Tastes may differ among countries. Finally, contractual obligations may present fairly long adjustment lags. For many purposes, even in the case of a single good, the view that wheat can be distinguished by place of origin appears to be a useful abstraction.

The current model was developed as a short-run forecasting model that makes the supply side exogenous. This formulation results in three sets of equations: (*a*) a set of demand equations:

$$(1) \quad Q_{ij} = f(P_{ij}^D, Z_i) \text{ for } i, j = 1, \ldots, n,$$

where Q_{ij} is quantity consumed in country i of wheat originating in country j, P_{ij}^D is consumer price in country i of wheat from country j, and Z_i is exogenous demand shifter for country i; (*b*) a set of price relations:

$$(2) \quad P_{ij}^D = rP_j^S + t_{ij},$$

where P_j^S is the supply price of country j and the t_{ij}'s are exogenous shifters that affect the difference between the origin price and the ultimate consumer prices, and r is the exchange rate between i and j; (*c*) a set of market clearing equations:

$$(3) \quad w_{1j}Q_{1j} + w_{2j}Q_{2j} + \ldots + w_{nj}Q_{nj} = S_j \text{ for } j = 1, \ldots, n,$$

where $\sum_i w_{ij} = 1$, w_{ij} is the fraction of the exports of country j that go to country i (including own consumption $w_{ii}Q_{ii}$), and S_j is the (exogenous) supply in j.

If all countries produced, exported, and imported the good in question, there would be n^2 flows, n^2 demand prices, and n supply prices that can be determined from the n^2 equations in equation (1), n^2 equations in equation (2), and the n equations in equation (3). The known exogenous shifters are the Z_i's, the t_{ij}'s, and the S_j's.[11]

The model consists of six endogenous countries and an exogenous rest of the world (ROW). The countries are the United States (U), Canada (C), Australia (A), Argentina (G), European Economic Community (E), and Japan (J). The endogenous variables of the model are thirteen trade flows, thirteen demand prices, and six supply prices (table 1).

The system used is deterministic. The price elasticities in the demand equations were obtained from Armington-type restrictions (see appendix). The basic elasticities used were an elasticity of substitution (common for all pairs of wheat) of -3.0 and domestic demand elasticities for wheat of -0.2 in the United States and Canada, -0.3 in Argentina and Europe, -0.33 in Japan, and -0.1 in Australia. From these basic elasticities, all the direct and cross price elasticities can be derived.

The model shows the effect on all thirty-two endogenous variables of any exogenous disturbance. The major exogenous variables are demand shifters (income, price of substitute grain, imports by ROW), supply shifters (production and inventory changes), and trade

[10] This model draws heavily on the work of Armington and similar models. One of the main differences is its use here for a single good rather than the more aggregate Standard International Trade Classification classes that have been the usual empirical application of these models.

[11] The model used was actually formulated in changes in the variables. Since the levels can always be recaptured, the simpler statements of equations (1) to (3) are used here.

Table 1. Endogenous Variables in Wheat Model

Trade Flows	Demand Prices	Supply Prices

Note: DIJ is the change in exports to I from J; DPIJ is the change in the price in I of J's wheat; DSI is the change in the supply price received by I's producers.

shifters (transport costs, trade controls, exchange rates).

The most important shifters for these purposes are the trade shifters that appear in the price equations. These include all the important policy changes, as well as changes in transport costs. Changes in tariffs, export taxes, and exchange rates can be introduced directly through the price equations to determine their effects on the thirty-two endogenous variables. This article is concerned with the domestic price of wheat in the United States (DPUU) and how it is affected by (*a*) dollar devaluation with respect to Europe and Japan, (*b*) lowering of the EEC variable levy, (*c*) higher export taxes by Canada and Australia, and (*d*) U.S. transport policy, which raises shipping costs between the United States and Japan and Europe. Hypothetical effects of each of these four sets of shifters on the price in the United States are shown in table 2.

One can think of the deterministic equations as

$$XY = A, \tag{4}$$

where X is a matrix of demand parameters, export weights, and any other weights that appear as coefficients on endogenous variables, A is a vector of exogenous shifters, and Y is the solution vector of endogenous variables. The inverse of X that is necessary for the solution can be thought of as a matrix of impact multipliers, where each element in the inverse is a partial derivative of an element in Y with respect to an element in A. Once X^{-1} is known, the direct, *ceteris paribus* impact on any endogenous variable from a policy change appearing in A can be found from the appropriate element in X^{-1}.

Wheat Market, 1973–74

Large price increases make 1973–74 a year of great interest, and many policy changes took place whose impacts may be distinguished with the model described above. The separate effects of the explanatory variables on the domestic price of U.S. wheat are estimated. For the devaluation calculation, the impact multiplier on the internal U.S. price of wheat of a change in the difference between the U.S. supply price and foreign demand prices is needed. From equation (2), this multiplier for a devaluation of the U.S. dollar against Japan is $\partial P_{uu}{}^{D}/\partial t_{Ju}$. This multiplier is the same for any change in t_{Ju} such as a transport cost change, tariff change, etc.

The multiplier is evaluated as follows. The

Table 2. Implications of the Wheat Model

Effect on the Price of U.S. Wheat of Exogenous Changes	DPUU (%)
1. Decrease of EEC tariff by 10% on wheat from	
U.S.	2.5
Canada	0.1
Argentina	−0.2
All imports	2.4
2a. Increase in Canadian export tax by 10% on wheat sent to	
Japan	0.3
Europe	−0.1
All markets	0.2
2b. Increase in Australian export tax by 10% on wheat sent to	
Japan	0.2
2c. Decrease in Japanese tariff by 10% on wheat from	
U.S.	0.7
Canada	−0.2
Australia	−0.1
All imports	0.4
Total: 2a + 2b + 2c	0.8
3. U.S. devalue by 10% against	
Europe	5.1
Japan	1.8
All currencies	6.9
4. Increase of 10% in cost of shipping U.S. wheat to	
Europe	−1.0
Japan	−0.4
All markets	−1.4

exogenous shift vector A has all zero entries except the 10% change in the row represented by the equation for the demand price in Japan for U.S. wheat. This vector is then multiplied by X^{-1} to yield the changes in the endogenous variables (Y) that would result from a *ceteris paribus* dollar devaluation in Japan. The specific change examined in this case is the change in the U.S. internal demand price, so the row in X^{-1} corresponding to that equation is multiplied by A and in this case yields a forecast change in the U.S. internal price of 1.8%. Since a devaluation against all other currencies is postulated as well, the calculation must be repeated for the element in Y that corresponds to the European demand price. That forecast is 5.1%, so the total impact on the U.S. internal price from a 10% devaluation against the yen and some average European currency is approximately 7%.[12]

The effects of the insulating trade policies are calculated in a slightly different fashion, and the results are shown in table 3. Column 1 shows the actual price changes in the various markets.[13] Column 2 shows the prices that would have occurred using actual values of 1973–74 exogenous variables, using the 1972–73 trade policies of the EEC, Canada, Australia, and Japan. If those countries had pursued constant trade policies, the U.S. price would have risen by 19.9% in 1973–74. Column 3 repeats the experiment but introduces the EEC's actual 1973–74 trade policy, which was a substantial tariff decrease. By increasing the demand for imported wheat, this insulating policy raises the wheat price in all other countries, increasing it by nearly ten percentage points in the United States. Column 4 repeats the experiment of column 3 but adds the actual insulating trade policies pursued in 1973–74 by Canada, Australia, and Japan. These policies depressed prices in those countries; by adding to the demand for U.S. wheat, they increased the U.S. price by approximately ten more percentage points to 40.8%. Thus, in 1973–74 the tariff policy of the EEC and the combined trade policies of Canada-Australia-Japan each caused a larger increase in the U.S. wheat price than a uniform 10% devaluation of the dollar against all countries.[14]

Table 3. Changes in Real Wheat Prices 1972–73 to 1973–74 for Different Wheat Policies

Country	Actual Change[a]	Estimates: 1972–73 Policies	Estimates: 1972–73 plus EC Variable Levy Change	Estimates: 1973–74 Policies
		%		
U.S.	59.1	19.9	29.3	40.8
Canada	15.7	27.1	39.7	8.5
Australia	−9.0	3.3	14.7	−28.8
Argentina	[b]	126.0	134.6	136.2
Europe	0	34.9	29.9	33.7
Japan	5.4	43.3	52.5	18.7

[a] The actual prices are internal wholesale price changes. The forecast prices are internal consumption price changes for the country's own wheat.

[b] Argentina embargoed wheat exports in early 1973–74 and controlled prices so rigidly that quoted prices are virtually meaningless.

The last explanatory variable investigated is shipping costs. Shipping costs are similar to devaluation in that they drive a wedge between a domestic supply price and a foreign demand price. Taking the 30% artificial increase in costs introduced above, a shift to a freer market in shipping in 1973–74 would have lowered the U.S. wheat price by 7%. We do not have great confidence in the exact numbers, but the example is instructive.

Dollar devaluation contributed to the rise in the U.S. domestic wheat price in 1973–74.

[12] If other importers were endogenous, this percentage would be different. However, 7% is not necessarily a lower bound for the exchange rate effect. After Japan and the EEC, the major importers of U.S. wheat are Communist countries or developing countries. The next five importers (in order) in 1973–74 were USSR, Korea, India, Brazil, and Algeria. In most Communist countries, currencies are inconvertible, and prices are less important in determining the volume of imports. In nearly all developing countries, the dollar appreciated in 1973–74, which should have decreased the U.S. price.

The Schuh reference that represents the focal point of the devaluation argument is concerned with all agricultural exports, while the text is only concerned with wheat. The argument for the smallness of the devaluation effect thus may not generalize. For wheat, 25% of U.S. exports went to Europe and Japan, for corn, 54% went to the EC and Japan, while for soybeans 65% went to the EC and Japan. (Of soybean oil, hardly any went to the EC and Japan.) The effect on all agriculture might be understated by using the wheat figure, but it must also be remembered that for all U.S. imports the effects run the other way.

The effect in the text is net of any EC variable levy offset. When the "world" price is below the EC internal price (the normal situation), the variable levy provides an automatic (essentially) offset, attenuating any overvaluation effect. See next paragraph in text.

[13] The percentage changes in the actual change columns are computed as arc-type changes; that is, for a variable X in periods 1 and 2, our percentage change is $(X_2 - X_1)/[1/2(X_2 + X_1)]$. The nominal, yearly average Kansas City price per metric ton of wheat changed from $83.04 to $169.39 between the two years. The base of a percentage change is ultimately arbitrary; very large changes can lead to quite different comparisons between different bases.

[14] Josling uses a different technique to measure the effect of changes in government trade policy on agricultural trade in the 1970s. He converts all trade controls into equivalent producer and consumer subsidies, and his results in terms of the importance of insulating trade controls are similar to ours.

This monetary effect should not be ignored, but neither should it be exaggerated. In the same year the insulating policies that restrained wheat exports and encouraged wheat imports had a more powerful effect in raising the U.S. wheat price. For a general discussion of the trade-offs between exchange rate and tariff policies for agricultural exports, see Scobie and Johnson. The U.S. shipping policy that raised transport costs depressed the wheat price at least as much as devaluation raised it.

Overvaluation and Factor Prices in Agriculture

The impact of the policies discussed above is not confined to the price of the product involved. Product prices affect factor prices if factors are specific to the industry. Agricultural land is an obvious example of such a factor, and specialized labor may be a quasi-fixed factor. Lopes and Schuh, in a sequel to the Schuh reference, look at this distributional aspect of international trade distortions and product price changes. They point out that a persistent overvaluation of the dollar, absent any other changes, has the effect of lowering product prices and thus land rents. This has the opposite effect on factor rewards to land from the usual array of income support measures for agriculture.

Floyd (1965a) constructed a six-equation model of the agricultural sector that provides links between product and factor prices. He provides numerical estimates of the parameters of the system, so that for specified policies affecting agricultural output limits can be put on the resulting changes in output price, factor use, and factor prices. Lopes and Schuh use this framework for their qualitative analysis. It should be instructive to carry the analysis further by using the numbers adduced in the first part of the paper to calculate some impacts on factor rewards. Specifically, the relative size of the impact of overvaluation and trade controls on factor prices is measured.

How important were monetary forces in altering agricultural land values in 1973–74? This is a complex question, since land has many alternative uses and this model concentrates on wheat. However, some insights might be gained into the relationship by noting that most product prices (food grains, feed grains, soybeans, and cotton) tended to move together during this period, so that the wheat price might serve as a crude index of all other prices.

Floyd's (1965a) model implies that factor prices rise relative to product prices, the specific limits for the factor price change being 1.5 to 3 times the product price change. This model predicts that a 10% devaluation increases wheat prices by 7%. Thus, the implied increase in land rent resulting from a 10% devaluation is 10.5% to 21%. Is there any evidence that land markets reflected changes of this magnitude?

Table 4 contains land price data for 1970–75 for the real land price (reported values deflated by the CPI), the index of prices received for agricultural products, the ratio of prices received to the index of prices paid, and the consumer price index (CPI). Comparing the land price change in each year with the preceding year's product price change, it can be seen that in no year was the land price change as large as the product price change. A devaluation occurred in 1971, and product prices rose 7% in real terms, while land values increased 4.5%. In 1973–74, there was a devaluation just prior to the beginning of the U.S. crop year. The real price of farm products rose by 19%

Table 4. Real Land Price per Acre of U.S. Farmland and Price Indexes, 1970–75

Year	Real Land Price ($/Acre)	Percentage Change	Index of Prices Received	Price Ratio (1967 = 100)[a]	CPI
1970	167.7		110	96	116.3
1971	167.3	−0.3	112	93	121.3
1972	174.8	4.5	126	100	125.3
1973	185.6	6.2	172	119	133.1
1974	209.9	13.1	184	109	147.7
1975	219.6	4.6	186	103	161.2

[a] Index of prices received divided by index of prices paid.

from the calculations in table 4, while the land price rose by 13.1%. For this year, land prices rose less than the all-product index, less than observed wheat prices, and less than our forecast wheat prices. These crude data do not seem consistent with the view that devaluation had a major effect on land markets.

The above evidence may not be a refutation of Floyd's (1965a) model, since a number of identification problems associated with the table were not considered. Since land is a durable asset, it should be important to distinguish between transitory and permanent changes in land rent. The price of land is the present value of future expected land rent, and an event that raises present rent but not future rent causes only a small increase in the land price. A possible explanation is that the variables that raised grain prices were perceived as transitory; these perceptions have been vindicated by subsequent experience. All of the policies held responsible for raising prices in 1973–74 have subsequently been reversed. Japan has returned to its previous tariff policy, and the ECC has a higher wheat tariff in 1977 than it had in 1972. Canada, Australia, and Argentina are now promoting wheat exports instead of restricting them as they did in 1973–74. Although the dollar has moved unevenly against other currencies, on the average the 1973–74 devaluation has been more than reversed, since the dollar is worth 5% more in May 1977 than it was in February 1973 in terms of the Morgan Guaranty index. These transitory changes should not be expected to have a large impact on land prices.

The relationship between devaluation and land prices deserves more systematic study than is provided here. However, this interpretation of the data is that land prices rose less than product prices, and much of the observed product price increase seems attributable to government policies other than devaluation. Since this does not leave much of a residual to be explained by dollar devaluation, the tentative conclusion is that devaluation was probably not the dominant factor in the agricultural land market in 1973–74.

Conclusions

Many distortions can be found in the international pricing of grains, including the international market for wheat in 1973–74. In addition to a dollar devaluation that took place at that time, all the major importers and exporters except the United States adopted insulating policies to protect their consumers from sharply rising prices. The dollar devaluation was of lesser importance for the U.S. domestic price than foreign commercial policy. Fragmentary evidence indicates that continuation of distortions in U.S. shipping policy was as important as the devaluation of the dollar.

Appendix

The Workings and Sensitivity of the Model

Care is necessary in isolating causes for certain relative price changes for agricultural products. The evidence in this article comes from a structure involving thirty-two endogenous variables, but the current effort does not warrant the space necessary to set out the model in its complete statement. The reader may legitimately ask about the validity of the numbers used. The purpose of this appendix is to make some succinct statements about the model and say something about the sensitivity of the numbers to different assumptions and events.

As noted in the text, the basic structure consists of equations (1) to (3), which relate thirteen flows, thirteen demand prices, and six supply prices to certain exogenous shifters. The coefficients on these endogenous variables (the X matrix in equation (4)), are the direct and cross price elasticities of demand, a set of weights on P_j^S in equation (2) (taken to be 1's here), and the export share weights w_{ij} in equation (3). The direct and cross price elasticities are found from a set of restrictions on the parameter space that allows their calculation from some basic demand elasticities and (in our case) a basic elasticity of substitution among different kinds of wheat. These restrictions are basically those of Armington. His model, and our variant, can be derived by formally maximizing an underlying utility function in a two-stage process. For these purposes, the significant feature of the model is the result and not the exact nature of the restrictions. A significant reduction in information necessary for parameter estimation is achieved. Using a common elasticity of substitution, only $n + 1$ basic elasticities are needed to generate the n^2 implied demand elasticities. (For details, see Armington or Johnson et al.) The calculations involve the use of import shares of particular kinds of wheat into each market. These shares are one in the case of the major exporters, which only import from themselves, and they

vary for the importers such as Japan and Europe. The weights (w_{ij}) are found from the observed export shares of country j's exports to country i in some particular time period.

The forecasts from the model vary according to the accuracy of the basic elasticities and according to the behavior of past exports and imports. Import shares for the regions considered in this article have been quite stable compared with export shares. A ten-year average for these shares is used calculating elasticities. The basic elasticities used are close to those used by other researchers and do not appear to be a cause of concern. The elasticity of substitution (σ) used (3) is on less firm ground. However, two considerations ameliorate our concern. An estimate of 3 from direct estimation of this elasticity in both the Japanese and British markets cannot be rejected statistically. Second, some sensitivity analyses of varying values of σ indicate the model is not particularly sensitive to different values. It is difficult to make this last point with precision, but a change in an exogenous shifter such as transport costs of 10% has much more impact on forecast values than changing σ by a factor of two.

Our use of the model has utilized the previous year's weights (w_{ij}) for each forecast. This article concentrates on a particular year, 1973–74, so the export shares for 1972–73 enter the matrix X of coefficients on the endogenous variables. At the moment this procedure is dictated by the logic of the model, but in practice it is not sacrosanct.

The information in X is treated as deterministic, so that a reduced form set of equations for equation (4) can be found as

$$Y = X^{-1}A. \tag{A.1}$$

A particular solution for given exogenous shifters in A is then found by evaluating equation (A.1) for Y.

Table A.1 amplifies the discussion in the text of the 10% devaluation of the dollar. The left-hand column headed exogenous shifter shows thirteen flows, thirteen demand price changes, and six supply price changes as well as five exogenous export shifters. These identify the row in A (the equation in the structure) where an exogenous shock is going to take place. The right-hand column lists the elements of row 14 in the inverse of X. Row 14 is the equation for the change in the demand price for U.S. wheat.

The forecast price change in 1973–74 for the internal price of U.S. wheat is the sum of these multipliers each multiplied by the corresponding exogenous shock. Looking down that column, one can see the large changes are from a change in demand such as income or competing prices, a change in supply, or a change in ROW exports. For instance, a 10% change in projected shipments to the USSR increases the U.S. price by 18.5%, *ceteris paribus*.

The devaluation example involves the multipliers for the price differences EU and JU. A 10% devaluation is equivalent to a shift in those two equations of 10%; the multipliers are -0.51 and -0.18 for Europe and Japan, respectively. The sum of the effects on the U.S. price are 5.1% and 1.8% for a total increase of 6.9%.

The Impact of Trade Restrictions on Price Stability in the World Wheat Market

Shun-Yi Shei and Robert L. Thompson

A thirteen-region quadratic programming model of world wheat trade is utilized to simulate the effects of unanticipated quantity changes on prices in the world wheat market under different degrees of trade restriction. Three scenarios characterized by different numbers of regions that permit price signals from international markets to be reflected into their domestic markets are specified. As the number of countries whose wheat trade is price responsive increases in the simulations, the percentage change in world price is smaller in response to a shock such as U.S. export controls or an unanticipated change in Soviet imports.

Key words: export control, export demand, simulation, stability, trade model, wheat.

Price stability has emerged as an important issue in agricultural policy discussions in the past several years. The increased price instability in U.S. grains markets in the 1970s compared with an earlier period has been associated with greater dependence on the world market, a reduced level of stocks, and the near elimination of our land reserve. In this period a number of shocks to international grain markets have occurred, including two Soviet crop failures and varying degrees of U.S. export controls. A number of theoretical analyses of the social gains and losses from price stabilization are available (for a summary, see Just). There have also been a number of simulation studies of the effects of various stocks schemes to stabilize domestic and/or world wheat prices (e.g., Sharples, Walker, and Slaughter; Cochrane and Danin; Reutlinger).

D. G. Johnson, Schuh, and the U.S. Council of Economic Advisers have argued that trade restrictions or barriers to free agricultural trade are important causal factors in increasing instability in world markets. The theoretical arguments concerning the global gains from free trade due to more efficient resource use are well known. Less well recognized are the price-stabilizing effects of free agricultural trade. Nontariff trade restrictions, such as quantitative controls and variable levies, cut the link between the world market price and the domestic price. These force all of the adjustment in response to crop failures and other shocks to the system onto those countries that do permit world price signals to be reflected in their domestic markets.

Multilateral trade negotiations under the General Agreement on Tariffs and Trade (GATT) are now going on in Geneva, and barriers to agricultural trade are on the agenda. However, many industrial countries maintain their domestic agricultural prices above the world market level through some combination of price supports, variable levies, and quantitative restrictions on trade with the objective of raising farm income. As long as present domestic policies continue, negotiation of freer agricultural trade will be precluded, and few countries consider their domestic policies negotiable in international fora. Therefore, many observers doubt that any more progress will be made in removing agricultural trade barriers than occurred during the Kennedy round of trade negotiations.

In discussion of world price stability, repeated calls are made for a New International

Economic Order. This usually involves greater international commodity trade restriction via buffer stocks, commodity agreements, cartels, and the like. There is also some tendency towards longer term export contracts or purchase agreements. Such moves are in the direction of greater trade restriction, not less.

The premise of this article is that, if price stability in the world market is desired, trade liberalization, not greater restriction, is more likely to provide it. A simple model of world wheat trade is utilized to simulate the effects of abrupt quantity changes on prices in the world wheat market under alternative assumptions concerning the number of regions of the world that permit price signals from international markets to be reflected into their domestic markets. The model is specified for 1972–73, a crop year in which world supply was very tight and prices of wheat rose substantially above historical levels. The model is used to simulate the effects of two hypothetical shocks to the world market: a purchase by the Soviet Union of about half as much wheat as was actually purchased in 1972–73, and imposition by the United States of a global export quota on wheat exports in order to restrain the rapid rise in the domestic price. The article deals with the central issue of trade liberalization and price stability and incidentally provides rough estimates of the potential impact of such shocks on the world trade flows in wheat.

Theoretical Framework

This section illustrates the effect of a shock to the international market on price in exporting and importing countries under varying degrees of price responsiveness of the participants in the world market. A one-commodity, two-country trading world is assumed initially in order to simplify the presentation of the theoretical framework. It is assumed that the single homogeneous commodity is produced and consumed under competitive conditions in both trading countries. Transportation costs are ignored at this point and, for simplicity, fixed exchange rates are assumed. In the empirical thirteen-region model below, transportation costs are explicitly introduced.

Figure 1 presents the theoretical framework in graphical terms. In the outside panels the domestic supply (S_i) and demand (D_i) curves of the exporting (1) and importing (2) countries are represented. The center panel, which represents the world market, contains the excess supply curve (ES_1) of country 1 and the excess demand curve (ED_2) of country 2. Under free trade, the market price is equalized in both trading countries at $OA = OH = OM$, and country 1 exports $EF = OK = VY$ to country 2.

Assuming a drought in the importing country shifts its supply curve from S_2 to S'_2 and its excess demand curve from ED_2 to ED'_2, the equilibrium price in both countries rises to $OB = OI = ON$, and exports from country 1 to country 2 increase to $CG = OL = TX$. Under free trade, shocks to the system such as a short crop in the importing country are transmitted through the world market into the exporting country such that both countries share in the adjustment. The greater the slope of the domestic supply and/or demand relation in

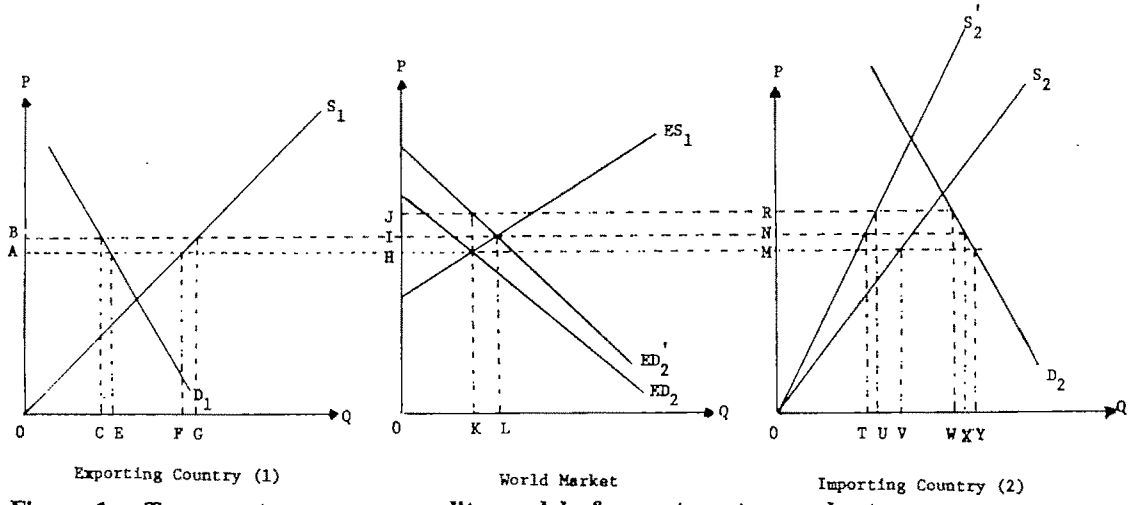

Figure 1. Two-country, one-commodity model of export quota on wheat

each region, the less the price adjustment necessary to clear the market in response to a shock, *ceteris paribus*. This is equivalent to saying that the more elastic the excess supply and excess demand relations, the larger is the quantity adjustment in the volume of trade and the smaller is the price adjustment in response to the shock.[1]

The exporting country can avoid sharing in the adjustment to shocks in the importing country and thereby stabilize its domestic price by cutting the link between the domestic and world market prices. This may be accomplished by means of a quantitative export restriction or an export tax. In figure 1, country 1 can stabilize the domestic price at OA by limiting exports to $EF = OK$ or by imposing an export tax of HJ per unit.[2] At level OK of exports the world market price is bid up to OJ, which equals OR in the importing country. This exceeds the equilibrium price under free trade, $OI = ON$. Since the exporting country refuses to share in the adjustment to the crop shortfall in the importing country, the price adjustment required to clear the world market is greater.

The importing country could have attempted to stabilize its domestic price at OM by increasing its import of the product to ZY. This would have increased the price in the exporting country to a level above OB. Here, the failure of the importing country to let its price adjust forces a larger adjustment onto the exporting country than it would otherwise have experienced.

The theoretical framework has been presented in terms of a two-country world for facility of presentation. The importing country might be considered the rest of the world, whose "domestic" supply and demand curves would be, respectively, the horizontal sums of the domestic supply and demand relations in all other countries, importers and exporters alike. The excess demand relation confronted by the exporting country would then be a net excess demand relation (total imports of all importers minus the exports of all other exporting countries). When there are multiple exporting countries in the market, the price elasticity of excess demand confronted by each independently would be greater than if it were the only exporter in the market. When an importing country cuts the price link between its market and the world market by quantitative restrictions or variable levies, its elasticity of excess demand is perceived to be zero by the other world market participants. This reduces the elasticity of excess demand confronted by any individual exporting country. As above, since fewer countries share in the adjustment in response to any shock to the system, the price adjustment required to clear the market is greater.

The Empirical Model

At first sight the simplest means of utilizing the framework described in the previous section to estimate the effects of shocks to the world wheat market appears to be to directly estimate the domestic U.S. supply and demand functions and an aggregate excess demand function for the rest of the world.[3] This procedure was not employed in this study, however, because the direct estimation of an aggregate excess supply or demand relationship for the rest of the world is notoriously laden with econometric problems (see Magee and Leamer and Stern for discussions of the econometric problems associated with directly estimating such excess demand relationships). In addition, it does not permit explicit account to be taken of the effects of market distortions and transportation costs on the volume of trade flows. Instead of attempting to utilize a

[1] The price elasticities of excess supply and excess demand are, respectively,

$$\epsilon_i = \frac{dQ_i^X}{dP_i}\,\frac{P_i}{Q_i^X} = g_i\left(\frac{Q_i^S}{Q_i^X}\right) - e_i\left(\frac{Q_i^D}{Q_i^X}\right)$$

and

$$\eta_i = \frac{dQ_i^M}{dP_i}\,\frac{P_i}{Q_i^M} = e_i\left(\frac{Q_i^D}{Q_i^M}\right) - g_i\left(\frac{Q_i^S}{Q_i^M}\right);$$

where for country i, Q_i^S is the domestic production, Q_i^D is the domestic consumption, Q_i^X is the export quantity, Q_i^M is the import quantity, e_i is the domestic price elasticity of demand, and g_i is the domestic price elasticity of supply. These formulas, which have become common in the literature, are attributed by Orcutt to Yntema (pp. 43–45).

[2] While *ad valorem* and specific tariffs drive a wedge between domestic and world market price, the price signals still get through from the world market to the domestic market, albeit in a distorted form. In effect, a tariff rotates the excess demand curve of the rest of the world, making it less elastic; a quota or a variable levy turns it vertical over a range of prices.

[3] The price elasticity of an excess demand function for U.S. wheat exports has been directly estimated by P. R. Johnson at −3.8 using data from 1951–63. His estimate is much more elastic than that of Meinken based mainly on prewar data. Fletcher and Just estimate short-run price elasticities of import demand for U.S. wheat exports in four regions of the world. Their estimated elasticities are: (*a*) Western Europe, −0.10, (*b*) Asia (including PRC), −1.32, (*c*) Western Hemisphere (excluding United States and Canada), −0.52, and (*d*) all other importers (Africa, USSR, Eastern Europe, and Oceania excluding Australia), −1.49 (pp. 8–9).

direct estimate of an excess demand function of the rest of the world for U.S. wheat exports, a small quadratic programming model of world wheat trade of the type developed by Takayama and Judge was specified. (A full presentation of the model specification, data utilized including transportation costs, and limitations of the model is contained in Shei.) This implicitly provides the excess demand function of the rest of the world that the United States confronts.

The world wheat market is divided into five exporting regions (the United States, Canada, Australia, Argentina, and the European Economic Community (EEC)) and nine importing regions (Japan, People's Republic of China (PRC), USSR, EEC, Other Western Europe, Eastern Europe, Other South America, Other Asia, and Africa). Wheat is taken here to be a homogeneous commodity. Three alternative specifications of the world wheat trade model are formulated to permit simulation of the effects of shocks to the world wheat market under varying assumptions concerning the number of importing countries that permit world market price signals to be reflected in their domestic markets. The basic specification of the model assumes that the imports of all importing regions and the exports of the EC are fixed (assumed not price responsive) at the 1972–73 observed levels.[4] Only exports from the United States, Canada, Argentina, and Australia are assumed to be price responsive. We shall call this specification scenario 1.

This specification is considered an extreme case in its rather unrealistic assumption that the excess demand or import quantities of all countries are fixed and do not respond to price changes—even, say, in the face of a doubling of the world market price. (Countries with zero price elasticity of import demand over some range of prices may have nonzero elasticities at higher prices.) Scenario 2 is identical with scenario 1, except that the imports of Other Asia, Africa, and Other South America are also made price responsive. This specification is consistent with D. G. Johnson's description of the world grains economy. Scenario 3 is the full free trade case in which all importing and exporting regions are assumed to be price responsive.

The linear excess supply functions utilized in the annual quadratic programming model are based on Liu's recent econometric estimates of domestic supply and demand relations in the principal wheat exporting countries. To generate short-run excess supply relations, it is assumed that, once the crop is planted, that year's production is no longer price responsive within the crop year. Therefore, each country's production in 1972 is taken as fixed. Liu's demand equations are "collapsed" (expressed as functions of only current prices) by substituting the respective values of all other explanatory variables for 1972 into the respective equations. Each country's short-run excess supply equation then equals the fixed supply quantity minus its domestic demand equation. Observed changes in stocks in 1972–73 are treated as exogenously given intercept shifters in the respective excess supply equations.[5]

For the United States: $Q^X = 21{,}851 + 64.427P$; $\epsilon = 0.20$; Canada: $Q^X = 15{,}926 + 2.625P$; $\epsilon = 0.02$; Australia: $Q^X = 8{,}029 + 1.972P$; $\epsilon = 0.03$; Argentina: $Q^X = 791 + 12.089P$; $\epsilon = 0.30$; and EEC: $Q^X = 3{,}291 + 122.25P$; $\epsilon = 2.38$; where Q^X is the volume of excess supply of wheat in thousands of metric tons; P is the domestic market price in U.S. dollars per metric ton (converted at official par value rates of exchange following Bjarnason, McGary, and Schmitz);[6] and ϵ is the short-run price elasticity of excess supply at observed 1972–73 prices and quantities for each respective country.

No excess demand equations for importing countries were estimated by Liu. To specify

[4] Certain wheat-importing countries maintain their domestic wheat price above or below the world market level, necessitating some form of trade control to sever the link between the domestic and world market prices. For example, the link between internal EEC agricultural prices and world market prices is cut by means of the variable import levy and export tax. The Japan Food Agency, which is the sole importer of wheat in Japan, has variously resold wheat in the domestic market at prices above and below the import price. In centrally planned economies, the quantities demanded and supplied may not be determined by a market mechanism.

[5] The assumed non-price responsiveness of stock-holding activities is probably a rather restrictive assumption. One anonymous *Journal* reviewer argued that non-price responsiveness legislated by some importing countries might be expected to increase the price responsiveness of the remaining countries through increased storage activity. To the extent that this occurs, greater world price stability than suggested by this study would be expected. A number of simulation studies of reserve stock behavior have been carried out in which the effect of trade restrictions on price stability has tended to be ignored. This study focuses upon the latter issue, ignoring the former.

[6] Fixed or unchanging exchange rates are assumed. Under a floating exchange rate regime, this would require that the value of trade in wheat be insignificant relative to the total value of international transactions on current and capital account in the countries included in the model. Failing this, as the total value of trade in wheat between a pair of countries increases, one would expect the currency of the importing country to depreciate relative to that of the exporting country.

scenarios 2 and 3, excess demand relations for each importing region were synthesized by Shei. Estimates of the domestic price elasticities of demand for wheat in a number of countries have been estimated by Rojko, Urban, and Naive, and data on volumes of domestic consumption and imports (International Wheat Council) were utilized in synthesizing an excess demand equation for each importing region.

To calculate short-run price elasticities of import demand, it is assumed that, once the crop is planted, that year's production is no longer price responsive within the crop year. Therefore, the short-run price elasticity of excess demand in a given region is taken to be $\eta = e(Q^D/Q^M)$, where e is the domestic price elasticity of demand, Q^D is the quantity demanded domestically, and Q^M is the quantity imported in the respective country. The estimate of η calculated in this manner should be a lower bound estimate of the price elasticity of excess demand because no price responsiveness of supply or change in stocks is permitted. The resulting import demand equations, which are admittedly somewhat crude estimates, are as follows: Japan: $Q^M = 7{,}476 - 19.1721P$; $\eta = -0.35$; PRC: $Q^M = 8{,}410 - 30.0049P$; $\eta = -0.59$; Other Asia: $Q^M = 26{,}596 - 134.3731P$; $\eta = -1.13$; USSR: $Q^M = 35{,}528 - 204.6402P$; $\eta = -1.33$; E. Europe: $Q^M = 6{,}538 - 56.0224P$; $\eta = -4.72$; EEC: $Q^M = 20{,}085 - 149.42P$; $\eta = -2.41$; Other W. Europe: $Q^M = 6{,}025 - 48.8055P$; $\eta = -3.93$; Africa: $Q^M = 10{,}940 - 48.083P$; $\eta = -0.78$; and Other S. America: $Q^M = 8{,}733 - 25.1786P$; $\eta = -0.40$; where Q^M is the excess demand for wheat in thousands of metric tons, and η is the price elasticity of excess demand calculated at observed 1972–73 prices and quantities for each respective region. The price elasticity of excess demand η varies considerably among countries. This is not unexpected, since, *ceteris paribus*, the smaller the fraction of a country's consumption that is imported, the larger its elasticity of excess demand.

Empirical Results

The trade flows and prices contained in the solution of the basic model specification (scenario 1) are presented in table 1. The quadratic programming model restricts the number of trade flows in solution to one less than the total number of exporting and importing regions (i.e., 5 + 9 − 1 = 13 in this case).[7] Bearing this in mind, the results generated by the model replicate fairly closely the principal observed trade flows in 1972–73 presented in table 2, with one main exception. Africa was the EEC's most important wheat export market in 1972–73. In the solution, however, Africa is entirely supplied by the United States, and Other Asia takes all of the EEC's exports

[7] The quadratic programming algorithm QP360 developed by Cutler and Pass at the RAND Corporation was employed to solve the model. Because of the transportation constraints and the nature of the solution algorithm utilized, the total number of trading activities must be one less than the total number of origins (m) and destinations (n), i.e., exactly equal to $n + m - 1$.

Table 1. Simulated Exports of Wheat, 1972–73, Scenario 1

Destination	Source					Total	Import Price (U.S. $/ Metric Ton)

of wheat. The discrepancy between the solution and observed EEC exports may be due to former colonial ties, bilateral trade agreements, and/or special credit arrangements that affect the pattern and flow of world wheat trade but that are not adequately represented in the model.[8] A second discrepancy is that the EEC is solely supplied by Canada and Japan by the United States in solution, while in reality both Canada and the United States were important suppliers of both markets. A possible explanation may lie in the assumption that wheat is a perfectly homogeneous commodity. In reality, many varieties and qualities exist. Moreover, an importing country may not consider otherwise identical wheat supplied by two different exporters to be perfect substitutes. A country's desire to diversify its source of import supply would be consistent with such behavior.[9]

The solution export and import prices are fairly close to observed levels in 1972–73. For example, the U.S. export price in solution is $87.7 per metric ton, while the observed average price was $92.4.

The model solution for scenario 2, in which the three developing country importers are assumed to be price responsive, is almost identical to that of scenario 1 presented in table 2.

The results from running scenario 3, the full free trade case, are presented in table 3.

[8] Rich's study of trade patterns between the United States and Western Europe suggests that the difference is due to bilateral agreements between Western Europe and the African countries.

[9] Armington developed the theory for a class of trade models in which import goods are distinguished by their place of origin. P. R. Johnson argues for analysis of substitution and market share relations in agricultural trade research.

Export price (U.S. $/metric ton)	78.16	77.96	82.26	82.06	80.76		

Under free trade conditions, the total volume of wheat moving in world trade increases rather dramatically and at lower prices. This is accounted for mainly by the large increase in EEC wheat exports under free trade that has been exogenously fixed at a substantially lower level in scenario 1. The scenario 1 solution presented in table 1 is closer to the observed wheat trade flows and prices than the free trade case in table 3. This suggests that the real world may be somewhat closer to the base case than to the full free trade case.

The results presented here for the three scenarios provide a basis for comparison with the simulated effects of shocks to the world wheat market.

Sudden Change in Soviet Purchase

About 80% of the year-to-year fluctuations in world wheat trade since 1960 have been accounted for by swings in USSR imports (Mackie). In 1972–73 the Soviet Union purchased 15.3 million metric tons of wheat on the world market—an increase of about 12 million metric tons from the purchase of the previous year. This level of Soviet imports is reflected in the scenario 1 specification.

The first shock to the world wheat market to be evaluated here is the case of the USSR importing only 7.0 million metric tons of wheat instead of the observed 15.3 million metric tons. When scenario 1 is rerun with this change, all export prices are driven to zero. The positive import prices equal the transportation cost from the supplying country. Table 4 presents the model solution under scenario 2. When only three importing regions are made price responsive, the world wheat price is not nearly as severely depressed by the "shock" as in scenario 1. While USSR imports fell by 8.248 million metric tons, total wheat trade declined by only 2.348 million metric tons. The three price-responsive import regions collectively increased their imports by 5.9 million metric tons.

Table 5 illustrates the effect of the smaller Soviet purchase when all exporters and other importers are assumed to be price responsive (scenario 3). The percentage fall in world market prices is substantially smaller in this case than in the previous case. (The results in tables 4 and 5 should not be compared; rather, they should be compared with those in tables 1 and 3, respectively.) The results are all consistent with the implications of the theoretical framework specified.

U.S. Export Controls

Given the high level by historical standards of Soviet wheat imports in 1972–73, one might ask what the price and trade effects would have been if the United States had imposed global export controls on wheat exports to stop the run-up in price in the United States. In 1972–73 the United States exported 29.9 million metric tons; in the base case solution U.S. exports are 27.5 million metric tons. Although the model is not exactly on target, the latter is taken here as the basis for comparison. The U.S. excess supply equation presented above suggests that by reducing exports from 27.5 to 26 million metric tons the

Destination	Source					Total	Import Price (U.S. $/ Metric Ton)
	U.S.	Canada	Australia	Argentina	EEC		
	1,000 Metric Tons						
Japan	6,000					6,000	77.00
PRC		4,515	1,498			6,013	79.90
Other Asia			6,666		9,059	15,725	80.90
USSR	4,913	2,087				7,000	75.00
E. Europe	2,493					2,493	72.20
EEC		9,491				9,491	70.90
Other W. Europe					2,399	2,399	74.30
Africa	7,305					7,305	75.60
Other S. America	5,238			1,607		6,845	75.00
Total	25,949	16,093	8,164	1,607	11,458	63,271	
Export price (U.S. $/metric ton)	63.60	63.40	68.30	67.50	66.80		

domestic U.S. wheat price would be expected to fall to $64.4 per metric ton. This is about the price level of the previous year and close to the average annual level of the 1960s.[10]

The three scenarios were rerun under the constraint that U.S. exports of wheat could not exceed 26 million metric tons. In scenario 1 in which no importers are price responsive, when the United States insulates its domestic market from world market price signals by imposing global export controls, the world market price is pushed up markedly. As illustrated in table 6, the U.S. export price in solution more than doubles from $87.7 to $177.5, and the U.S. domestic price falls from $87.7 to $64.4 per metric ton.

In this scenario, all of the decrease in U.S. exports from imposing export controls comes out of its exports to the USSR and Other South America. Argentina makes up for the latter and Canada for the former. As Canada's exports to the USSR rise, its exports to the PRC decrease, which is made up by Australia. The 1,499,000 metric ton reduction in U.S. exports is offset by increases of 236,000, 177,000 and 1,086,000 metric tons, respectively, from Canada, Australia, and Argentina.

Table 7 presents the results of the second scenario in which importers are price responsive. In this case, the U.S. export price rises

[10] We implicitly assume that the quotas are imposed at the beginning of the export marketing year. If imposed in the course of the year, external and internal prices would be the same until controls were imposed. Subsequently, prices would diverge. If the latter situation were the case, the estimates presented would overstate the price effects in the domestic market and understate the effects in the world market.

Table 6. Simulated Exports of Wheat, 1972–73, Scenario 1, with U.S. Global Export Quota of 26 Million Metric Tons

Total	26,000	16,173	8,225	1,979	5,436	57,813	
Export price (U.S. $/metric ton)	94.38	94.18	99.08	99.28	97.58		

only from $87.70 to $94.40, rather than to $177.50 when no importers are price responsive. Table 8 illustrates the effect of U.S. imposition of export controls when all other countries in the market are assumed to be price responsive. Relative to the prices observed in table 3, the prices here rise only slightly.

The parametric change in the level of U.S. exports permits calculation of the arc elasticity of excess demand over the range from 26 million to 27.5 million metric tons. It equals −0.053 in scenario 1, the basic specification in which no importing countries respond to price. By making only the three less-developed-country importing regions price responsive, in scenario 2, the arc elasticity of excess demand confronted by the United States rises to −0.71 over the same range of export quantities. When all exporting and importing regions are made price responsive, the implicit arc price elasticity of excess demand confronted by the United States is −2.48 in scenario 3. As the excess demand confronted by the United States becomes more price elastic, the percentage increase in the price necessary to clear the world market falls. These results suggest that, when trade restrictions that cut the link between domestic and world market are removed, the world market price structure is much more stable in the face of shocks to the system.

The foregoing analysis applies only to the case of global export controls. When specific controls are imposed on exports to certain countries, as has occurred in the case of ex-

Table 8. Simulated Exports of Wheat, 1972–73, Scenario 3 with U.S. Global Export Quota of 26 Million Metric Tons

ports from the United States to the Soviet Union, a reshuffling of trade flows occurs. Marginal changes in equilibrium prices and quantities occur with an accompanying increase in total transportation costs; global welfare is reduced.

Limitations and Conclusions

The price elasticities of the respective excess supply and demand relations determine the magnitude of the effects of shocks to the system.[11] The excess demand equations utilized are synthesized in an admittedly crude fashion. Further econometric evidence is needed on the elasticities of the excess supply or excess demand relations for most of the trading regions before much faith should be put in the absolute magnitudes of the price adjustments obtained.

The foregoing analysis ignores the longer run effects such as would be expected when producers react in the following year to changed relative prices. Another likely important longer run effect arises from the fact that export controls may stimulate importing countries to diversify their sources of supply, even at a higher cost.[12]

The model ignores many institutional aspects of the world wheat market that may exist, such as trade agreements, forward contracts, and political decisions to buy or to embargo a certain country's wheat. Furthermore, wheat is not a perfectly homogeneous commodity as assumed in the model, nor are changes in stocks exogenously determined without reference to the present and expected prices. The model also ignores the fact that the wheat harvest occurs in different parts of the year in the northern and southern hemispheres. All of these factors may affect the pattern of world wheat trade and are not taken into account explicitly in the solution prices in the model. They should be borne in mind when interpreting the results.

The most significant result of this study is the demonstration that greater world market price variability results as more countries prevent world price signals from being reflected across their borders into the domestic market through some form of trade control. As the number of countries whose imports are price responsive increases in the simulation, the percentage increase in world price is smaller in response to a shock, such as U.S. export controls or an unanticipated change in Soviet imports.

Today, many countries of the world are considering creation of commodity agreements or cartels to stabilize the world market in primary commodities. Such policies involve increased government intervention in trade. The results reported here suggest that a movement toward trade liberalization, rather than greater restriction, could contribute substantially towards smoothing out world market price fluctuations. The present study has provided evidence that price movements are magnified if large sectors of the world economy are effectively insulated from changing conditions in the world economy.

[*Received December 1976; revision accepted April 1977.*]

[11] To test the sensitivity of the results to the specific parameter estimates utilized, an alternative set of excess supply equations is synthesized. To do this, a linear equation is passed through the observed export price-quantity point for each country with the following short-run elasticities of excess supply: United States, 0.217; Canada, 0.097; Australia, 0.098; and Argentina, 0.625. With the exception of the United States, these elasticities are all at least twice as large as those employed in the study. Under scenario 1 when the United States imposes a 26 million metric ton export quota, its export price rises 103% in the original specification. With the alternative synthesized excess supply equations, it increases 87%. A set of longer run excess supply equations is synthesized assuming that supply as well as demand adjust to price changes. The following elasticities are assumed: United States, 0.634; Canada, 0.691; Australia, 0.892; and Argentina, 1.393. Using this set of much more elastic excess supply equations, the U.S. export price increases only 19% when the export quota is imposed. While the prices in solution are relatively insensitive to changes in transportation costs, the magnitudes of specific wheat trade flows tend to be sensitive.

[12] Another limitation of the analysis is the implicit assumption that no retaliation occurs on the part of other countries that have some monopoly power in the world market. For example, if the behavior of Canada and the United States in the world wheat market is of a duopoly nature, as suggested by McCalla, Canada might counteract the effect of U.S. export controls in raising the world wheat price by releasing stocks. In this case the United States would achieve its objective of lowering its domestic price, but the world wheat price would not rise as much as suggested above.

Welfare Implications of Commodity Storage under Uncertainty

Peter Helmberger and Rob Weaver

Intertemporal equilibrium is determined for a competitive market when private inventories are held. Production and storage decisions respond to rational expectations of uncertain prices. Algebraic expressions for gains (losses) to buyers and producers are derived in this context. Competitive equilibrium maximizes gains to society. Government programs that stabilize price either completely or partially generate benefits to producers and losses to buyers relative to competitive equilibrium. Welfare effects are quantified assuming an initial period of abundance and various supply and demand elasticities.

Key words: buffer stocks, commodity storage, price instability, private storage, welfare analysis.

More than thirty years ago, Waugh showed that the consumer is better off with fluctuating prices than if prices are stabilized at or above their simple arithmetic means. Oi, in 1961, constructed a model in which a competitive firm earns greater total returns with unstable prices than with stable prices. These two pioneering works caused a modest stir in the economics profession and have given rise to a growing body of literature. Massell creates a linear model in which the Waugh and Oi results are shown to be special cases. Turnovsky correctly points out that much of the previous work is concerned with price variability, not price uncertainty. His models reflect a recursive system in which farm production decisions are made prior to the time when prices are known. More recently, Subotnik and Houck (1976) analyze the implications of stabilizing nonprice endogenous variables.

The main objective of this literature is to deduce the welfare implications of stabilization for producers, consumers, and society as a whole. A common approach is to compare market performance with no storage with performance when storage is used to stabilize price or some other variable.[1] It is fair to say that in much of this literature, including the works cited above, the existence of a private storage industry growing out of the quest for expected profits in an uncertain world is simply abstracted away.

The relevance of models that ignore private storage may be seriously questioned. Neither zero storage nor complete price stabilization is consistent with a competitive storage market. Thus, the analytical results shed little light on actual market situations. Furthermore, although one might conceive of a government buffer stock scheme in which the objective is price stabilization, it makes little sense to compare the resulting performance with that associated with zero storage. Clearly, such comparisons violate the with-and-without government principle conventionally employed in program analysis.

This article is concerned with modeling a competitive pricing system for a storable commodity produced and marketed under conditions of uncertainty. Various government buffer stock (stabilization) schemes are also considered. The major objectives are to evaluate for various groups of market participants the benefits and costs generated by a competitive storage industry and to show how these benefits and costs are affected by alternative government programs. Rough quantitative estimates of various welfare effects are provided.

Peter Helmberger is a professor in the Department of Agricultural Economics, University of Wisconsin, Madison, and Rob Weaver is an assistant professor, Pennsylvania State University.

[1] This approach is also characteristic of a growing body of empirical research (Cochrane and Danin; Reutlinger; Walker, Sharples, and Holland).

Competitive Storage under Conditions of Uncertainty

Because of the recursive nature of grain production, the quantity produced in crop year t depends on expected price at planting time (P^*_t). Quantity demanded for consumption depends on the current price. Thus,

$$(1) \qquad D_t = \alpha_0 - \alpha_1 P_t + U_t$$
$$S_t = \beta_0 + \beta_1 P^*_t + V_t,$$

where D and S equal the quantities demanded and supplied, P equals market price, and U and V are independent, random variables.[2] The expected values of the random variables, $E(U_t)$ and $E(V_t)$, equal zero. Following Muth, it is assumed that $E(P_t) = P^*_t$. This model is similar to those analyzed by Massell, Turnovsky, and Subotnik and Houck (1976) in which the possibility of private storage is ignored.

With a storage industry, however, the clearing of the market implies

$$(2) \qquad D_t - S_t - I_{t-1} + I_t = 0,$$

where I_{t-1} is the carryin and I_t is the carryout. Taking the expectation of equation (2) yields

$$(3) P^*_t = \frac{1}{\alpha_1 + \beta_1} (\alpha_0 - \beta_0 - E(I_{t-1}) + E(I_t)).$$

From equation (3), the value of P^*_t is immediately determinate for all t in the absence of storage. With storage, the values of P^*_t, $E(I_{t-1})$, and $E(I_t)$ are determined simultaneously; competitive equilibrium in period t is affected, potentially at least, by market performance in all past periods and by expected performance in all future periods.

It is convenient to begin through analysis of a special case. Consider the first period, assuming that $I_0 = 0$. It follows that $E(I_1) = 0$ and

$$(4) \qquad P^*_1 = P^* = \frac{\alpha_0 - \beta_0}{\alpha_1 + \beta_1}.$$

To prove this, assert $E(I_1) > 0$. This implies that P^*_1 is larger than P^* and that P^*_2 is less than P^* given expected demand and supply for the first two periods. But if $P^*_1 > P^*_2$, there would be no motivation for storage from the first to the second period. The assertion that $E(I_1) > 0$ leads to an inconsistency. We consider subsequently the case where $I_0 \geq 0$ and $E(I_1) \geq 0$. Under the latter conditions, there is the possibility that P^*_1 is determined through equating the expected demand and supply for storage rather than for consumption and production.

Actual demand (DD_1) and supply (SS_1) in the first period are given in figure 1. Since $P^*_1 = P^*$, Q_{12} is produced. Algebraically,

$$(5) \qquad S_1 = Q_{12} = \frac{\beta_0\alpha_1 + \beta_1\alpha_0}{\alpha_1 + \beta_1} + V_1$$

If $I_1 = 0$, then price sinks to P_{10} given by the intersection of DD_1 and the vertical dashed line Q_{12}, and $P^*_2 = P^*$ just as in the first period prior to planting. Let T equal the per unit cost of storage for one period and assume that T is constant for all storage levels. If $P^* - P_{10} > T$, then positive expected profit is consistent with a sufficiently small carryout.

Assuming risk neutrality, pure competition, and no barriers to entry, equilibrium requires[3]

$$(6) \qquad (P^*_t - (t-1)T) \leq P_1 \text{ for } t > 1.$$

In particular, if $P^* - P_{10} > T$, competition results in a level of storage such that $P^*_2 - T = P_1$; expected profit equals zero. Finding the competitive level of storage requires derivation of a supply and a demand function for storage. The intersection of these two func-

[2] The stochastic term affecting domestic supply (V_t) may be given the standard justification of arising from the occurrence of natural phenomena and random errors in decision making. By recognizing that D_t may be interpreted as the sum of domestic and foreign demand for grain, U_t may be thought of as following in part from shocks to foreign supplies of grain.

[3] Discounting and risk premiums, in the case of risk aversion, are ignored to keep the argument simple, but the analysis can be generalized to include these complicating factors.

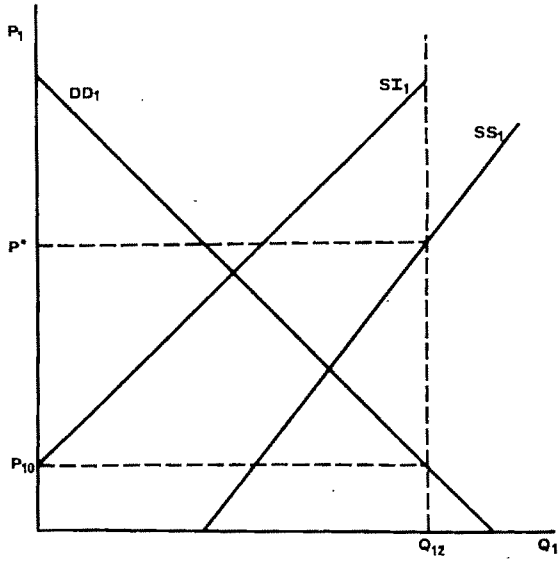

Figure 1

tions yields competitive equilibrium. If $P^* - P_{10} < T$, then no storage occurs, and the intersection of DD_1 and SS_1 gives competitive equilibrium.

Let I_{s1} equal the quantity supplied for storage in the first period. By definition, $I_{s1} = Q_{12} - D_1$. The supply function for storage may be derived by making the relevant substitutions. Thus,

$$(7) \qquad I_{s1} = \alpha_1 P_1 + Q_{12} - \alpha_0 - U_1.$$

In figure 1, the supply curve for storage is derived graphically by simply subtracting laterally DD_1 from the vertical dashed line above Q_{12} and is labeled SI_1.

To derive the competitive demand for storage, let i_{1t} equal the quantity of storage undertaken in the first period and planned for expected delivery in the tth period for $t > 1$. Let I_{d1} equal the total quantity demanded for storage in the first period. By definition, $I_{d1} = i_{12} + i_{13} + i_{14} + \ldots$. Positive storage in the first period drives down the expected price in the second and, possibly, subsequent periods. Moreover, lower first period prices encourage storage for planned delivery in a successively larger number of periods.

Consider a set of potential prices in the first period such that $P^* - 2T \leq P_1 < P^* - T$. Positive profit can be expected from at least a limited amount of storage for planned delivery in the second period but not for delivery in the third and subsequent periods. (Competition would, of course, push storage to such a level that expected profit is driven to zero.) Further, the lowest price in the set under consideration, $P_1 = P^* - 2T$, is a "switch" price in that if P_1 falls below $P^* - 2T$ then storage for delivery in both the second and third periods becomes consistent with positive expected profits.

If $P^* - 2T \leq P_1 < P^* - T$, then using the above arguments $I_{d1} = i_{12}$ and $i_{1t} = 0$ for all $t \geq 3$. Moreover, if $P^*_2 = P^*$, then expected supply and demand quantities are equal for the second period, and there is no demand for storage. Falling expected prices in the second period cause the difference between expected quantity demanded and expected quantity supplied to grow even larger. It is this gulf between expected demand and expected supply that creates a demand for storage in the first period. Thus, $I_{d1} = i_{12} = E(D_2) - E(S_2)$. By substitution,

$$(8) \qquad I_{d1} = \alpha_0 - \beta_0 - (\alpha_1 + \beta_1)P^*_2.$$

Zero expected profit from positive storage implies that $P^*_2 - T = P_1$. Therefore, the demand for storage in the first period for planned delivery in the second period only is given by[4]

$$(9) \qquad I_{d1} = \alpha_0 - \beta_0 - (\alpha_1 + \beta_1)(P_1 + T) \quad \text{for } P^* - 2T \leq P_1 < P^* - T.$$

A graphical derivation of equations (8) and (9) is given in figure 2. Expected demand and supply, $E(DD_2)$ and $E(SS_2)$, are given in the second quadrant. The graph of equation (8),

[4] The function (9) holds only for $I_{d1} \leq \bar{i}_{12}$, where $\bar{i}_{12}$ is the specific value for I_{d1} when $P_1 = P^* - 2T$.

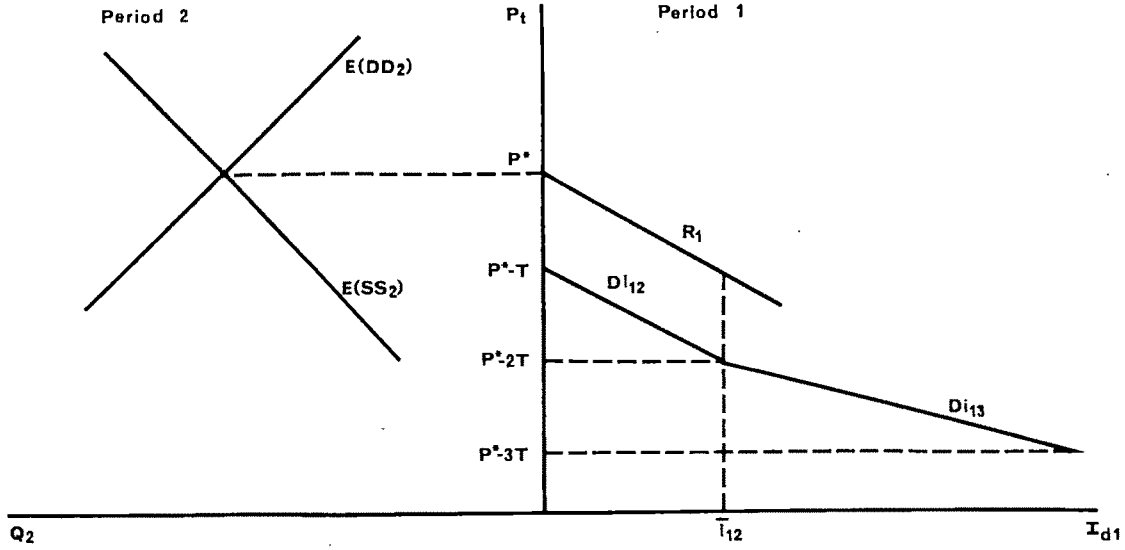

Figure 2

R_1, is obtained by subtracting laterally $E(SS_2)$ from $E(DD_2)$ for prices less than P^* and plotting the positive differences in the first quadrant. The graph of equation (9), Di_{12}, is obtained by subtracting vertically T from R_1 and taking into account the restrictions on its range of applicability.

Considering the range of prices $P^* - 3T \leq P_1 < P^* - 2T$, storage for planned delivery in the second and third periods, but not beyond, is consistent with positive expected profit. Moreover, $P_1 = P^* - 3T$ becomes the new switch price in that a lower price would give rise to planned expected storage for at least the first three periods beyond the first. Given the price range here considered, $I_{d1} = i_{12} + i_{13}$. Therefore, $I_{d1} = E(D_2) - E(S_2) + E(D_3) - E(S_3)$. Zero expected profit implies that $P_1 = P^*_2 - T = P^*_3 - 2T$. Making the relevant substitutions[5]

$$(10)\quad I_{d1} = 2(\alpha_0 - \beta_0) - 2(\alpha_1 + \beta_1)P_1 - 3(\alpha_1 + \beta_1)T \text{ for } P^* - 3T \leq P_1 < P^* - 2T.$$

The graph of equation (10), Di_{13}, is given in figure 2. The slope of Di_{13} is greater algebraically than is the slope for Di_{12}. Thus, the demand for storage is "kinked" at $P_1 = P^* - 2T$.

These results can be generalized for the case where storage from the first period is planned for expected delivery in each of $n - 1$ subsequent periods. Thus,

$$(11)\quad I_{d1} = (n-1)(\alpha_0 - \beta_0) - (n-1)(\alpha_1 + \beta_1)P_1 - (\alpha_1 + \beta_1)T\sum_{2}^{n}(t-1)$$

$$\text{for } P^* - (n-1)T \leq P_1 < P^* - (n-2)T.$$

In sum, the demand for storage in the first period (assuming $I_0 = 0$) is a kinked function consisting of a finite number of linear functions each restricted to its own range of values. If storage occurs, the competitive equilibrium is given by $I_{s1} = I_{d1} = I_1$. The equilibrium can be found graphically or algebraically using trial-and-error methods. The resulting model can be used to generate a large number of internally consistent hypotheses as to the impacts of exogenous changes on price, quantity consumed, and quantity stored in the first period as well as on the expected values for prices and quantities consumed, produced, and stored in all future periods. Examples of exogenous change include structural shifts in demand and/or supply, changes in storage costs, and weather anomalies both in the United States and abroad.

We now relax the assumption that $I_0 = 0$ and show how P^*_1 can be determined at planting time when $I_0 \geq 0$. Let $E(C_1)$ equal the expected total supply in the first period, consisting of expected supply plus the carryin I_0. Through substitution,

$$(12)\quad E(C_1) = \beta_0 + \beta_1 P^*_1 + I_0.$$

The graphs of expected demand and expected supply in the first period, $E(DD_1)$ and $E(SS_1)$, are given in figure 3. The graph of the expected demand for storage, $E(DI_1)$, is the same as for the demand for storage, since the latter has no stochastic elements. The graph of equation (12) for a specific value of I_0, $I_0 = I_{01}$, is given by $E(AS_1)$. The supply for storage in the first period is the modification of equation (7) given by

$$(13)\quad I_{s1} = \alpha_1 P_1 - \alpha_0 + \beta_0 + \beta_1 P^*_1 + V_1 - U_1 + I_0.$$

The expected supply for storage, $E(SI_1)$, is also given in figure 3, assuming $I_0 = I_{01}$. An increase (decrease) in I_0 shifts $E(AS_1)$ and $E(SI_1)$ to the right (left). For all values of $I_0 \leq I_{01}$, $E(SI_1)$ lies above $E(DI_1)$ for positive levels of storage; expected competitive equilibrium is given by the intersection of $E(DD_1)$ and $E(AS_1)$. Therefore,

$$(14)\quad P^*_1 = \frac{1}{\alpha_1 + \beta_1}(\alpha_0 - \beta_0 - I_0) \text{ for } I_0 \leq I_{01}.$$

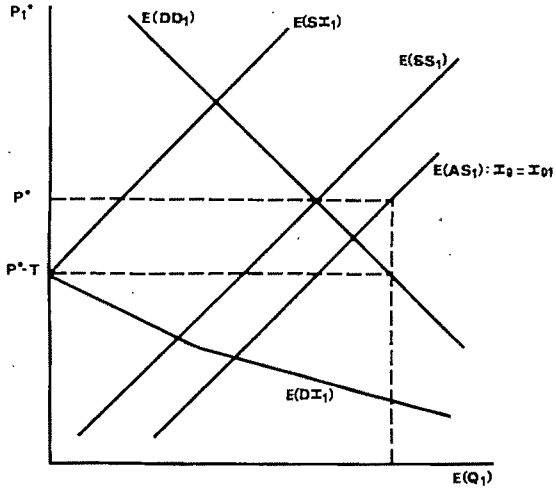

Figure 3

[5] The function (10) holds only for $\bar{i}_{12} < I_{d1} \leq \bar{i}_{12} + \bar{i}_{13}$, where $I_{d1} = \bar{i}_{12} + \bar{i}_{13}$ when $P_1 = P^* - 3T$ and where $\bar{i}_{12}$ is as defined previously.

For all values of $I_0 > I_{01}$, P^*_1 is determined by the expected demand and expected supply for storage. As noted, the latter shifts to the right with increases in I_0, whereas the former is stationary. Thus, P^*_1 can be determined for every possible level of I_0. Once P^*_1 is determined, the previous analysis of competitive storage is applicable with minor modification.

In order to gain some insights as to the quantitative significance of competitive storage, average grain disappearance in United States in recent crop years is assumed to be "normal" production and consumption. Over the period 1969–70 through 1975–76, average grain disappearance (wheat, corn, sorghum, oats, and barley) equaled roughly 9 billion bushels. The weighted average price deflated for price level changes for farm inputs (1967 = 100) was \$1.24 per bushel. Given the elasticities of demand and supply for the "normal" situation, α_0, α_1, β_0, and β_1 can be calculated. Although definitive estimates of the elasticities are not available, various ballpark estimates may be considered in a sensitivity analysis. The supply elasticities (E_s) considered are 0, 0.2, 0.4, 0.6, and 0.8. Demand elasticities (E_d) considered equal −0.2, −0.4, −0.6, and −0.8. The storage cost T is set equal to 0.186¢ per bushel, which equals 15% of the normal grain price (see Jones). In order to consider a year of substantial abundance, U_1 is set equal to −1.8 billion bushels (20% less than normal) and V_1 is set equal to 1.8 billion bushels (20% more than normal). Given these circumstances, the competitive levels of price and storage of the first period are given in table 1.

Table 1. Estimated First Period Grain Prices (P_1) and Quantities Stored (I_1)

Elasticity of Demand	Elasticity of Supply 0	0.2	0.4	0.6	0.8
	Billions \$				
$E_d = -0.2$					
P_1(¢/bu.)	0.372	0.567	0.657	0.717	0.761
I_1 (billion bu.)	2.338	2.623	2.754	2.837	2.904
$E_d = -0.4$					
P_1 (¢/bu.)	0.651	0.721	0.769	0.801	0.824
I_1 (billion bu.)	1.890	2.092	2.232	2.325	2.392
$E_d = -0.6$					
P_1 (¢/bu.)	0.778	0.812	0.835	0.851	0.864
I_1 (billion bu.)	1.590	1.735	1.835	1.908	1.964
$E_d = -0.8$					
P_1 (¢/bu.)	0.847	0.864	0.880	0.896	0.909
I_1 (billion bu.)	1.320	1.414	1.512	1.602	1.680

Note: See text for explanation and interpretation.

These estimates suggest a number of important conclusions. First, a competitive storage industry does not forestall large swings in grain prices. If $E_s = |E_d| = 0.4$, for example, the first period price (77¢) only amounts to 62% of that expected (\$1.24). Such deviations between actual and expected prices would likely cause considerable financial stress among farmers and the farm finance establishment. Second, differences between expected and actual prices are found to be much greater in the absence of competitive storage. For example, if $E_s = |E_d| = 0.4$, price in the absence of storage drops to zero. Third, as one might suppose, greater elasticities in demand and supply both act to reduce differences between expected and actual prices. Finally, storage levels are quite sensitive to elasticities, ranging from 12% to 32% of normal production.[6]

Benefit-Cost Analysis of Competitive Storage

Consider competitive equilibrium in the first period assuming that storage occurs ($I_1 > 0$) for planned expected delivery in each of $n - 1$ future periods and that $I_0 = 0$. Under these conditions, storage tends to enhance price in the first period and lower expected prices in each of the $n - 1$ future periods. Farm producers are made better off in the first period but can expect to lose benefits in future periods. Buyers, on the other hand, are made worse off in the first period but can expect gains in future years. On balance are farm producers made better off because of storage? Are buyers made better off? What level of storage maximizes the net gains to society?

In considering these questions, recall that competitive equilibrium at the first period yields determinate values for i_{1t}. By definition, $E(I_t) - E(I_{t-1}) = -i_{1t}$.[7] Using this result plus equation (3),

$$(15) \quad P^*_t = \frac{1}{\alpha_1 + \beta_1}(\alpha_0 - \beta_0 - i_{1t}) \quad \text{for } t > 1.$$

[6] In most cases, future deliveries are planned for three years or less. This plus a liberal estimate of storage cost suggest that introduction of the discount apparatus would not seriously alter our empirical results.

[7] In the first period $E(I_t) = i_{1(t+1)} + i_{1(t+2)} + \ldots$ and $E(I_{t-1}) = i_{1t} + E(I_t)$.

Let $P^*_t = P^*$ when $i_{1t} = 0$. Let $P^*_t = P^*_{tc}$ when $i_{1t} > 0$.

In figure 4, the expected demand and supply functions are given by $E(DD_t)$ and $E(SS_t)$. The area given by b measures the expected loss to producers in the tth period because i_{1t} lowers expected price from P^* to P^*_{tc}. The area $a + b$ measures expected gains to buyers. We take as the producer gain the sum of the certain gain in period one and the total expected losses from the $n - 1$ future periods. The buyer gain, on the other hand, equals the certain loss in period one plus the expected gains in the $n - 1$ future periods. The entrepreneurs in the storage industry, hereafter referred to as the arbitrageurs, earn no profit with zero storage and zero expected profit from competitive equilibrium. Explicit treatment of the gains to the arbitrageurs is nonetheless necessary in considering the net gains from storage to society as a whole.

Gains to Producers

Since first period production costs have already been incurred, producer benefits in the first period may be measured by total receipts. Let W_{P1} equal the gain in first period benefits arising out of storage, then

$$(16)\quad W_{P1} = (P_1 - P_{10})S_1 = \frac{\beta_0\alpha_1 + \beta_1\alpha_0 + V_1}{\alpha_1(\alpha_1 + \beta_1)} I_1,$$

where P_{10} equals price with zero storage and other variables are as defined previously. In this and subsequent discussion of producer and consumer gains, all endogenous variables such as S_1, P_1, and I_1 are considered equal to their competitive equilibrium values.[8]

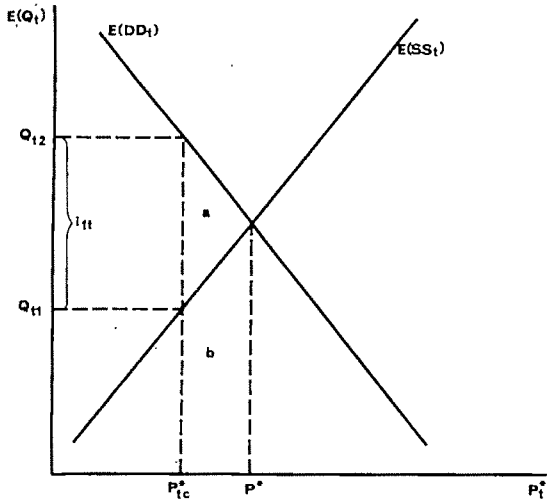

Figure 4

Let $E(W_{Pt})$ equal the expected producer loss of benefits in the tth period, then $E(W_{Pt})$ is given by the definite integral of the expected supply function in the tth period with $P^*_t = P^*_{tc}$ and $P^*_t = P^*$ the lower and upper limits, respectively. Hence, the area b in figure 4 is given by

$$(17)\quad E(W_{Pt}) = \frac{\beta_0\alpha_1 + \beta_1\alpha_0}{(\alpha_1 + \beta_1)^2} i_{1t} - \frac{\beta_1}{2(\alpha_1 + \beta_1)^2} i_{1t}^2.$$

Let $E(W_p)$ equal the producer gain in the first period minus expected losses in all subsequent $n - 1$ periods. Then

$$(18)\quad E(W_p) = W_{p1} - \sum_2^n E(W_{pt}) = \frac{\beta_1(\beta_0\alpha_1 + \beta_1\alpha_0) + (\alpha_1 + \beta_1)V_1}{\alpha_1(\alpha_1 + \beta_1)^2} I_1 + \frac{\beta_1}{2(\alpha_1 + \beta_1)^2} \sum_2^n i_{1t}^2.$$

If $V_1 \geq 0$ or if $V_1 < 0$ and $(|V_1|) \leq \beta_1(\beta_0\alpha_1 + \beta_1\alpha_0)/(\alpha_1 + \beta_1)$, then quasi rents to producers increase with storage. If demand is stable ($U_1 = 0$) and supply is unstable, storage occurs only if $V_1 > 0$. Under these circumstances, producers gain from competitive storage. If supply is stable ($V_1 = 0$) and demand is unstable, storage occurs only if $U_1 < 0$. Under these circumstances, producers also gain.

In figure 5, U_1 and V_1 are plotted on the vertical and horizontal axes, respectively. In the absence of storage $P_1 = P^* + (U_1 - V_1)/\alpha_1$. Storage only occurs if $P^* - P_1 > T$ or if $-(U_1 - V_1)/\alpha_1 > T$. These inequalities exist for any point below the graph of $U_1 = V_1 - T\alpha_1$ given by L in figure 5. Using equation (18) and figure 5, producers can expect to gain from storage for any point below L and in the first and fourth quadrants including the axes. It is only in the case of a point below L and within the third quadrant that the sign of $E(W_P)$ is incon-

[8] Although all endogenous variables may be expressed as functions of exogenous variables and of the stochastic terms, we shall for simplicity express welfare measures in terms of endogenous inventories. The fact that U_1 does not appear explicitly in equation (18) should not be taken to mean that U_1 has no effect on welfare gains (losses).

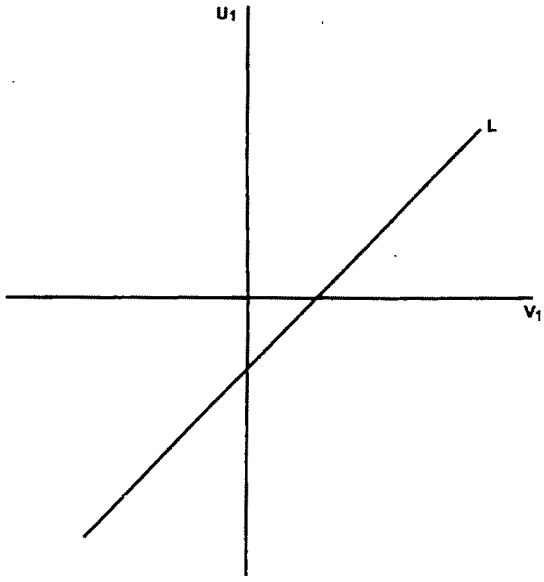

Figure 5

clusive in the absence of quantitative information. This leads to an important conclusion. Whether prior to planting time producers can expect to gain (lose) from competitive storage depends in part on the joint probability density function for U_1 and V_1. For example, if storage in practice almost always occurs because of large values of V_1, with U_1 close to zero, then it is likely that producers prior to planting in the first period could expect to gain from the existence of a competitive storage industry.

Gains to Buyers

The demand for consumption as conceptualized here is a derived demand. If the marketing margin (the difference between retail and farm gate price) is a constant, then the area to the left of the derived demand and between any two price lines gives a correct measure of Marshallian consumer surplus. Within the confines of a short-run model, however, it is unrealistic to assume a constant marketing margin. It is assumed here that the "marketing" industry, which includes the livestock sector, has the appropriate levels of fixed assets and fixed costs consistent with expected retail demand and farm output supply. The increase in marketings above normal therefore entails intensification on fixed plants and increasing marginal costs for the provision of marketing services.

In figure 6, let DD_t equal the derived demand as before. The curve S_{mt} shows the margin required to market alternative levels of Q_t. The retail demand is given by RRD_t. Subtracting S_{mt} from RRD_t vertically yields DD_t. The area to the left of the derived demand and between any two price lines equals the sum of Marshallian consumer surplus and quasi rents to the marketing sector. Thus, the shaded area, hereafter referred to as buyer benefits (losses), equals the sum of the crosshatched areas.

Let W_{b1} equal the loss in the first period caused by competitive storage. Then W_{b1} is given by the definite integral of the first period demand function with P_{10} and P_1 the lower and upper limits, respectively:

$$(19)\quad W_{b1} = \frac{\beta_0\alpha_1 + \beta_1\alpha_0 + V_1}{\alpha_1(\alpha_1 + \beta_1)} I_1 - \frac{1}{2\alpha_1} I_1^2.$$

Let $E(W_{bt})$ equal the expected gain in buyer benefits in the tth period. Then $E(W_{bt})$ is given by the definite integral of the expected demand function in the tth period with $P^*_t = P^*_{t0}$ and $P^*_t = P^*$ the lower and upper limits, respectively:

$$(20)\quad E(W_{bt}) = \frac{\beta_0\alpha_1 + \beta_1\alpha_0}{(\alpha_1 + \beta_1)^2} i_{1t} + \frac{\alpha_1}{2(\alpha_1 + \beta_1)^2} i_{1t}^2.$$

Let $E(W_b)$ equal the total expected buyer gains in periods beyond the first minus the loss in the first, then

$$(21)\quad E(W_b) = \sum_2^n E(W_{bt}) - W_{b1} = -\frac{\beta_1(\beta_0\alpha_1 + \beta_1\alpha_0) + (\alpha_1 + \beta_1)V_1}{\alpha_1(\alpha_1 + \beta_1)^2} I_1 + \frac{1}{2\alpha_1} I_1^2 + \frac{\alpha_1}{2(\alpha_1 + \beta_1)^2} \sum_2^n i_{1t}^2.$$

If $V_1 < 0$ and $(|V_1|) > \beta_1(\beta_0\alpha_1 + \beta_1\alpha_0)/(\alpha_1 + \beta_1)$, then buyers gain from storage. If $V_1 \geq 0$, it becomes difficult to determine the sign of $E(W_b)$. As in the case of producer benefits, whether prior to planting time buyers can expect to gain (lose) from competitive storage depends on the joint probability density function for U_1 and V_1.

Economic Efficiency

Though arbitrageurs cannot expect gains from competitive storage, they could expect gains (or losses) from noncompetitive storage

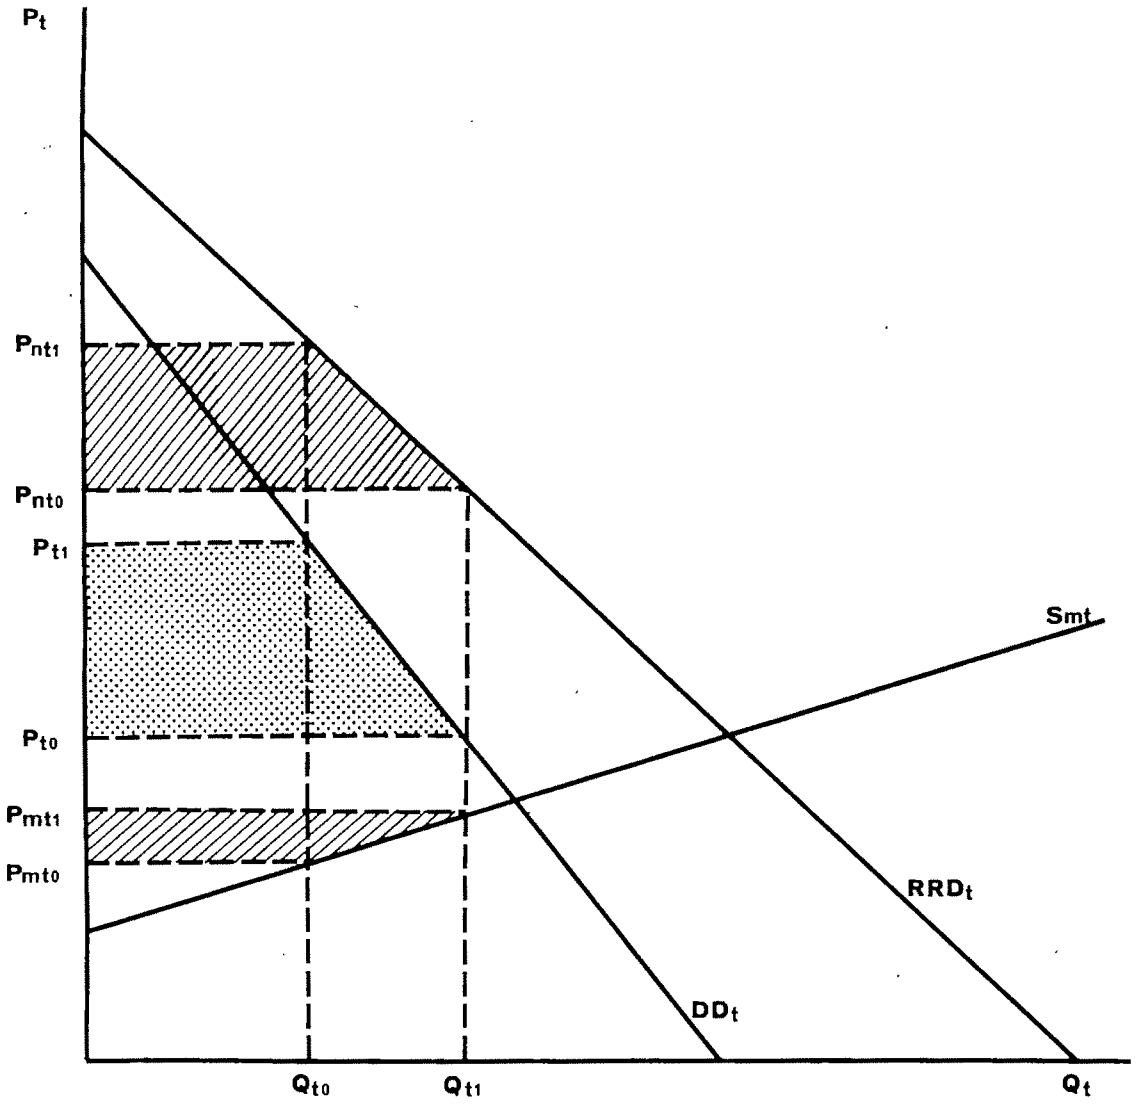

Figure 6

levels. Dropping the assumption that all endogenous variables are in equilibrium necessitates including explicitly the gains to arbitrageurs in measuring the net gains to society from alternative storage levels. Let W_s equal gains to arbitrageurs. By definition,

$$(22) \quad W_s = \sum_{2}^{n} (P_t - P_1 - (t-1)T)i_{1t}.$$

Making the relevant substitutions and taking the expectation,

$$(23) \quad E(W_s) = \frac{\alpha_0 - \beta_0}{\alpha_1 + \beta_1} I_1 - \frac{1}{\alpha_1 + \beta_1} \sum_{2}^{n} i_{1t}^2 - \frac{I_1^2}{\alpha_1} - \sum_{2}^{n} (t-1)Ti_{1t}.$$

The expected gains to producers, buyers, and arbitrageurs taken together are given by $E(W) = E(W_p) + E(W_b) + E(W_s)$ (externalities are assumed to be absent). Maximizing $E(W)$ with respect to i_{1t} subject to the constraint that $I_1 = i_{12} + i_{13} + \ldots + i_{1n}$ requires

$$(24) \quad i_{12} = i_{1t} + (t-2)(\alpha_1 + \beta_1)T \quad \text{for } 3 \leq t \leq n.$$

Using the $n - 2$ relations given by equation (24) plus the constraint $I_1 = i_{12} + i_{13} + \ldots + i_{1n}$ allows solving for i_{1t} in terms of I_1 for $2 \leq t \leq n$. Thus, for example,

$$(25) \quad i_{12} = \frac{I_1}{n-1} + \frac{\alpha_1 + \beta_1}{n-1} T \sum_{1}^{n-2} t.$$

Expressing i_{1t} in terms of I_1 allows writing $E(W)$ as a function of I_1 only. Maximizing $E(W)$ yields an algebraic expression for I_1 that is exactly the same as that obtained by solving the supply and derived demand for storage for I_1. Thus, the maximization of $E(W)$ yields a solution for I_1 and, therefore, P_1 that equals the competitive equilibrium values. Moreover, using the $n - 2$ equations given by equations (24) plus (15) yields

$$(26)\quad P^*_t - P^*_2 = (t - 2)T \text{ for } 3 \leq t \leq n.$$

Finally, since I_1 and P_1 equal competitive equilibrium values, equation (11) may be used together with equations (15) and (25) to show that $P^*_2 = P_1 + T$. Thus, the first-order conditions for the maximization of $E(W)$ are identical to those given by the competitive solution. It can also be shown that the net gain to society is given by the area under the kinky demand for storage and above the supply for storage. Graphically, this area is maximized when storage is at the competitive level.

Estimates of Distributional Impacts

Using the information given in table 1 and related figures, the welfare impacts of competitive storage are calculated for various supply and demand elasticities. The results are given in table 2. The net gains and distributional consequences are sensitive to demand and supply elasticities. Net gains to society range from $275 million to over $3 billion. Gains to producers range from $70 million to over $15 billion. Buyers only gain when supply is perfectly inelastic; otherwise, they lose. Understanding the distributional and efficiency impacts of competitive storage clearly requires precise estimates of supply and demand elasticities. Previous empirical analyses based on a single set of ad hoc elasticity estimates are suspect.

Table 2. Expected Gains to Grain Farmers, Grain Buyers, and Society from Competitive Storage in Comparison with No Storage

Benefit-Cost Analysis of Government Stabilization Programs

Three government stabilization programs are analyzed. Under the first, the government seeks to stabilize price at P^*. Under the second, the government establishes upper and lower limits on price but allows price to vary freely between those limits. The third program involves stabilization of quantity purchased. For complete and partial price stabilization, our objective is to assess the gains (or losses) to buyers and sellers under the program in comparison with competitive storage. The government is assumed to have no initial stocks.

Complete Price Stabilization

Obviously, the government is not able to stabilize price at P^* after harvest in the first period if it has no initial stocks and P_1 is larger than P^*. Of interest here is a period of abundance, the first, say, which requires the government to acquire stocks in order to force the price up to P^*. The demand for storage on the part of the government (D_{g1}) becomes perfectly elastic at the price P^* (figure 7).[9] The level of government storage equals Q_{13} and is found by the intersection of D_{g1} with the supply for storage (SI_1). The demand for storage on the part of private traders (DI_1) is no longer relevant in explaining storage levels. Traders only undertake storage if the expected price in the second period is larger than or equals $P_1 + T$.

Turning to welfare analysis, it is important to recognize that the expected price in future periods is above P^*. This is true because the government, in the absence of a budget constraint, can always assure a price no less than P^* but, because of limited stocks, cannot

[9] The specific prices and quantities given in figure 7 are not to be confused with those given in previous figures.

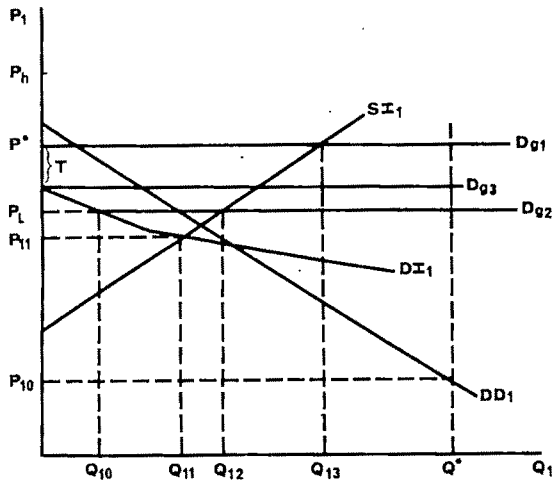

Figure 7

guarantee that price will not rise above P^*. This asymmetry poses serious theoretical complications. In what follows, these complications are avoided by assuming that the expected price in future periods is P^* and developing expressions for what might be called the minimum gain in producer benefits and the maximum consumer loss. The bias in the resulting estimates decreases as government stocks acquired in the first period increase.

In figure 7 the competitive price is P_{11} given by the intersection of SI_1 and DI_1. The first period gain in producer benefits equals $(P^* - P_{11})S_1$. Additional expected gains accrue to producers, however, because the expected losses from expected competitive deliveries in future periods are avoided. Let $E(W_{pg})$ equal the minimum expected gains to producers from complete price stabilization. Then,

$$(27)\quad E(W_{pg}) = (P^* - P_{11})S_1 + \frac{\beta_0\alpha_1 + \beta_1\alpha_0}{(\alpha_1 + \beta_1)^2} I_1 - \frac{\beta_1}{2(\alpha_1 + \beta_1)^2} \sum_{2}^{n} i_{1t}^2.$$

The last two terms on the right-hand side come from summing equation (17) over t. The conclusion is that producers gain from the government policy.

Turning to buyers, the buildup of stocks in the first period beyond competitive levels drives the first period price up and lowers buyer surplus. Moreover, the complete destruction of competitive storage eliminates the expected gains from lower expected prices in future periods. Thus, the expected gain to buyers is negative.

We maintain the simplifying assumption that expected future prices equal P^*. Letting $E(W_{bg})$ equal the maximum expected buyer losses from complete price stabilization,

$$(28)\quad E(W_{bg}) = (\alpha_0 + u_1)(P^* - P_{11}) - \frac{\alpha_1}{2}(P^* - P_{11})^2 + \frac{\beta_0\alpha_1 + \beta_1\alpha_0}{(\alpha_1 + \beta_1)^2} I_1 + \frac{\alpha_1}{2(\alpha_1 + \beta_1)^2} \sum_{2}^{n} i_{1t}^2.$$

The last two terms on the right-hand side are obtained by summing equation (20) over t.

Without going into detail, it follows from previous analysis that economic efficiency is sacrificed by the acquisition of stocks beyond the competitive level. Competitive storage implies that a bountiful year gives rise to increased expected consumption and reduced expected production, relative to normal levels, in future years. Complete price stabilization destroys these effects. This explains in part the source of inefficiency. The expected monetary gain to the government is negative. Any losses that materialize in fact are presumably made up through increased taxes.

Table 3 provides estimated expected gains to grain farmers and losses to buyers resulting from complete price stabilization. The empirical basis for these estimates is the same as for previous estimates. In particular, $U_1 = -1.8$ and $V_1 = 1.8$. For an initial period of such abundance, the distributional effects appear to

Table 3. Expected Gains to Grain Farmers and Expected Losses to Buyers from Complete Price Stabilization in Comparison with Competitive Storage

Buyers	7.378	6.868	6.453	6.101	5.807

Note: See text for explanation and interpretation.

be quite significant. For $E_s \leq 0.4$ and $|E_D| \leq 0.4$, a price stabilization program entails a transfer of benefits from buyers to grain producers of over $8 billion. Although the estimated gains and losses are very close, it should not be assumed that the efficiency loss would be of minor importance. The discounted flow of expected future costs associated with holding the government inventory in perpetuity could run into the billions of dollars.

Partial Price Stabilization

While the theoretical literature centers largely on complete price stabilization, proponents of buffer stock schemes have often favored establishment of upper and lower price limits. Let P_H and P_L in figure 7 be the upper and lower price limits, respectively. In this case, the demand for storage (D_{g2}) consists of DI_1 for prices in excess of P_L and becomes perfectly elastic at P_L. This buffer stock scheme drives price up to P_L and lowers private storage from Q_{11} to Q_{10}. Government storage equals $Q_{12} - Q_{10}$. Again, producers gain, consumers lose, and economic efficiency is decreased. Relative to competitive equilibrium, the expected price in the second period and perhaps in other future periods is increased with corresponding consequences for expected production and consumption levels.

The analysis of benefits and costs for this case involves an integration of the analyses for competitive storage and complete price stabilization. The derivation of equations for the welfare effects is straightforward and, to conserve space, is omitted. Continuing the empirical analysis, the gains to grain producers and losses to buyers, in comparison with competitive storage, are given in table 4. Again, $U_1 = -1.8$ and $V_1 = 1.8$. The price floor (ceiling) was set at 99.2¢ per bushel ($1.49 per bushel). As expected, the gains to grain farmers (losses to buyers) fall relative to those given in table 3.

Stabilization of Quantity Purchased

Subotnik and Houck (1976) consider the welfare implications of stabilizing consumption and production as an alternative to stabilizing price. Weaver and Helmberger question whether quantity stabilization on the part of the government is consistent with the existence of a competitive storage industry.[11] The concepts developed above allow a rigorous development of a contraexample in which stabilization of "consumption" (private purchases) is inconsistent with competitive market behavior. The example assumes that first period supply is a bit less than expected and demand is much less than expected such that private storage would occur under competitive conditions. In figure 7, SI_1 and DI_1 have been constructed accordingly.

Assume the government has large initial stocks and adopts a program in which the objective is to stabilize consumption at Q^*, where Q^* is obtained by equating expected demand and expected supply. Since demand is stochastic, stabilization involves price setting via buffer stock transactions. In figure 7, consumption only equals Q^* if the price is driven

Note: See text for explanation and interpretation.

[10] Our comment has elicited a reply and extension by Subotnik and Houck (1977) that modifies their original model through postulating a supply for storage equation given by $M_t = \gamma(P^* - P_t)$, where $M_t = I_t - I_{t-1}$. Their claim that the algebraic expressions for the gains to producers and consumers as developed in their original paper are unaffected by the inclusion of the supply for storage equation appears to be in error. Their proposed measure of gains to speculators also appears to be in error. Moreover, Subotnik and Houck claim that their supply for storage equation is supported by Brennan, Peck, and Working. We believe, on the contrary, that the results obtained by Brennan, Peck, Working, Muth, and others are mainly inconsistent with the Subotnik and Houck supply for storage equation. The feasibility of quantity stabilization within the Subotnik and Houck model of private storage is not so much support for the view that quantity stabilization may be operational as it is evidence of an inadequate theory. Interested readers may write to us for an unpublished note containing our arguments and proofs.

down to P_{10}. Even with large initial stocks, the government is unable to achieve its objective under the assumed conditions.

Suppose tentatively that all market participants believe the government can achieve its objective, then market price as a function of pegged consumption is given by

$$(29) \quad Q^* = \frac{\alpha_0\beta_1 + \alpha_1\beta_0}{\alpha_1 + \beta_1} = \alpha_0 - \alpha_1 P_t + U_t,$$

and $E(P_t) = P^*$. With a competitive storage industry, $P^*_2 - T = P_1$. If P^*_2 is pegged at P^* by the government, then the demand for storage on the part of competitive arbitrageurs in the first period is perfectly elastic at the price $P^* - T$ (see D_{g3} in figure 7). This being the case, the government is not able to force price down to P_{10}. If it foolishly announces that it stands willing to sell its stocks at P_{10}, arbitrageurs will be in a frenzy to buy the entire stock at P_{10}, planning to sell it all back to the government at P^* in the very next period. In addition, even more of current production goes into storage than under competitive equilibrium. Far from increasing consumption to Q^* in the first period, the government program has the very opposite effect. This example suggests that quantity stabilization schemes may not be feasible in a free market economy.

Comparison with Previous Results

As noted, the previous literature on stabilization compares the welfare effects of zero storage with those of complete stabilization (usually of price). At the assumed levels of generality, it has not been possible to predict whether producers (buyers) gain or lose from stabilization. It has been shown in the present formulation, however, that relative to the case of competitive storage producers can expect to gain and buyers can expect to lose from complete or partial price stabilization on the part of the government. Economic efficiency is also reduced in that the expected losses exceed expected gains. The quantitative example suggests that the redistributive effects increase as demand and supply elasticities decline. For an initial period of abundance, the redistributive effects could be very substantial, amounting to several billion dollars. These results stand in sharp contrast to those reached by several writers, including Reutlinger and Hillman, Johnson, and Gray.

Concluding Observations

Under conditions assumed in this paper, competitive storage leads to the maximization of net benefits. However, competitive storage is consistent with wide price fluctuations and significant differences between expected and realized prices. External costs could, therefore, be quite significant and require further study and documentation. Risk aversion could give rise to insufficient storage and presumably greater price instability. Market participants might base their expectations on poor information relative to what may be available to, say, a government board. This possibility takes on added significance if structural parameters are changing. Finally, the distribution of benefits associated with competitive storage might be objectionable.

The possibility of market failure might provide a rationale for government intervention in the form of a stabilization program. Support for such programs has become commonplace in recent years; however, it has not been based on the evidence of market failure, which rigorous policy analysis requires as a prerequisite to policy prescription. We agree with Subotnik and Houck (1976), for example, that Cochrane and Danin, among others, appear to accept price stabilization as an ultimate policy goal requiring no further analysis of the linkages between the degree of price stability and welfare consequences. With this position, we take sharp exception. A carefully reasoned paper by Robinson supports the view that the case for a grain reserve program is not so pressing as to require immediate action without the benefit of further research.

An important objective of this paper has been to pave the way for more meaningful theoretical and empirical work on the efficiency and distributional consequences of grain storage. The theoretical analysis should be extended through allowing for changing stochastic demand and supply, risk aversion, and possible externalities. Precise estimates of demand and supply elasticities are required for many purposes, including the understanding of welfare effects of storage. Measurement of the joint probability density function for U_1 and V_1 would facilitate estimation of expected values for producer, buyer, and net efficiency benefits. Such information would represent an important advance over the exploratory findings given in this paper.

The Distribution of Welfare Gains from International Price Stabilization under Distortions

Richard E. Just, Ernst Lutz, Andrew Schmitz, and Stephen Turnovsky

In a two-country model with distortions and general demand and supply functions, the welfare implications of international price stabilization are analyzed. The degree of nonlinearity of the excess demand function in the free trade exporting country as well as the distortions are found to be of crucial importance in determining who gains from stabilization. With a high degree of nonlinearity, producers in both countries as well as the exporting country as a whole lose from stabilization, whereas consumers in both countries and the importing country gain. This is contrary to previous results with linearity.

Key words: distortions, grain reserves, multiplicative disturbances, nonlinearity, price stabilization.

Some of the important distortions in international trade with agricultural commodities are tariffs, variable levies, quotas, and, for planned economies, state trading in general. With these policies, importing countries insulate their agricultural sectors from the unstable world market and achieve a high degree of price stability. By maintaining internal price stability, these countries, in effect, export their domestic instability to the exporting countries. Thus, while domestic stabilization may be attained as one of the benefits of these policies in the importing country, considerable repercussions may be realized in the form of instability in the exporting countries. The 1972–75 commodity boom, where internal Soviet and Common Market prices were artificially held nearly constant while U.S. export prices increased more than 200%, provides a good example (USDA 1974, 1976; International Wheat Council).

In view of the substantial instability that has developed in world grain markets during the 1970s, several proposals have been made for stabilizing world food prices (e.g., Hillman, Johnson, and Gray; Brookings Institution; Josling; Cochrane). All these proposals include some type of provision for setting up world buffer stocks to establish price stability. The question thus arises: who gains and who loses from stabilization? It appears that negotiations under the auspices of the World Wheat Council for implementing a world stabilization scheme are, at present, stalled partly because the issue of who gains and who loses is not clear. Would stabilization be a Pareto-superior move or would compensation be required? The purpose of this article is to analyze the distribution of the welfare gains from international price stabilization when prices are fixed by authorities in either the importing or the exporting country—the other country having a free market.

This article is an extension of the earlier work of Hueth and Schmitz, which considers stabilization in an international free trade framework, and of Bieri and Schmitz, which considers a similar issue where distortions are present. However, a major shortcoming of these papers is that linearity is used throughout. As pointed out in an important paper prepared for the World Food Conference, it is

> plausible that demand will become more elastic with the return of ample grain supplies, owing to the conversion of more grain to meat and the expansion of

Richard E. Giannini Foundation Paper No. 458. The authors would like to thank the U.S. Department of Agriculture for financial support under contract 12-17-05-8-1328-X.

consumption in poorer countries. A demand curve grown steeper at higher prices and shallower at lower prices enhances the consumer stake while diminishing the producer stake in reserves (Hillman, Johnson, and Gray, p. 8).

When considering the implications for stabilizing the prices of basic food items, it thus appears to be unrealistic to assume that demand is linear.

The introduction of nonlinearity in trade models has been exposited in an earlier paper by Just et al. However, that paper considers only free trade, whereas the present paper attempts to consider distortions that seem to be significant in international agricultural trade. Conclusions are similar to the earlier free trade results, and thus they appear to be fairly robust. The general conclusion is that producers in exporting countries prefer instability, but consumers in importing countries gain from stabilization. Exporting countries are generally worse off and importing countries are better off with stabilization, but with appropriate compensation, the world as a whole gains from stabilization.

The paper begins by conceptualizing the role of nonlinearity in determining gains from stabilization. The added complications of distortions in importing countries are also considered. Then a corresponding general mathematical framework is developed for examining the welfare impacts of stabilization on producers and consumers in both importing and exporting countries, depending on which of the four groups is responsible for the instability. The results are discussed first focusing on the exporting country, then on the importing country, and, finally, on the world as a whole. The extent to which the qualitative effects of stabilization can be reversed depending on nonlinearity is also considered.

Conceptualization

The intuition underlying the importance of the issues raised in this article is shown in figure 1, a standard diagrammatic two-country trade model with nonlinearity in demand and supply. For simplicity, consider only instability generated in the supply sector of the exporting country. Suppose supplies S'_1 and S''_1 each occur with probability 0.5 in the exporting country.[1] As shown in figure 1, D_1, S_2, and D_2

[1] Figure 1 is drawn so that S'_1 and S''_1 (and S_1) have a common origin to be consistent with the mathematical model presented later in the paper. The justification for and implications of assuming multiplicative rather than additive disturbances have been discussed by Turnovsky. It may also be noted that supply curves are drawn with some positive degree of elasticity not necessarily indicating that prices are forecast without error but merely that producer response is possible after the stabilization program is implemented.

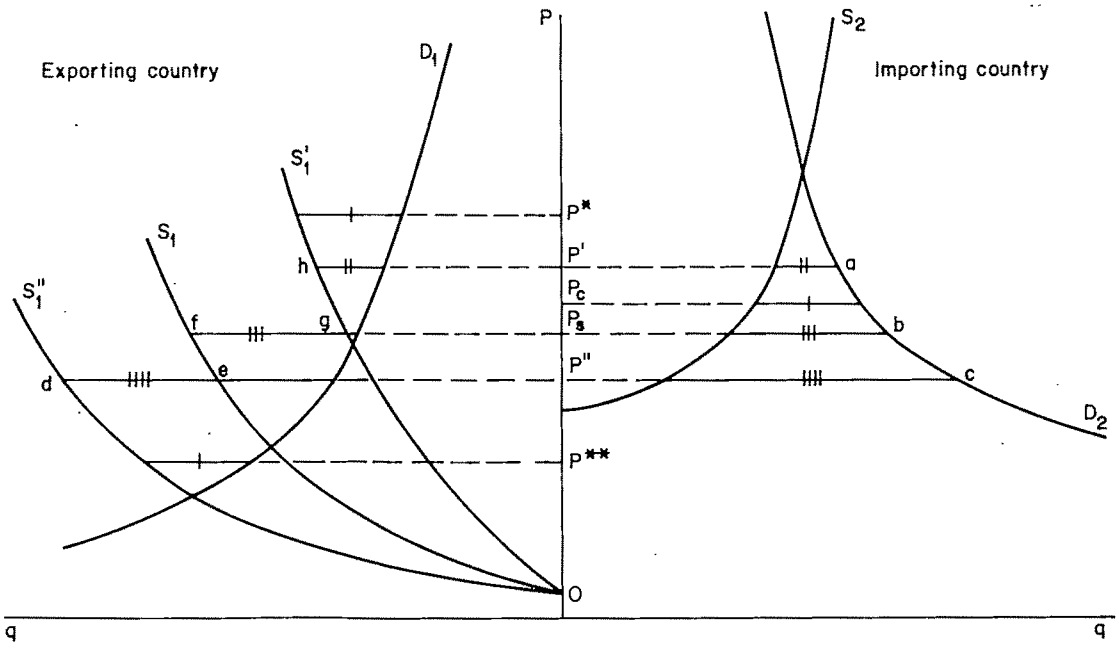

Figure 1. International price stabilization with nonlinear demand and supply functions

represent demand in the exporting country and supply and demand in the importing country, respectively. Under free trade, price P' results with supply S'_1 and price P'' results with supply S''_1. If supply in the exporting country is stabilized at S_1, however, the resulting stabilized price is P_S.[2]

Using standard surplus analysis, Hueth and Schmitz have previously shown that under linearity stabilization leads to gains for producers in the exporting country but losses for consumers in the exporting country and for both producers and consumers in the importing country.[3] However, these results can be reversed under nonlinearity for certain groups. For example, with stabilization at price P_s, consumers in the importing country gain the surplus area $P'abP_s$ when S'_1 occurs and lose the area P_sbcP'' when S''_1 occurs. With the curvature in figure 1, the area $P'abP_s$ is by visual inspection larger than P_sbcP'', and, hence, expected gains from stabilization are positive, not negative as in the Hueth and Schmitz case.

Considering the producers in the exporting country, a reversal can be obtained in this case since, in figure 1, producers lose the difference in Ode and P_sfeP'' when S''_1 occurs and the difference in $P'hgP_s$ and Ofg when S''_2 occurs. By visual inspection, the sum of these losses is positive; gains are not made as in the Hueth and Schmitz case.

Consider further the case where distortions are introduced by price fixing in importing countries. Suppose for simplicity that price P_c is imposed for both production and consumption in figure 1. In this case, excess demand is fixed and, hence, price P^* results in the exporting country when supply is S'_1; P^{**} results when supply S''_1 occurs. This demonstrates how price fixing in the importing country can export price instability to the exporting country. In the absence of stabilization policies in the exporting country, prices vary between P^* and P^{**} (with price fixing in the importing country) rather than between P' and P'' (as in the absence of price fixing in the importing country). Thus, instability in the exporting country can be increased.[4]

When price fixing is introduced, it is also clear that the welfare impacts on the various groups are changed, and the gains or losses from stabilization are modified. A diagrammatic analysis of these gains or losses becomes much more difficult with such price fixing. Thus, a mathematical analysis is pursued in the remainder of this paper.

The Model

The mathematical model used in this paper is an extension of the two-country, free trade model developed by Just et al. As in the earlier paper, the methodology is based on Turnovsky's nonlinear generalization of the Massell framework.[5]

Consider two countries, 1 and 2, having demand and supply functions

$$(1) \qquad d_i = u_i D_i(P) \text{ for } D'_i < 0 \ (i = 1, 2)$$

and

$$s_i = v_i S_i(P) \text{ for } S'_i > 0 \ (i = 1, 2),$$

where d_i is demand in country i, s_i is supply in country i, and P is price. The terms u_i and v_i denote stochastic disturbances with means $\bar{u}_i$ and $\bar{v}_i$, respectively, each having finite second moments. The producer and consumer prices in country 2 (taken to be the importing country) are assumed to be fixed by governmental policies at P^P and P^C, respectively.

Excess demand in country 1, the exporting country, is defined by

$$(2) \qquad X_1(P, u_1, v_1) = u_1 D_1(P) - v_1 S_1(P),$$

where

$$(3) \qquad \partial X_1(P, u_1, v_1)/\partial P \equiv X_{1P} = u_1 D'_1(P) - v_1 S'_1(P) < 0.$$

[2] Note that this stabilization could be accomplished by a costless storage activity, increased information availability, quotas, or other forms of government programs. If S_1 is attained by buffer stocks, then the horizontal difference between S_1 and S'_1 (S''_1) at price P_s represents the amount released (acquired) by the buffer stock authority. The area above S_1 and below P_s measures expected producer surplus in this case because it is the expectation of the areas above S'_1 and S''_1 and below price when S_1 represents the (horizontal) expectation of S'_1 and S''_1.

[3] Although the standard surplus analysis has several important shortcomings (see Currie, Murphy, and Schmitz for a useful survey), better tools are extremely difficult to apply in the detailed problem of this paper. For this reason, surplus analysis has come to be a rather standard approach in analyzing price stabilization. Hence, this approach is also used here, but the limitations should be kept firmly in mind.

[4] The reader may verify, however, that whether or not price instability is increased in the exporting country depends on where P_c is set (or, equivalently, on trade volume).

[5] However, Turnovsky (as well as the present paper) uses multiplicative rather than additive disturbances. A rather lengthy justification for doing so can be found in Turnovsky. Also, the larger the quantities involved, i.e., the larger the distance between the demand and supply functions and the price axis, the less important is the difference between additive and multiplicative disturbances.

For expositional ease, the excess demand function is assumed convex (or linear), so that

$$(4)\quad \partial^2 X_1(P, u_1, v_1)/\partial P^2 = X_{1PP} = u_1 D''_1(P) - v_1 S''_1(P) \geq 0.$$

While the assumption of convexity seems reasonably plausible, it is made largely for convenience. The subsequent results can be easily reinterpreted in the case of a concave excess demand function.

Excess demand in country 2 is defined by[6]

$$(5)\quad X_2(u_2, v_2) = u_2 D_2(P^C) - v_2 S_2(P^P).$$

Since country 1 is the exporting country and country 2 is the importing country,[7]

$$(6)\quad X_1 < 0 \text{ and } X_2 > 0.$$

Aggregate excess demand is then defined by

$$(7)\quad X(P, u, v) = X_1(P, u_1, v_1) + X_2(u_2, v_2),$$

where $u = (u_1, u_2)$, $v = (v_1, v_2)$, and

$$(8)\quad X_P = X_{1P} < 0 \text{ and } X_{PP} = X_{1PP} \geq 0.$$

It will be seen that $X(P, u, v)$ is linear in the random variables u and v. In the absence of price stabilization, the short-run market price P is determined, where

$$(9)\quad X(P, u, v) = X_1(P, u_1, v_1) + X_2(u_2, v_2) = 0,$$

the solution of which can be written in the form

$$(10)\quad P = \phi(u, v).$$

Suppose that an international stabilization authority establishes a buffer stock and is willing to buy or sell the commodity at a price P_s such that, at that price, the buffer stock is self-liquidating; that is, at the stabilized price P_s, the authorities expect the random fluctuations in u and v to even out so that, on the average, they neither accumulate nor deplete stocks of the commodity. Thus, P_s is the solution to the equation

$$(11)\quad X(P_s, \bar{u}, \bar{v}) = 0,$$

from which it follows that

$$(12)\quad P_s = \phi(\bar{u}, \bar{v}).$$

Following Turnovsky and Just et al., the welfare gains to producers are evaluated in terms of their effects on expected producers' surplus. Likewise, the welfare gains to consumers are measured in terms of their effects on expected consumers' surplus. Since numerous cases could be considered, the method is illustrated with only a single case; results are then presented for all cases.

Consider the gains from stabilization to producers in country 1 in a situation where the only random disturbance is in v_2, that is, where supply disturbances exist only in country 2. All other variables remain fixed at their respective means, $\bar{u}_1$, $\bar{v}_1$, and $\bar{u}_2$. The gains from stabilization to producers in country 1 are given by

$$(13)\quad G_1^P = \int_{P(\bar{u}_1, \bar{v}_1, \bar{u}_2, \bar{v}_2)}^{P_s(\bar{u}_1, \bar{v}_1, \bar{u}_2, \bar{v}_2)} \bar{v}_1 S_1(P')\mathrm{d}P'.$$

From Jensen's inequality, expected gains are

$$(14)\quad E(G_1^P) \gtrless 0 \text{ according as } \partial^2 G_1^P/\partial v_2^2 \gtrless 0.$$

Differentiating equation (13) twice with respect to v_2 yields

$$(15)\quad \partial^2 G_1^P/\partial v_2^2 = -v_1 S'_1(\partial P/\partial v_2)^2 - v_1 S_1\, \partial^2 P/\partial v_2^2.$$

Differentiating the equilibrium condition (9) with respect to v_2,

$$(16)\quad \partial P/\partial v_2 = S_2(P^P)/X_{1P} < 0,$$

and

$$\partial^2 P/\partial v_2^2 = -S_2^2(P^P)\, X_{1PP}/X_{1P}^3 > 0.$$

Inserting equation (16) into equation (15) yields the direction of the gains from stabilization for producers in country 1 when supply fluctuations in country 2 are stabilized:

$$(17)\quad \frac{\partial^2 G_1^P}{\partial v_2^2} = \frac{S_2^2(P^P)}{X_{1P}^2}\left[-v_1 S'_1 + v_1 S_1 \frac{X_{1PP}}{X_{1P}}\right] < 0.$$

Thus, producers in country 1 (the exporting country) always lose from stabilization of country 2's supply disturbances when country 2 (the importing country) has fixed prices. Conversely, this would imply that U.S. wheat producers are likely to benefit from destabilized production in importing countries that have controlled prices.

[6] In reality, excess demand may be somewhat responsive to prices even in such countries as Japan and those in the Common Market. However, this model is intended to provide a tractable and thus useful abstraction. In the more general case, the results would presumably be closer to those in Just et al. (which are also more ambiguous).

[7] If the indices are reversed, the model addresses the question of who gains from stabilization in a situation where the exporting country fixes prices and dumps any excess onto a free market in importing countries. This situation might apply for perishable products and for exporting countries that have no storage facilities.

Results

Calculations like those above can be performed to evaluate the welfare gains for each producer or consumer group or country from stabilization of any of the four disturbances in the model. Following this approach, table 1 has been developed to show the direction of impacts on the exporting country when price controls are imposed by the importing country. Table 2 shows the direction of impacts on various groups in the importing country where price controls are in effect.

Comparing these with the Just et al. results under free trade, in their case the aggregate excess demand function is important as far as the nonlinearity of the demand and supply functions is concerned. Under price fixing and restricted trade, however, the excess demand function of the country with a free market is the determining factor. The properties (other than location) of the demand and supply functions in the importing country where price is controlled are of no consequence.

Gains of the Exporting Country

Evidently, if disturbances originate in either the demand or the supply sector of the importing country, producers in the exporting country lose from stabilization. This is in contrast to the earlier results obtained by Just et al., where a loss is only certain for supply disturbances but where the results for demand disturbances are ambiguous.

The results for stabilization of disturbances in the exporting country are ambiguous. However, with increasingly inelastic supply, producers tend to lose from stabilization. Thus, because of price fixing by importing countries, producers in the exporting country prefer instability more strongly than under free trade.

The welfare gains for consumers from price stabilization are ambiguous in all cases. However, consumers tend to gain with an increasing level of domestic demand, an increasing elasticity of demand, and an increasing slope of domestic supply.

The exporting country as a whole unambiguously loses from stabilization if the disturbances originate in the importing country. By comparison with Just et al., a similar result is not obtained for the stabilization of demand disturbances when prices are not controlled in the importing country. In the same situation the effects on country 1 are ambiguous and depend on relative elasticities and curvatures. If domestic supply variations are stabilized,

the country loses from stabilization with increasing levels of exports and with a decreasing elasticity of supply. If domestic demand disturbances are stabilized, the country loses with increasing elasticity of demand.

Gains for the Importing Country

Producers lose from stabilization if the disturbances originate in the demand sector of the importing country or the supply sector of the exporting country. The stabilization of demand fluctuations in the exporting country produces an ambiguous result, but producers in the importing country tend to lose with increasing elasticity of demand in the exporting country. If domestic supply is stabilized, producers tend to lose with an increasing level of supply.

The distribution of the welfare gains between producers and consumers in the importing country is arbitrary in this case, since prices for both groups are fixed and since the government, which does the trading or strongly regulates trade, could also take care of the distribution of surpluses or deficits.

The stabilization of supply and demand fluctuations in the importing country and supply fluctuations in the exporting country results in welfare gains for consumers in the importing country. If demand fluctuations in the exporting country are stabilized, consumers in the importing country tend to gain with an increasing elasticity of demand in the exporting country.

The importing country gains from the stabilization of domestic supply and demand and also foreign supply disturbances. It also tends to gain from the stabilization of demand disturbances in the exporting country with an increasing elasticity of demand.

Gains of the World

In all cases the gains from stabilization for the world as a whole are positive. Thus, there are economic incentives for cooperation, since all countries and all groups within countries could be made better off with stabilization with appropriate compensation. However, since other diverse economic and political objectives are involved, the negotiations of an international stabilization scheme are complex and encounter major obstacles.

Importance of the Degree of Nonlinearity

To investigate the role of nonlinearity, note that X_{1PP} is the second derivative of the excess demand curve in the free market country; X_{1P} is the first derivative. The ratio $|X_{1PP}/X_{1P}|$ might be considered a measure of the local nonlinearity in the excess demand for country 1.[8] A similar concept might be defined for country 2. However, the degree of nonlinearity in country 2—the country with price fixing—plays no role in determining the effects of stabilization in tables 1 and 2.

Noting that $X_{1PP}/X_{1P} \leq 0$ by assumption, the effect of the degree of nonlinearity can be investigated by considering a change in the (negative) magnitude of X_{1PP}/X_{1P}. For example, consider gains for country 1 producers when demand is fluctuating in country 1. Since $(D_1^2/X_{1P}^2)v_1S_1 > 0$, a sufficiently large degree of nonlinearity (X_{1PP}/X_{1P} sufficiently small) would cause country 1 producers to lose from stabilization of u_1. Similarly, the situation of extreme nonlinearity can be examined in each of the other cases considered in tables 1 and 2 to get an idea of the effect of nonlinearity. The results of doing so are presented in table 3 along with the implied results for the case of linearity (where $X_{1PP}/X_{1P} = 0$).[9]

Reversals of impacts take place in several cases as the degree of nonlinearity is altered; whereas, in other cases, the incidence of reversal depends on the supply or demand elasticity (slope). As nonlinearity increases,[10] the country 1 effect from stabilizing internal demand (u_1) switches from positive to negative. Similarly, country 2 gains switch from negative to positive as do gains for consumers in country 2. In both the cases of stabilizing dis-

[8] The ratio is similar in definition to the Arrow-Pratt measure of local or absolute risk aversion. The properties of a function, defined by the second derivative divided by the first, are discussed extensively by Pratt.

[9] $X_{1PP}/X_{1P} = 0$ implies linearity of the excess demands. Excess demand would necessarily be linear if supply and demand are linear. However, certain situations of nonlinear supply and demand could also lead to a linear excess demand.

[10] An increase in nonlinearity implies an increase in nonlinearity of the excess demand curve for the free market country. This could result from an increase in nonlinearity in either its supply or demand.

Table 3. International Price Stabilization: Who Gains and Who Loses in Polar Cases of Nonlinearity

Impact Group	Demand Fluctuations in Country 1 (u_1)		Demand Fluctuations in Country 2 (u_2)

[a] + indicates a gain; − indicates a loss; 0 indicates no impact; and ? indicates uncertain.

turbances in country 1, the impacts on producers and consumers in country 1 may or may not switch depending on elasticities of the respective supply and demand functions. In the cases of stabilizing disturbances in country 2, few reversals occur as the degree of nonlinearity is altered. With extreme nonlinearity, all groups are affected the same (qualitatively) regardless of which disturbance is stabilized. With stabilization, producers in both countries lose, consumers in both countries gain, the exporting country loses, the importing country gains, and the world as a whole gains (assuming appropriate compensation is made).

Nonlinearity need not be unrealistically excessive to reach a reversal (from the case of linearity), at least in some cases. For example, consider the impact on the exporting country (country 1) of stabilizing demand fluctuations in the exporting country. Suppose the exporting country's supply and demand follow the popular log-linear formulation with

$$D_1 = AP^{-\delta} \text{ for } 0 < \delta < 1, \tag{18}$$

$$S_1 = BP^{\gamma} \text{ for } 0 < \gamma < 1, \tag{19}$$

and

$$X_1 = AP^{-\delta} - BP^{\gamma}. \tag{20}$$

From table 1, it is evident that a reversal is obtained if

$$2D'_1/D_1 - X_{1PP}/X_{1P} > X_{1P}/X_1, \tag{21}$$

since $D_1^2/X_{1P}^2 > 0$ and $X_1 < 0$. Inserting equations (18), (19), and (20) and noting that $D'_1 = -\delta D_1/P$, $X_{1P} = (-\delta D_1 + \gamma S_1)/P$, and $X_{1PP} = [\delta(\delta + 1)D_1 + \gamma(\gamma - 1)S_1]/P^2$, equation (21) becomes

$$-2\frac{\delta}{P} - \frac{\delta(\delta + 1)D_1 + \gamma(\gamma - 1)S_1}{P(-\delta D_1 + \gamma S_1)} > \frac{-\delta D_1 + \gamma S_1}{P(D_1 - S_1)}.$$

Finding a common denominator on the left-hand side and cross multiplying, one finds that equation (21) is satisfied if

$$S_1^2[2\gamma(\delta - \gamma) + \gamma] + S_1D_1[\gamma(\gamma - 1)\delta(\delta + 1)] \gtrless 0, \tag{22}$$

according as $\gamma S_1 - \delta D_1 \gtrless 0$. Thus, a sufficient condition for equation (21) is that

$$\gamma S_1 - \delta D_1 > 0, \tag{23}$$

$$2\gamma(\delta - \gamma) - \gamma < 0, \tag{24}$$

and

$$\gamma(\gamma - 1) - \delta(\delta + 1) < 0. \tag{25}$$

This is a reasonable possibility, since equations (24) and (25) obviously hold if $\gamma > \delta$ and $0 < \gamma, \delta < 1$. Also, $X_1 < 0$ implies $D_1 - S_1 < 0$; hence, $\gamma > \delta$ implies $SD_1 - \gamma S_1 < 0$ or that equation (23) holds. In summary, the Hueth and Schmitz result under linearity is reversed under log-linearity if the supply price elasticity is greater than the (absolute value of the) demand price elasticity in the exporting country (for the case where exporting country demand disturbances are stabilized). Hence, this case of reversal seems quite possible given, e.g., the empirical study by Sarris, who estimated for Canada supply elasticities of 0.86 and demand elasticities of −0.13 under the assumption of log-linearity.

These results emphasize the importance of econometric work focusing on the degree of nonlinearity in determining exactly who gains and who loses from stabilization and by how much. Even the qualitative effects from stabilization can be reversed as the degree of nonlinearity changes. The results suggest that, before the validity of many simulation studies on the effects of stabilization can be established, considerable econometric investigation is required to verify functional forms. This unfortunately has not been the case in the large number of such studies that have been recently forthcoming.[11]

However, these results emphasize the importance of econometric work only on free market countries, since information on the degree of nonlinearity is important in determining an appropriate policy only for those countries. Econometric work in determining the degree of nonlinearity in controlled economies is not of the same importance for stabilization policy purposes. This is a comforting result since econometric work in controlled economies is very difficult if not impossible because of multicollinearity and identification problems.

[11] A specific citation of these studies is avoided because a comprehensive list would be required for fairness (see Sarris for a partial enumeration of these attempts). Although a few such studies have examined cases of both linear and log-linear equations, this is also insufficient. For example, with a log-linear function $Z_1 = AP^{\alpha}$, one finds $Z_{1PP}/Z_{1P} = (\alpha - 1)/P$. Thus, there is little flexibility with respect to nonlinearity. The degree of nonlinearity is completely determined by the elasticity (for a given price).

Conclusions

Under free trade, with convexity of the aggregate excess demand function (Just et al.), the importing country as a whole and consumers in both exporting and importing countries tend to gain from price stabilization, whereas exporting countries and producers in these countries tend to lose, although this result was not obtained in every case. Under the price-fixing policies in the importing countries considered in this article, these conclusions are even more strongly supported.

With strong nonlinearity, producers and exporting countries (as a whole) lose, while consumers and importing countries gain from stabilization in every case. The conclusions thus support the assertion by Hillman, Johnson, and Gray that

> A demand curve grown steeper at higher prices and shallower at lower prices enhances the consumer stake while diminishing the producer stake in reserves. This calls for a dramatic reversal from policies which accumulate reserves ostensibly in the producer's interests, away from the notion that stocks acquisitions benefit producers, toward explicit recognition of the overriding consumer interest (p. 8).

However, if nonlinearity is not sufficiently strong, then the conclusions of Hillman, Johnson, and Gray may not apply. For example, under insufficient nonlinearity, country 2 producers benefit and country 2 consumers lose; and the exporting country gains and the importing country loses from stabilizing country 1 demand disturbances (u_1).

To gain more insight into the situation in the world food stock issue, one can consider the associated economic conditions. The major component of instability is generated by fluctuating supply either in importing or exporting countries. Also, agricultural supply is rather inelastic. Hence, the more relevant results where world food stocks are concerned are contained in the last part of table 3. If supply is sufficiently inelastic in these cases, the three quantities that result in uncertain impacts (last half of table 3) approach zero. Hence, the general conclusion that can be reached regardless of nonlinearity and the source of supply disturbances is that producers in the exporting country and the exporting country as a whole either lose or are unaffected and that consumers in the importing country and the importing country as a whole gain or are unaffected by stabilization. The results thus tend to explain why major exporters such as the United States are reluctant to participate in a world wheat reserves program. Judging solely on the basis of economic efficiency criteria, it seems that some type of compensation may be needed to induce major exporters to comply with an internationally coordinated reserve system or that importers should operate their own reserves. In the case of other groups and in determining the quantitative effects, however, only sufficient econometric investigation into the degree of nonlinearity can lead to valid and useful answers.

The approach used in this article does not capture all of the economic gains (or losses) that are likely to result from stabilization. It has been argued by Just and shown in rigorously developed theorems and propositions by Batra and Feder, Just, and Schmitz, for example, that a reduction in instability would result in a more efficient allocation of resources and, hence, in a higher income. Clearly, through price fixing the importing countries can capture those gains. But because of price fixing, the importing countries may be exporting their price instability to the free markets of the exporting countries, increasing the uncertainty in their economy and causing a loss in efficiency and income.[12] The size of this loss for exporting countries has not been investigated here.

[12] One can easily show that this would be the case in a two-country Massell framework. Suppose demands in country 1 (the exporting country) and country 2 (the importing country) are given by $p = a_i - b_i q + \delta_i$ for $i = 1, 2$, and supplies are given by $p = \alpha_i + \beta_i q + \epsilon_i$, where p is price; q is quantity; a_i, b_i, α_i, and β_i are parameters; and δ_i and ϵ_i are random disturbances. It can be shown that

$$\frac{\bar{\sigma}_p}{\sigma_p} = \frac{[b_1\beta_2(b_1 + \beta_1) + b_1\beta_1(b_2 + \beta_2)]^2}{b_2^2\beta_2^2(b_1 + \beta_1)^2} > 1,$$

where σ_p is the variance of price under free trade conditions and $\bar{\sigma}_p$ is the variance with price fixing in the importing country. Thus, it is evident that price fixing in the importing country actually causes a transfer of instability from the importing country to the exporting country.

A Welfare Analysis of Long-Term Forest Products Price Stabilization

Darius M. Adams, Richard W. Haynes, and David R. Darr

The prospective welfare and market impacts of federal efforts to stabilize prices of wood products are examined for two alternative strategies involving manipulating Forest Service harvest levels. Generally, these stabilization strategies yield substantial net benefits. Consumers consistently gain, while losses by stumpage producers and by end product suppliers in the South are largely offset by gains in the West.

Key words: forest policy, price stabilization, welfare gains.

The management of federal forest lands has traditionally been governed by policies oriented toward maintaining stable timber harvest levels without regard to the influence these levels have on prices and consumption of wood products. In the wake of the volatile lumber and plywood price movements of the past decade, however, there is growing interest in the potential role of public harvests in damping cyclical price fluctuations. Continued large-scale substitution of other materials for wood products has also led to pressures on federal agencies to expand harvests to retard the long-term rise in relative prices of stumpage and products. These pressures flow from the relative adverse impacts of substitutes compared with wood products. Consideration of price and market effects in the establishment of federal timber harvest policy could markedly alter harvest levels on national forest lands. Changing harvest levels, in turn, have the potential to affect the economic welfare of a broad spectrum of producers and consumers of timber and wood products.

The purpose of this article is to examine the prospective market and welfare impacts of federal efforts to stabilize prices of wood products. This examination is restricted to stabilization strategies involving only the manipulation of national forest timber supply. Perspective on the economic and policy issues involved is provided in the first two sections, which review the current role of national forests in timber markets and previous proposals for federal price stabilization programs in forestry. The third section outlines the econometric model used to simulate wood products markets under price stabilization programs. The treatment is brief, however, since the central concern here is with the market and welfare outcomes of alternative strategies. In the final sections, two specific supply-based price stabilization strategies are examined in terms of their impacts on the net economic welfare of consumers and producers, the real wealth of timber producers, payments to variable factors of production, and revenues received by public timber management agencies.

The Current Role of National Forests in Timber Markets

Since the turn of the century, the federal government has been the largest single owner of standing timber. It assumed this role at the instigation of early conservationists who advocated the development of renewable resources by the public sector for the benefit of the people as a whole (Ise). Presently, federal agencies control 21% (107 million acres) of commercial timberland in the United States (USDA Forest Service 1973). The bulk of these holdings (97 million acres) is managed by the U.S. Forest Service and contains 51% of the domestic softwood sawtimber inventory (volume of standing timber). The Forest Service sells standing timber, or stumpage, from the national forests through public auction. In 1970, more than 2 billion cubic feet of soft-

wood timber (22% of the total harvest) was harvested from the national forests.

The bulk of national forest timber (96%) lies in the Rocky Mountain and western coastal states. Because of the uneven geographical distribution of national forest lands, the influence of Forest Service harvests on wood products markets and the wood-using industry is not uniform across regions. In many areas of the West, the Forest Service is the dominant supplier of timber and has the potential to exert a strong influence on the prices of stumpage. This influence extends to the East inasmuch as shifts in western stumpage prices affect the prices of lumber and other end products in national markets.

Recent congressional legislation directs the Forest Service to manage the national forests for multiple uses in an effort to provide a broad range of goods and services in nondiminishing quantities over time.[1] Beyond this broad mandate, however, there has never been an explicit determination, nor is there any public consensus, regarding what role national forests should play in supplying the nation's wood demands. In determining harvest levels on national forest lands, the Forest Service has generally attempted to maintain a neutral posture in dealing with issues that affect either prices or the structure of the wood products industry. Although at times it has supported the argument that lower wood prices lead to lower housing costs (which would benefit a broad segment of the public), the Forest Service has never increased its harvest levels with this specific objective in mind. Similarly, in the administration of timber sales, the Forest Service has pursued its objective of securing a fair return while neither penalizing the efficient firms nor subsidizing the inefficient firms that purchase public timber.[2]

National forests in the West typically contain a high proportion of old growth timber. Inventories per acre of land for this old growth timber are higher than would be maintained in future timber stands. The reason for the number of proposals on how to schedule the harvest on national forest lands is that the old growth timber can be liquidated at various rates over time. Alternative proposals for scheduling the harvest vary in terms of the criteria used for measuring the impacts of the flow of timber from national forests. There is less debate over the scheduling method to be used to determine timber flow after the old growth has been liquidated. Growth potential after harvest of the old growth is generally referred to as the long-run sustained yield potential.

Currently, harvest levels on the national forests are established so as to produce a "nondeclining even flow" of timber over the planning period.[3] Plans are usually developed for a minimum of thirty decades and, in some cases, longer. Under the even flow policy, output is a function of the current volume and condition of the timber inventory and anticipated growth. Given these physical attributes, a fixed level of cut is calculated that can be sustained without variance to the planning horizon. Prices and potential future market demands for stumpage and wood products are not considered.

Previous Proposals

The potential impacts of national forest harvest on prices of stumpage and wood products have been recognized for many years. In the early twenties, Mason and other foresters foresaw the opportunity to relieve the perennial problem of weak and unstable lumber prices by constraining lumber supplies from public lands. Mason urgued the Forest Service and private landowners to adopt a policy of "sustained yield" in setting harvest levels. During the Depression, there was also some evidence that the Forest Service voluntarily restricted harvests to stem the decline in wood prices. In the period of rapid economic expansion following World War II, lumber prices rose steadily, prompting Gulick and others to suggest that national forest harvests might be expanded during periods of rising demand to stabilize prices. Gulick's proposal has been repeated on numerous occasions (Zivnuska, Newport) in the past decade as prices in the forestry sector have climbed sharply under unprecedented levels of housing activity.

[1] This legislation comprises the Multiple Use Sustained Yield Act of 1960, the Renewable Resources Planning Act of 1974, and the National Forest Management Act of 1976.

[2] The Forest Service has placed restrictions on the exportation of logs cut from national forest lands and has developed a program designed to set aside timber for small operators in response to congressional legislation.

[3] The National Forest Management Act of 1976 has defined the criteria for establishing harvest flows as a "quantity equal to or less than a quantity which can be removed from a forest annually in perpetuity on a sustained yield basis" (U.S. Code, p. 1610). Current Forest Service criteria are under review for compliance with the Act.

The first detailed examination of a price stabilization program was presented by Vaux in his analysis of public timber supply alternatives in the Douglas Fir region of western Oregon and Washington. Vaux concludes that the national forests of that region have sufficient inventory volumes of timber to support a program of regional stumpage price stabilization to the year 2000, with little impact on long-term sustainable harvest potential. More recently, the Forest Service (USDA Forest Service 1976) has examined a somewhat more comprehensive national program to stabilize real prices of end products. Like the Vaux study, however, the analysis focuses almost exclusively on the physical availability of timber for an agency to conduct a program of price stabilization. To date, no proposal has been examined in terms of the prospective welfare impacts of price stabilization on consumers and producers nor has consideration been given to potential interregional effects of large shifts in public harvest.

Whether a price stabilization strategy uses stumpage or end product prices as a proximate criterion is, in part, an artificial distinction, since under a given set of projected exogenous conditions, one strategy is readily translated into the terms of the other. For example, a strategy of stabilizing stumpage price increase at 5% may, under a fixed set of external conditions, be equivalent to a strategy of stabilizing end product price increase at 4%. The principal concern here is for the degree or extent of stabilization efforts. Under stumpage price stabilization, an agency sets some objective for stumpage price increase, accepting whatever increase rate that results in end product prices.

Proposals Examined

Two specific price stabilization strategies based on stumpage supply are examined in the following sections. The period of simulation analysis runs from 1975 to 2000, with strategies being implemented in 1978. In both strategies, only the levels of national forest timber harvest in the western regions are varied. National forests in the East could sustain little increase in harvest due to the lack of any significant excess volume in merchantable diameter classes. Private timber harvest varies in the analysis depending on price and inventory conditions, but no specific strategies to increase private supply are examined.

The first strategy assumes a goal of maintaining constant real stumpage prices in the western regions for the remainder of this century. In this strategy, the relative regional mix of western national forest harvests is not fixed but is set as needed to obtain the desired price levels. The second strategy attempts to maintain constant end product prices. In calculating the volumes of national forest harvest required to meet strategy objectives, we set the relative regional mix of harvest in the western regions equal to the mix found for the corresponding year under stumpage price stabilization. Thus, the two strategies differ only in the price used as a criterion.

The base for comparison with the two price stabilization strategies is a continuation of the "current" method of calculating allowable harvests. Continuation of this strategy is assumed to result in future annual harvest levels on national forest lands in the western regions that are equal to the annual harvest levels observed for the period from 1970 to 1974.

Model of the Forestry Sector

The alternative stabilization strategies are examined by policy simulations with an econometric model of the U.S. softwood stumpage, lumber, and plywood markets. An outline of the structure of the model is presented in figure 1. We estimated model parameters by two-stage least squares with a reduced number of first-stage instruments, using annual data for the period 1947 to 1974. This section describes the elements of the model in general terms. Further details of the model and its development are given in the study by Adams.

Four domestic softwood supply regions are recognized: western coastal (WC), western pine (WP), southern pine (SO), and northern.[4] Production of softwood products in the northern region is relatively minor and is taken as exogenous. Supply relations are developed for lumber and plywood from each endogenous region and for softwood lumber imports from Canada. The model does not distinguish among domestic demand regions. Thus, for a

[4] The western coastal region includes western Washington, western Oregon, and the California redwood area. The western pine region consists of all states west of North Dakota, South Dakota, Nebraska, Kansas, Oklahoma, and Texas (except for the western coastal region). The southern pine region comprises the twelve states from Virginia to Texas. The northern region comprises the remaining states north of the southern pine region and east of the western pine region.

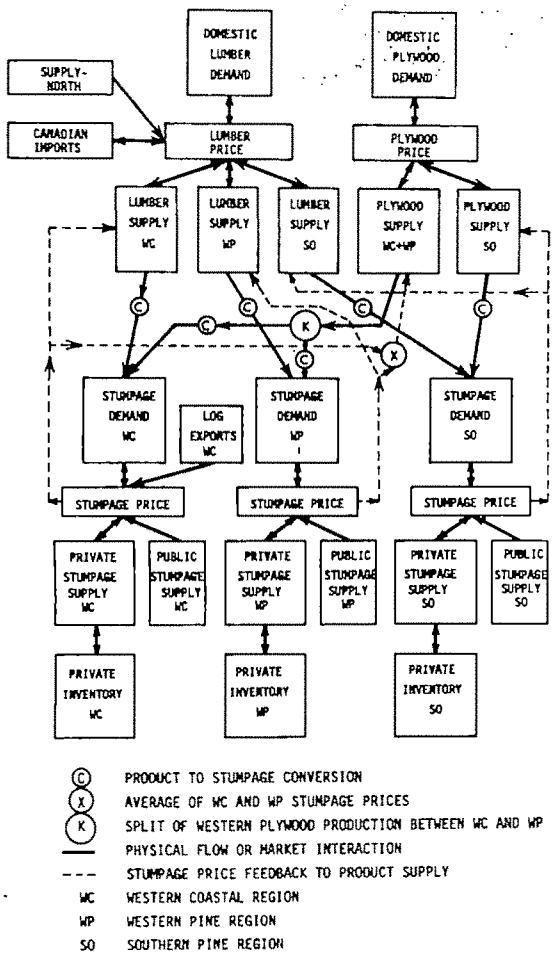

Figure 1. Structure of the model of the softwood timber market

given product, regional and import supplies are assumed to enter a single, national market where equilibrium price and volume are determined by the interaction of aggregate (regional plus import) supply and aggregate (domestic plus exogenous export) demand. Transportation costs between producing and consuming regions are not explicitly considered in the model. However, transportation costs and other factors that determine regional competitive advantage are reflected in the time-series data used to estimate the model. Thus, the model, although regionally disaggregated on the supply side, is nonspatial. Stumpage is a factor in the production of softwood lumber, plywood, and other products and is explicitly considered by our modeling the stumpage market separately for each supply region.

Demand Elements

Softwood lumber and plywood are the only end products treated as endogenous. Consumption of softwood pulpwood, miscellaneous products (such as shingles, poles, etc.), and fuelwood is considered exogenous. Harvests for these products enter the model as additional demands on regional stumpage markets.

Demand equations for softwood lumber and plywood contain variables reflecting the level and changing composition of housing and other industrial activity. These equations also contain relative price terms to account for substitution among wood and nonwood substitutes for softwood lumber and plywood.

The demand for stumpage by lumber and plywood producers in each supply region is derived by converting product output volumes to stumpage equivalents. This conversion assumes that softwood lumber and plywood are made from fixed proportions of stumpage and other inputs. Exogenous (price inelastic) components of harvest for pulpwood, miscellaneous products, fuelwood, and log exports are added to lumber and plywood stumpage demand to obtain aggregate regional derived demand for stumpage.

Supply Elements

The supply of either lumber or plywood refers specifically to regional production at the mill level. Market activities at the wholesale and retail levels are ignored, as are inventories at all market levels. Supply relations are developed for softwood lumber for each endogenous region, for southern pine softwood, and for softwood plywood from the combined western (coastal plus pine) regions. All supply relations are of the simple partial adjustment form and include the current product price, regional stumpage price, a regional wage rate variable, the price of petroleum products as an indicator of energy costs, a one-year lagged supply term, and, in the plywood equations, indicators of labor productivity. Division of western plywood output between western coastal and pine regions is taken as a function of relative production costs (stumpage and labor) in the two regions.

Stumpage supply is defined as the volume of timber made available for immediate harvest. In each region, stumpage supply is disaggregated into public and private components.

Public supply, comprising harvests on national forests and lands owned by other federal, state, and local governmental agencies, is taken as exogenous. Private stumpage supply equations relate harvest to stumpage price and private stumpage inventory. Inclusion of this latter variable assumes that harvesting costs vary inversely with the level of inventory. When inventories decline, as has been the case in the western regions, transportation distances increase, logging conditions become more adverse, and stands are generally of lower volume per acre. With increasing inventories, which is the general condition in the southern pine region, these trends are reversed. Thus, private harvest fluctuates directly with levels of private inventory. Over time, however, sufficiently large changes in price can shift harvest up or down, regardless of trends in inventories. Thus, increasing harvest in the face of declining stocks, as observed on private lands in the West, is a feasible outcome of the model.

The level of private cut determined in the stumpage market represents total product output from private timberlands. These volumes are adjusted to obtain estimates of total removals from the live timber inventory. A separate set of relations for each region adjusts private inventory for these removals, natural mortality, and growth, yielding an updated inventory figure for use in the following period. Relations describing inventory dynamics derive from work by Larson and Goforth.

Trade

Lumber exports to all countries and imports from countries other than Canada, together with plywood imports and exports, are taken as exogenous in the model. Absolute levels of these trade flows are small (less than 5% of domestic consumption in each case) and involve a large number of countries. Softwood lumber imports from Canada, on the other hand, are large (more than 20% of domestic consumption) and seem likely to grow in the future. Canadian import supply was modeled as a function of a moving average of relative Canadian and domestic lumber prices and a lagged imports term.

Measures of Program Impact

The objective of the welfare analysis in this paper is to estimate the distribution of gains and losses between consumers and producers and among consuming regions resulting from the adoption of price stabilization programs. We have followed King's suggestion in attempting to identify as many impacts as possible on the parties involved in the forestry sector. For the most part, various measures of changes in expenditures, economic surplus, and values of stocks have been employed. Such measures are incomplete and at best only indicators of actual changes in welfare.

Impacts of the price stabilization programs are measured by the effects of shifting from one discretionary supply policy to another. The impacts are measured relative to the current strategy, which represents a continuation of current methods of calculating the harvest. The prices, production, and consumption levels projected under this strategy are not those that would result from a competitive market equilibrium solution. Thus, the estimates of welfare and other impacts cannot be interpreted as deviations from some socially optimal condition. (See Currie, Murphy, and Schmitz for elaboration on the uses of competitive equilibria as optima in empirical welfare analyses.)

Estimates of welfare impacts on consumers and producers of end products are restricted to lumber and plywood and do not consider effects on pulp and paper and miscellaneous products. Errors introduced by ignoring the latter category are minor, since the volumes involved are extremely small (less than 4% of total softwood roundwood production). The pulp and paper industry, on the other hand, consumes large volumes of softwood products. However, consumer demand for paper products and producer demand for stumpage are both highly inelastic with respect to price (USDA Forest Service 1973). As a result, changes in consumers' welfare for this product group are likely to be small and positive with only limited changes in product price and volume consumed. Impacts on producers' welfare, however, may be somewhat larger, given relatively inflexible product prices and varying stumpage prices.

A similar problem arises in connection with the effects of changes in wood products prices on the consumption and production of nonwood products. An attempt is made to account for reductions in consumers' expenditures on nonwood substitutes. No satisfactory approximations were developed for the potential reduction in the producers' surplus of nonwood substitutes.

Impacts Considered

It is customary to gauge consumer welfare effects by means of shifts in consumers' surplus. (See Currie, Murphy, and Schmitz for an extensive examination of consumers' and producers' surplus and rent and their use in empirical welfare analysis and Willig for conditions under which measures on ordinary demand functions provide useful approximations of the compensatory and equivalent variations in consumer income.) Under a price stabilization program based on stumpage supply augmentation, prices should be lower and volumes consumed higher than in the absence of price control. The associated change in consumers' surplus is expected to be positive and can be measured as the change in consumer expenditures on both lumber and plywood between the current and the price stabilization strategies.

The demand for lumber has been estimated in the model, however, to be perfectly inelastic with respect to prices in the current period but to respond to a moving average of relative lumber and substitute prices in previous periods. Thus, in general, at any point after the initiation of price stabilization strategies, the lumber demand function has shifted relative to its position under a continuation of current trends. This is illustrated in figure 2, where D_0 is demand under a current strategy and D_1 is demand with stabilization strategy initiated in some prior period. Under these conditions, the change in consumers' surplus cannot be calculated, since the area between D_0 and D_1 and above P_1 is not finite. As an alternative, the change in consumer expenditures (the area $A + B - (B + C) = A - C$ in figure 2) on both lumber and plywood was calculated and used as a substitute for the change in consumers' surplus.

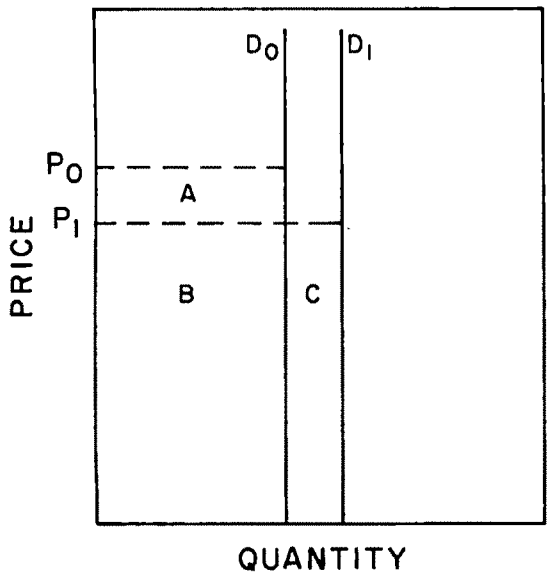

Figure 2. Measures of consumer welfare

A decline in the prices of lumber and plywood entails reductions in consumer expenditures on substitutes. McKillop argues that the increase in consumption of wood products (resulting in this case from the price control program) evaluated at the lower prices prevailing after the shift in supply is a reasonable estimate of the reduction in expenditures for substitutes (area C in figure 2). After we employ a similar approximation here, the estimate of net change in expenditures for lumber and plywood reduces to the product of the change in price and the original volume consumed in the absence of a price control program. This is area A in figure 2.

Examination of welfare impacts on producers is more complex because of the regional structure of the lumber and plywood industries and because both stumpage and end product markets are considered. Direct welfare impacts on producers of lumber and plywood have been estimated for each endogenous region by means of changes in producer surplus. Net change in national producer surplus is estimated as the sum of shifts in each region, excluding the exogenous northern region. This region produces no softwood plywood and less than 5% of total national softwood lumber output; only 1/3 of 1% of its softwood inventory is in federal ownership. As in the South, northern softwood lumber producers face lower product prices under price stabilization with no concomitant expansion in stumpage supply. Producer surplus for the northern region would probably decline, making the estimate of aggregate national change in producer surplus across all regions somewhat high.

Potential difficulties arise in the calculating changes in producers' surplus in the stumpage market, since some forest products firms produce both stumpage and end products. Integrated firms are assumed to value their own stumpage at equilibrium market prices. This eliminates possible "double counting" involved in considering both an end product and a stumpage surplus for these producers.[5] The

[5] For purposes of federal tax calculations, integrated firms are required to value stumpage cut from their own lands at "market prices."

total surplus of integrated firms is divided between processing and stumpage-growing operations.

In addition to direct consumer and producer impacts, price stabilization strategies may also lead to changes in the value of timber sales receipts to the Federal Treasury and to state and local governments. Each country receives 25% of the net receipts from national forest timber sales within the country's borders. The prices that state governments receive from the sale of timber on state lands is also affected by the change in national forest harvest. The total impacts can be computed and constitute a rough estimate of further welfare gains or losses to both consumers and producers. The exact amount of the impact on state and local governments cannot be estimated because of uncertain local, state, and federal taxation shifts included by the change in revenues.

As prices and levels of end products output vary under a price stabilization strategy, payments to the variable factors of production (including stumpage, labor, energy, and so on) also change. Measures of returns to and surpluses of stumpage suppliers have already been discussed. In both the lumber and plywood industries, the largest component of the remaining nonstumpage costs is labor.

Some estimate of returns to nonstumpage variable factors is of considerable interest, since it gives an indication of the magnitude of changes in direct payments to households. These returns have been calculated here by deducting payments to stumpage from total variable costs. The latter was computed as the area under regional industry supply curves at the various levels of projected industry output. Estimates are not reported for the southern pine plywood industry owing to the highly tentative nature of the supply relation.

The remaining producer impact considered in this analysis is the change in the value of private stumpage inventories induced by shifts in stumpage price under price stabilization strategies. Inventory valuation effects occur at all market levels under price stabilization strategies. In stumpage production, however, the effects on real wealth of producers may be substantial, since rather large volumes of merchantable timber are carried even in the most efficient operations. Under a price stabilization strategy, reductions in stumpage prices lead to an uncompensated "windfall loss" for stumpage producers, which may have some impact on their net welfare positions quite apart from gains or losses in producers' surplus. These shifts are measured as the differences between values of merchantable timber inventories with and without a price stabilization strategy.

Results

Average rates of end product and stumpage price increase over the control period are shown in table 1 for the three simulations.[6] As expected, stabilization of real prices of end products requires a reduction in real stumpage prices in the West by the year 2000. Very large stumpage price reductions are obtained in the WC region, since both stabilization strategies act to offset a sharp declining trend in regional harvest projected under the current strategy.

Because of continued expansion in end product demand and declining inventories on private lands in the West, steady increases in the Forest Service cut are required to stabilize prices in both simulations. By 2000, the Forest Service cut under the price stabilization strategy for end products is 2.8 times the cut under current strategy, but the price stabilization strategy for stumpage levels is 2.6 times higher. Substitution of public for private cut in the western regions is extensive during the first decade of attempting to stabilize prices. This serves to accelerate the expansion of private inventories in the WP region and reduces the rate of private inventory depletion in the WC region. As a result, private harvest does not decline as rapidly toward the end of the control period as was the case under the current strategy, and in the WC region private cut actually increases after 1995 after either of the stabilization programs is implemented. These developments in private cut and inventory reduce the needed expansion in the Forest Service cut between 1990 and 2000.

Production and consumption levels of the stabilization programs are indicated in table 2. Differences between the two programs are minimal. Expansion of national forest harvest in the West reduces stumpage costs, increases

[6] The simulation procedure employed to obtain the market and welfare impact estimates is as follows. First, a set of current levels for the endogenous variables is established by simulating market behavior over the simulation period for a given set of projections of the exogenous variables. These latter projections are detailed in Adams. Then, each stabilization strategy is simulated changing only the levels of Forest Service cut as appropriate for the strategy. All other exogenous variables are held constant. The resulting changes between stabilization and current simulations are taken as the effects of the shift in Forest Service cut.

Table 1. Average Rates of End Product and Stumpage Price Increase under Alternate Strategies, Target Year 2000

Price Index	Strategy		
	Current Market Procedures	End Product Price Stabilization	Stumpage Price Stabilization
	%/Annum		
Softwood lumber	1.22	—[a]	0.15
Softwood plywood	2.69	0.03	0.42
Lumber and plywood	1.46	0	0.19
Stumpage			
WC[b]	3.47	−0.80	0
WP[c]	2.88	−0.48	0
SO[d]	2.26	0.03	0.36

[a] Between 0 and −0.01% per annum.
[b] Western coastal region: western Washington, western Oregon, the California redwood area, Alaska, and Hawaii.
[c] Western pine region: all states west of North Dakota, South Dakota, Nebraska, Kansas, Oklahoma, and Texas (except for the western coastal region).
[d] Southern pine region: the twelve states from Virginia to Texas.

aggregate end product output, and allows a substantial increase in aggregate consumption. The largest increases are realized in plywood because of its higher demand elasticity and sensitivity of plywood supply to changes in costs.

Under the current strategy, the two western regions are projected to lose market share (regional production as a percent of U.S. consumption) to the southern pine region and to imports in both lumber and plywood. The WC region, which faces a major long-term decline in private harvest, suffers the greatest loss. Institution of either stabilization program sharply reverses this trend in market share for the West, with the greatest gains realized by the WP region. Production and market share continue to decline for the WC region but somewhat less rapidly than under continuation of the current strategy. The SO region faces declining product prices and no corresponding expansion of internal stumpage supply under the stabilization programs. As a result, end product output and market share in the region fall relative to expected shares under continuation of the current strategy. Under end product control, for example, SO lumber production by the year 2000 is 54% below levels for the current strategy. Although production in the region is depressed under control, it does exhibit some growth, and at no point during the remainder of the century does output of either lumber or plywood fall below precontrol (1975–78) levels.

[a] Expenditure reductions listed as positive values indicate welfare gains.
[b] Regions defined in table 1.
[c] Sum over all regions.

Results of the welfare analysis are shown in table 3 for 1980 and 2000.[7] Net welfare impacts, balancing changes in consumer expenditures and producers' surplus, are positive for both price strategies. Of the two strategies, welfare impacts are larger for the end product price stabilization strategy. Consumers gain under price stabilization throughout the simulation period, and these benefits clearly dominate the net welfare changes. Relative to the current strategy, total end product expenditures are 8% lower under the end product price stabilization strategy by 1980 and nearly 22% lower by 2000.

Changes in producer's surplus are substantially smaller than consumer expenditures and are not uniformly positive. Stumpage producers lose under both forms of price stabilization, since their prices fall with no concomitant reduction in costs. Western stumpage producers incur larger losses at the onset of control, but losses are more nearly equal between the West and the South by 2000. The critical aspects of producer impacts, however, are the nearly offsetting interregional changes in producers' surplus of end products. Western producers realize large gains as stumpage costs fall more rapidly than product prices. Southern producers, facing a similar reduction in prices but a less rapid decline in stumpage cost, suffer losses nearly as large as the gains in the West. Taken together, stumpage and end product changes yield small net losses to producers under both stabilization programs during the simulation period.

The regional pattern of changes in production and producer surplus is repeated in the estimates of returns to nonstumpage variable factors (mostly labor). Employment of and payments to variable factors decline in the South and rise in the West. The trend in net variable factor payments is essentially the reverse of that in producers' surplus. In the case of lumber, losses in the South increase more

[7] Values for intervening years trend smoothly between these two points and were omitted.

rapidly than gains in the West, yielding a declining net return, with losses greater than gains after 1995.

Net Forest Service revenues from timber sales increase under both stabilization strategies. On a regional basis, revenue increments in the WC region more than compensate for losses in the WP and SO regions.[8] Timber sales receipts by states and counties, however, decline sharply. Under price stabilization, Forest Service contributions to local governments are increased, but by less than the decline in the value of the fixed harvests from state and other publicly owner timberlands.

Under both stabilization strategies, rates of private harvest in all regions are substantially reduced and private inventories are somewhat larger than under the current strategy. These volume increments are more than offset by reductions in stumpage prices, resulting in substantial declines in the value of private inventories from current levels. Under end product price stabilization, for example, inventory value (for all regions) is roughly 40% lower than under the current policy by 2000. Total inventory values do not fall below pre-control levels, however, and do continue to increase at much reduced rates under the control programs.

Discussion

On the basis of estimated net welfare changes alone, both stabilization strategies yield substantial net benefits. Consumers consistently gain, while losses by stumpage producers and by end product suppliers in the South are largely offset by gains in the West. Thus, ignoring any concerns for interregional or interpersonal net welfare shifts, we conclude that price stabilization strategies of the form examined here would appear to offer a means of making consumers better off while producers are made at least no worse off than in the current strategy.

Both price stabilization strategies and the current strategy represent alternative courses of public action that may be undertaken beginning in 1978 and continued through the year 2000. Projected market activity under each policy represents distinct alternative developmental paths for the forestry sector.[9] The changes in welfare quantities represent potential gains or losses resulting from the selection of some developmental path other than that implied by the current strategy.

This interpretation is particularly important when one examine the interregional effects of the price stabilization programs. Under the current strategy, western industry continues to decline essentially along historical trends, while industry in the South expands production and acquires an increasing share of domestic markets. With either form of price stabilization, however, the wood cost advantage of the South is eliminated and its potential expansion in lumber and plywood sharply reduced. The welfare analysis suggests a substantial regional redistribution of potential future returns to manufacturing and variable factors of production but does not necessarily imply any major interregional migration of processing capacity or shifts in productive factors. Rather, the migration that might have occurred to the South under the current strategy is now precluded, and additional factors (capital and labor) must be attracted from other sectors to meet the projected requirements for expansion in the West. Indeed, as table 2 indicates, SO lumber and plywood output continues to expand under both stabilization strategies but at a much lower rate than under the current strategy.

The welfare analysis also suggests that real income transfers between producers and consumers are not a major effect of the price stabilization programs. Net producer welfare changes are positive after 1986, and in the period 1978–86 consumer gains are forty to seventy times greater than aggregate producer losses. This results from the inelasticity of end product demand and the relative elasticity of end product supply. Transfers between producer groups, consisting of shifts from stumpage to end product producers, are larger. Prior to 1986, stumpage producer losses exceed gains by end product suppliers, but after 1986, stumpage losses are roughly half of end product gains.

Of the several participant groups examined, stumpage suppliers are the only consistent losers under price stabilization. In all regions, stumpage prices rise less rapidly (or actually fall under end product price stabilization in the

[8] Loss of revenue in the WP region implies an inelastic demand for Forest Service stumpage, a result consistent with the dominance of public timber in this region and the lack of substitute sources.

[9] In effect, the analysis is the sort of year-to-year equilibrium evaluation of alternative policies suggested by Vaux and Zivnuska for forestry programs nearly twenty-five years ago.

West), and the real value of stumpage inventories declines relative to the current strategy. In addition to real income and wealth effects, these losses lead to two further problems of concern to policy makers. The prospect of lower stumpage prices over the next two to three decades under price stabilization reduces timber owners' expectations of the profitability of timber growing and hence the incentive to undertake more intensive silvicultural practices. Although not critical during the simulation period, growth of private inventories would decline as a result, thereby expanding potential price increases when price stabilization efforts end.

This analysis does not identify welfare impacts beyond the year 2000. Either price stabilization program would significantly reduce total timber inventories by 2000 compared with continuation of current policy. The prices of stumpage and end products after the year 2000 would probably be higher under either price stabilization program compared with current harvest policy. Although impacts were not identified beyond the year 2000, their occurrence was recognized. We further recognize that the intertemporal pattern of welfare impacts would be a factor in weighing the choice of a price control strategy.

Second, a slower increase in inventory values may pose important problems for local governments relying on real property taxation as a major source of revenue. The response to this development cannot be predicted, but one outcome might be the shifting of a greater portion of the tax burden to nonforest lands. This problem is further intensified by the projected reductions in direct timber sales revenues by state and local governments noted in table 3.

No deductions have been made in the welfare calculations to this point for the variable costs incurred by the Forest Service in accelerating harvest levels (including costs of timber sale preparation and administration, planning, etc.). Using cost estimates from a Forest Service study (USDA Forest Service 1976) and depending on what is assumed to be included in stabilization strategies in terms of efforts to increase yields, reduce environmental impacts, and other management activities, we find that annual costs might range from as low as $50 million per billion cubic feet harvested to $150 million or more as strategies become more elaborate. If increased timber harvesting costs are deducted from the estimated real income changes, both strategies still yield positive net welfare impacts, even at costs ten times higher than those noted above.

A final concern is the physical feasibility of stabilization programs, i.e., the availability of sufficient timber on the national forests to conduct price stabilization for the 1978–2000 period. Available Forest Service inventory data indicate that old growth reserves alone are adequate to support the end product program at least through 2000.

There are several unique aspects to the analysis of welfare impacts of stumpage and end product price stabilization strategies. First, the volume of timber harvested in one time period affects the flexibility of the program in later periods. The policy maker is faced with the problem of deciding how welfare impacts will be metered out over time. The effect of national forest timber management programs on future generations compared with current generations has been one of the major points of argument in current debates over national forest timber management policy.

Second, the effect on wealth from changes in the value of timber inventories is considerable. In this analysis, the annual effect of either strategy on inventory value amounts to tens of billions of dollars by 2000. Weighing this effect with income and other welfare impacts of alternative programs remains a task for policy makers and the political system.

Third, the strong differential regional effects of price stabilization programs based on manipulation of national forest harvest would probably be a major factor in congressional debates over alternative strategies. Even though the analyst can point out the welfare impacts for each region, the policy maker would have the problem of weighting interregional changes in welfare.

Finally, there are strong pressures in the current political climate against Forest Service initiation of a multidecade program to liquidate old growth timber holdings solely for the purpose of influencing stumpage and end product prices. Interest groups reflecting other forest uses such as recreation, water, and forage would undoubtedly demand a role in determining the objective of timber management. The present study, in identifying and quantifying some of the major welfare impacts, provides a first step in an objective evaluation of the relative merits of price stabilization programs.

Facilities Location: The Case of Grain Subterminals

Donald A. Hilger, Bruce A. McCarl, and J. William Uhrig

An analysis of a grain subterminal location problem within northwestern Indiana is presented. The problem is solved as a mixed integer program with Benders Decomposition, and discussion is presented on the technique. The empirical analysis concentrates upon the optimum number of subterminals within the region under different assumptions. Upon the concentration of grain in the export market, the results show that initially subterminals reduce costs somewhat regardless of location but as the optimum number is approached location becomes more critical.

Key words: Benders Decomposition, facility location, grain subterminals, mixed integer programming.

The location of facilities within a distribution network is a complex, recurring problem. This article reports on a distribution facility location model applied to the location of grain subterminals in Northwest Indiana. Early approaches to the facility location problem used mixed integer programming. It was later discovered that computational effort and cost could be reduced considerably using heuristic approaches (Elson). This has been particularly true in grain location studies (Ladd and Lifferth, Tyrchniewicz and Tosterud). Geoffrion and Graves have recently rekindled interest in mixed integer programming through the application of Benders Decomposition to specially structured location problems. The grain subterminal facility location problem presented in this paper is formulated and solved using Benders Decomposition. The advantages of the technique are pointed out. The technique should be of general interest to applied economists attempting to solve similar problems.

The study region in Northwest Indiana is a highly concentrated grain-producing area that marketed approximately 126 million bushels of corn and 33 million bushels of soybeans in 1972. Projected marketings used in this study involve 176 million bushels of corn and 47 million bushels of soybeans. The region consists of sixteen counties totaling 6,664 square miles. Currently, several new grain subterminals are being planned and built in the region. Four facilities are in various stages of construction, and two major grain companies have land options on other sites. This has led to a concern within the grain industry about the region possibly becoming overbuilt. This study was begun to investigate the optimum organization of subterminals within the region including an investigation of the factors under which the region would become overbuilt. A critical factor in the optimum organization is the access to export markets. Consequently, analysis is done under two alternative assumptions on the concentration of grain in the export markets.

Problem Formulation and Empirical Specification

The empirical analysis is based upon the following assumptions. Corn and soybeans are combined into an aggregate grain that is shipped from 124 origins through associated country elevators or subterminals, then possibly through subterminals, and finally arriving at thirteen destinations. Country elevators cannot ship to other country elevators nor can subterminals ship to other subterminals. Grain

Journal Paper No. 6727, Purdue Agricultural Experiment Station. The work was done under Research Projects 45053: "Methodological Support for Agricultural Economics Research" and 45040: "Grain Marketing." The authors wish to express appreciation for assistance to Richard Boisvert, Emerson Babb, Lee Schrader, Bruce Wright, Paul Farris, and three anonymous *Journal* reviewers for their assistance.

supply is adjusted for livestock and immediate local use. The resulting marketed grain supply is fixed by origin, on a monthly basis, as is grain demand by destination. Country elevators receive grain from local origins monthly and either store it, ship it to subterminals, or ship it to destinations. Subterminals receive grain monthly from local origins or country elevators and either store it or ship it to destinations. The analysis considers nineteen possible subterminal locations.

These assumptions lead to a mathematical programming model that minimizes total annual cost of grain movement from the local elevator or subterminal to destinations. Mathematically, the objective function is

$$(1)\quad \min \sum_j FC_j P_j + \sum_t \Big[\sum_i \sum_j C_{ijt} X_{ijt} + \sum_i \sum_k d_{ikt} Y_{ikt} + \sum_j \sum_k e_{jkt} Z_{jkt} + \sum_i b_t H_{it} + \sum_j b_t R_{jt} + \sum_i ME_{it} + \sum_j MF_{jt} \Big].$$

This function minimizes the summed annual fixed cost (FC_j) of opening each of the subterminals (j) times a zero-one variable representing subterminal status (P_j) plus the summed grain handling costs over twelve months (t).

The monthly grain marketing cost components include shipment and storage. Specifically, they are the summation of the costs (C_{ijt}) for country elevator (i) shipments to subterminals (j) times the quantity shipped (X_{ijt}) plus the costs (d_{ikt}) of country elevator shipments to destinations (k) times the quantity shipped (Y_{ikt}), plus the costs (e_{jkt}) of subterminal shipments to destinations times the quantity shipped (Z_{jkt}), plus the country elevator storage cost (b_t) times the volume stored (H_{it}), plus the subterminal storage costs (b_t) times the volume stored (R_{jt}), plus the cost of temporary (one month) storage (M) times the temporary storage used at country elevators (E_{it}) and subterminals (F_{jt}).

Empirically, the nineteen subterminal sites are the locations of four existing subterminals, nine country elevators that are likely candidates for expansion, two sites under consideration by the grain companies, and four sites chosen by the researchers considering grain density. Figure 1 gives the location of elevators and subterminals within the study region. Each of the facilities was specified with capacities for receiving, drying, loading, and storage. The fixed costs of constructing these facilities were calculated using the procedures in Baumel et al.

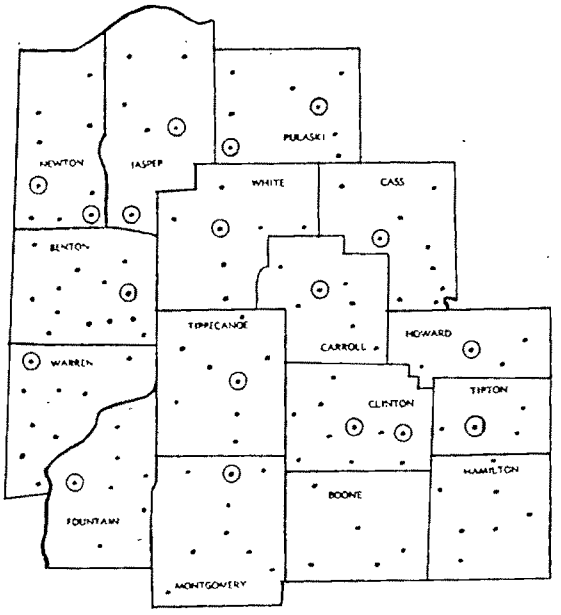

Figure 1. Locations of country elevators and subterminals

The shipment costs were found in a manner also patterned after that used by Baumel et al. and Ladd and Lifferth. Shipment costs consist of transport costs and handling costs. Transportation modes consist of truck and rail. Trucking rates per thousand bushels are $1.37 or $1.90 per mile depending on volume. Rail rates were collected from local grain companies; rates to the East Coast vary from 15¢ to 28¢ per bushel depending on volume.[1] Receiving and drying costs for grain directly from origins are assumed fixed in this study, as they do not vary significantly with the number of subterminals. Handling costs for subterminals were derived from the Baumel et al. study (2.24¢ per bushel) as were load-out costs for country elevators (2.2¢ per bushel) and subterminals (0.56¢ per bushel).

Storage costs consist of the cost of storing grain and the costs of using temporary storage. The cost of storing grain used was based upon the assumption that all stored grain is hedged. Based on a study by Gerke, the cost is fixed at zero, assuming hedging income covers storage costs.

The objective function is maximized subject

[1] Most of the soybeans are used locally, so the rail rates are based on corn shipments and involve one car, three car, five car, and one hundred car rates.

to a series of constraints. The first constraint,

$$(2) \quad \sum_t \sum_i X_{ijt} + \sum_t R_{jt} + \sum_t \sum_k Z_{jkt} \leq \beta_j P_j,$$

requires that total grain handled by a specific subterminal is zero if the subterminal is not constructed ($P_j = 0$) or a large number (β_j; $P = 1$) if the subterminal is constructed. The second constraint,

$$(3) \quad \sum_k X_{ijt} + \sum_k Y_{ikt} + H_{it} - H_{i,t-1} = S_{it} - \sum_j Per_{ijt} SS_{jt} P_j,$$

states that for each country elevator in each month total disposition of grain through shipments to subterminals (X), destinations (Y), or storage (H_t) equals grain received from origins (S) plus the previous month's storage (H_{t-1}) adjusted for the grain that would be diverted to subterminal j if opened ($Per_{ijt} SS_{jt} P_j$).

Empirically, shipments to a subterminal occur from every country elevator within forty miles. Each country elevator ships to every market and every country elevator stores grain. The supply of grain to the local elevators is determined by projecting quantities of grain marketed and then assigning this grain based on country elevator proximity, relative storage capacity, and interviews with industry personnel. The monthly marketing patterns were based upon a 1971 survey conducted by Jones, Sharp, and Baldwin.

The third constraint,

$$(4) \quad -SS_{jt} P_j - \sum_i X_{ijt} + \sum_k Z_{jkt} + R_{jt} - R_{jt-1} = 0,$$

insures that grain disposition is equal to grain inflow at subterminal j during month t. Outflows of grain are shipments to destinations (Z) plus storage (R). Inflows are direct receipts from origins ($SS \cdot P$) plus shipments received from country elevators (X) plus last month's storage (R_{t-1}). Farm receipts of grain are assigned to subterminals in the same fashion as grain is assigned to country elevators. Requiring that

$$(5) \quad \sum_i Y_{ikt} + \sum_j Z_{jkt} = D_{kt}$$

insures that grain received during month t at market k equals demand. Grain receipts consist of direct shipments from country elevators (Y) plus shipments from subterminals (Z).

Empirically, grain demand equals projected grain supplied. The thirteen destinations were aggregated from Jones, Sharp and Baldwin. Grain is allocated to these destinations under different assumptions about exports. The destination locations and their quantities are given in table 1. Monthly assignments were also based upon Jones, Sharp, and Baldwin. The relationship

$$(6) \quad H_{it} - E_{it} \leq Q_i$$

insures that monthly storage used at a country elevator (H) is less than or equal to storage capacity (Q) plus temporary storage (E). Temporary storage is most analogous to piling grain on the ground. The cost incurred and incremental capacity are for one month only. Storage capacity at the country elevators was specified by data obtained from the Indiana Grain and Feed Association. Finally, a sub-

[a] Grain marketed from the sixteen-county study area.

terminal's storage is limited by

$$-V_jP_j + R_{jt} - F_{jt} \leq 0. \tag{7}$$

In this constraint, fixed storage capacity (V) is a function of whether the subterminal is constructed or not.

As the model is specified, there are 19 potential subterminals, 105 country elevators, and 13 final destinations. The model is solved for one year with each of the twelve months included. This led to monthly grain shipment models with 2,371 transport activities, 124 storage activities, and 299 constraints. The resultant annual problem had 19 integer zero-one variables, 31,656 continuous variables, and 3,588 constraints.

Problem Solution

The problem as presented and formulated above is a large mixed integer program that was not solvable on the software readily available. The approach to the problem therefore necessitated the development of a solution strategy. The solution strategy used is based upon the technique of Benders Decomposition. Benders develops a technique that, in optimizing a mixed variable programming problem, decomposes the problem into two separate problems. Global optimality of the overall problem is attained through the use of dual information. In general terms, the approach is iterative, where a solution is proposed by a master problem then tried in the subproblem, which returns dual information to the master problem. The master problem then chooses a new solution based upon the duality information of this and all previous subproblem solutions. The new master problem solution is then returned to the subproblem and the iterations proceed. Termination of the procedure occurs due to bounding conditions. At each iteration involving the master problem the procedure gives a best possible objective value that could be found, and at each subproblem iteration the actual objective function value is computed. These outputs yield a monotonically nonincreasing bound spread, indicating to the researcher the maximum difference from optimality. These topics are discussed further in the appendix.

The application of Benders Decomposition to the grain problem leads to a master problem that consists of the integer-subterminal location variables with one new continuous variable and a subproblem that consists of the grain shipment and storage problem given known subterminal locations.

The master problem objective is given by

$$\min \sum_j FC_jP_j + Z_o, \tag{8}$$

which consists of the fixed cost of subterminal location plus the predicted cost of the subproblem (Z_o). The predicted subproblem cost is gained through the addition of constraints to the master problem, which are given by

$$Z_o \geq \sum_j \alpha_j^l \beta_j P_j + \sum_t \Big[\sum_i \gamma_{it}^l (S_{it} - \sum_j Per_{ijt} SS_{jt} P_j) + \sum_j \psi_{jt}^l SS_{jt} P_j + \sum_k \sigma_{kt}^l D_{kt} + \sum_i \xi_{it}^l Q_i + \sum_j \theta_{jt}^l V_j P_j \Big]. \tag{9}$$

These constraints occur for each solution l of the subproblem that has been done and effectively state that the predicted value of the subproblem is greater than or equal to the shadow prices from the subproblem times its right-hand sides. The right-hand sides, however, are affected by the subterminal location variables. The term α_j^l gives the shadow price for changes in the right-hand side of relation (2) and β_jP_j is the right-hand side passed to the subproblem when the subterminal locations have been chosen. Thus, the term $\sum_j \alpha_j^l \beta_j P_j$ gives the predicted contribution of the constraint on subterminals to the objective function of the subproblem. Similarly, γ_{it}^l is the shadow price from the lth solution of the elevator relationship (3), and $S_{it} - \sum_j Per_{ijt} SS_{jt} P_j$ is its right-hand side. The variables ψ_{jt}^l, σ_{kt}^l, ξ_{it}^l, and θ_{jt}^l are the shadow prices for relationships (4) through (7), respectively. Thus, relationship (9) states that Z_o is greater than or equal to the dual objective of the subproblem, i.e., the right-hand sides times the shadow prices over each subproblem solution. Since Z_o is minimized by the objective (8), it is equal to the best prediction of the subproblems objective. Thus, the master problem equations (8) and (9) represent the overall original problem.

This decomposition then creates two problems that must be solved iteratively.[2] The iterative procedure is: (*a*) choose a set of subterminals, (*b*) solve the grain distribution and

[2] This iterative procedure differs from previous heuristic approaches in that the procedure starts with an initial solution and generates multiple solutions in an optimizing sequence. Thus, a heuristic solution could be used as a starting point, and it could be improved upon.

storage problem, (*c*) form an equation like equation (9) and add to subterminal selection problem, (*d*) solve the subterminal selection problem, and (*e*) take the new set of subterminals and go to (*b*). This procedure continues until the predicted and actual outcomes converge to a degree acceptable to the researcher.

Problem Simplification

Following the application of Benders Decomposition, the two problems created are an integer programming problem with nineteen zero-one variables and a variable number of constraints and a linear programming problem with 31,656 variables and 3,588 constraints. The linear problem is a network problem and would be solvable by special purpose network algorithms (Bradley; Fuller, Randolph, and Klingman) or large linear programming algorithms (Barnes and Crisp). However, these were not available, and a simplification was made. The month-to-month grain distribution problems are connected by the storage variable. This study separates the problem into twelve separate problems, where the storage at time $t - 1$ is taken as given at t. The model thus moves forward in time without backward linkages.[3] Storage in a month is not affected at an elevator by the shipping pattern in succeeding months. This assumption removes guarantees of optimality and leads to solutions where future demands are not considered in current shipping patterns. The assumption may be as realistic as the total model solution wherein an elevator would plan its shipments with perfect knowledge of all twelve months' future demands.

Results

The principal empirical objective of this study is to obtain an optimum subterminal organization. This was done through the solution of a subterminal location problem. Two versions of the problem are analyzed. The versions differ due to assumptions on export demand.

High Exports

Solution of the high export subterminal location problem is accomplished in seventy-nine iterations of the algorithm given above.[4] During these iterations several proposed solutions were entered by the researchers, so the algorithm did not function exactly as presented. An overview of the algorithm performance is given in table 2, which presents the current objective function value, the best found so far, and the bound spread (difference between the best found so far of equation (1) and the current best prediction (8) at selected iterations). At each iteration a feasible set of subterminal locations and grain movements is generated. The algorithm is terminated when the bound spread reaches a point where it amounts to 3.4% of the current objective function value. This indicates that the best improvement in the objective function would amount to no more than 3.4% of the current objective function value. The researchers felt this to be well within the errors in data.

Table 2. Algorithm Performance by Iteration

Iteration	Objective	Best Objective So Far	Bound Spread
1	37,442,620	37,442,620	8,276,847
2	34,668,973	34,668,973	3,121,173
3	33,984,361	33,984,361	2,436,561
5	33,547,882	33,547,882	1,905,887
10	34,779,272	33,547,882	1,800,499
20	33,461,270	33,421,868	1,681,307
40	33,620,552	33,421,868	1,579,188
60	33,277,868	33,245,424	1,282,498
79	33,195,294	33,195,294	1,130,208

The high export problem solution indicates that five additional subterminals should be constructed in the study region. The total annual system cost is $33.2 million, which reflects an annual savings of $400,000 from the existing four subterminals and $4 million from zero subterminals. The majority of the subterminal construction involves the expansion of existing country elevators. The subterminal system selected and the grain flows to these sites are given in figure 2. In this solution, subterminals handle 69 million of the 233 million bushels of grain. The subterminals ship 67 million bushels to the coast (Baltimore and Norfolk), fulfilling these export destinations orders completely. The remainder of the subterminal grain flows principally to Canton,

[3] The same sort of assumption appears to be used in Ladd and Lifferth as they solve with one-month planning models.

[4] The approximate computer cost is $4,000. This attempt is the authors' first use of Benders Decomposition and was unnecessarily costly. The authors feel the cost could easily be reduced more than 90% through the suggestions discussed later involving fewer time periods, a priori constraints, and optimizing with a network algorithm.

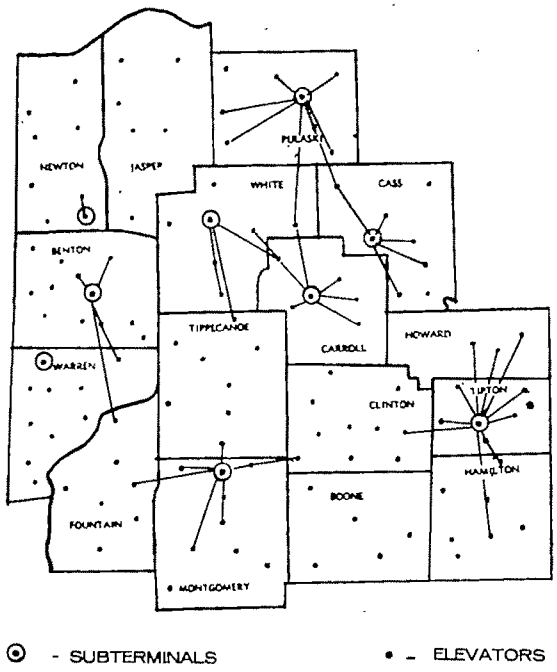

Figure 2. Subterminal placement and grain movement from elevator to subterminal under high export assumption

Georgia (1 million bushels), and Dayton, Ohio (1 million bushels). Country elevators handle 164 million bushels and ship directly to the remaining destinations.

One of the subterminal sites selected in this study was being considered by a major grain company. Subsequent to this study, a subterminal is under construction at this site.

A further concern leading to this study is the possibility of overinvestment in subterminals. Table 3 presents data summarizing all seventy-nine iterations, where the results are grouped by the number of subterminals in solution. The data give the number of observations with a given number of subterminals, the best objective found, the mean of the observations with this number of subterminals, and the standard deviation. These data are presented both in total dollar cost and in cents per bushel.

Several observations may be made on the data in table 3. These observations must be interpreted cautiously, as there are 2^{19} possible locational solutions, and the study only examined seventy-nine. Furthermore, these seventy-nine were part of an optimizing sequence and were not randomly drawn. However, trends emerged that can be pointed out. First, the difference between no subterminals and any subterminals is approximately 1.25¢ per bushel, indicating that subterminals offer significant savings in the grain marketing system. Second, the difference between five and nine subterminals in the region is on the order of 0.2¢ per bushel, indicating a fairly flat total cost curve. Third, the mean of the total cost decreases as the subterminal numbers are increased (within a relevant range), indicating that more subterminals generally reduce the total cost regardless of location. Finally, the standard deviation reaches a minimum at seven subterminals, then increases as more are added, indicating the location becomes more critical as optimality is reached.

In addition to this general overview, an entire solution of the problem is present at each iteration for all of the variables presented above. Further discussion of the results is presented by Hilger. A detailed analysis of the flows and temporary storage indicates other possible subterminal sites. One of these sites is on the fringe of the study region and is currently being considered by one of the large grain companies.

Table 3. Solutions by Number of Subterminals Present

Number of Terminals	Number of Solutions	Best Objective	Cents/Bushel	Mean Objective	Cents/Bushel	Standard Deviation	Cents/Bushel

Low Exports

Under the low export assumption, seven runs are made to analyze the situation. This analysis is much briefer, as it draws upon the numerical and practical experience gained in the high export analysis. The final low export solution consists of three additional subterminals with a total system cost of $33.9 million (or 14.5¢ per bushel) with a bound spread of $1.32 million or 3.9%.[5]

The solution and grain movement is portrayed in figure 3. The solution represents a cost savings of $3 million from the zero subterminal case and a savings of $400,000 from the nine subterminals found to be optimal in the high export solution. Grain generally flows in the same pattern from the country elevators, although the elevators in the Tipton region tend to ship to Louisville rather than to a subterminal. The grain subterminals handle 53.2 million bushels. Grain shipments involved 47 million bushels to eastern exporters, 3 million to Memphis, Tennessee, and 1.3 million to Dayton, Ohio. The results on overbuilding seem to be consistent with the general trends observed in the high export case.

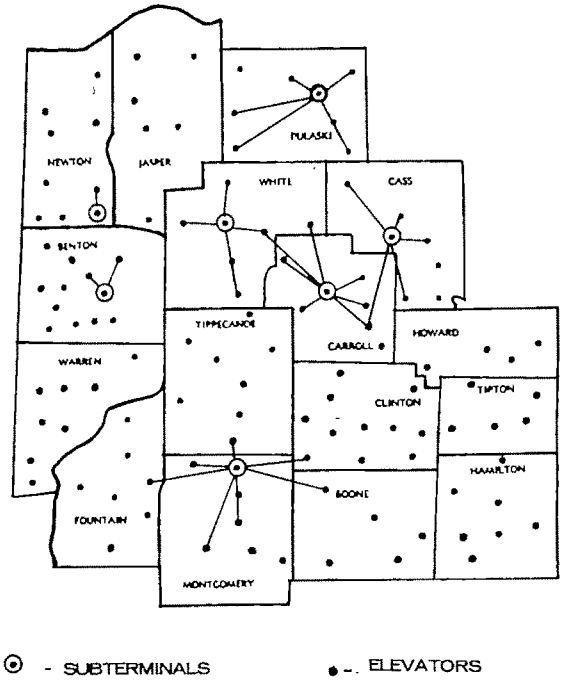

Figure 3. Subterminal placement and grain movement from elevator to subterminal under low export assumption

Concluding Remarks

This article has presented an analysis of a grain subterminal location problem. Details on a formulation, solution algorithm, empirical specification, and solution were presented. General trends were observed with respect to grain subterminals. Summarizing, total cost was significantly affected by the construction of subterminals with annual cost savings accruing to the study region as high as $4 million or 2¢ per bushel. Currently, the region does have four subterminals, and the addition of more subterminals could lead to a further savings of $400,000 or 0.2¢ per bushel. A reasonable amount of subterminal construction appears to yield a cost savings to the region regardless of location. However as an "optimum" number is reached, location becomes a more critical factor.

The specific numerical results of this study should be viewed with caution. In a cost-minimizing framework, subterminals should not be located in close proximity. However, in the real world other factors, both noneconomic and economic, may dictate different arrangements. An encouraging fact, relative to the specific results of this study, is the initiation of construction of a subterminal on one of the sites recommended. Another subterminal is also being considered in a fringe area (to the study region), which detailed model storage analysis indicates is an area where a subterminal could possibly be constructed. There is much detailed information available from the model that is not reported here. In addition, many questions such as rail line abandonment or the effect of new markets may be studied with the model proposed.

Methodologically, this study used Benders Decomposition to solve a large mixed integer programming problem but lost guarantees of optimality through a model simplification. The solution of the high export problem was very costly; however, with the experience generated the low export problem was solved more easily. If the study were to be repeated, the time dimension would probably be aggregated to fewer periods, and the model solved in an optimizing manner. The Benders approach has several advantages over traditional heuristic procedures. Specifically, the heuristics fre-

[5] Computer cost for the low export solution is approximately $200.

quently require detailed implementations for a particular problem (see Ladd and Lifferth, appendix, for example). The Benders procedure used standard mixed integer and linear programming routines with a small interfacing procedure. Benders Decomposition is an attractive solution algorithm and allows quite large mixed integer problems to be solved.

The use of Benders Decomposition allows the researcher to combine judgment with the solution methodology. Experience with the technique by others (such as Danok, Polito, and Geoffrion and Graves) has shown that judgment factors such as the choice of initial starting points, the imposition of a priori constraints on practical settings of integer variables,[6] and the proper choice of solution tolerance lead to faster solutions. The algorithm is applicable to the whole class of facility problems and has been used with machinery selection (Danok) and spatial equilibrium problems (Polito).

From a policy viewpoint, the results of this study seem to present three items of interest. First, the savings due to subterminals are highly dependent upon the rail rate structure and the export market. If the rate differential for unit trains was reduced, much of the attractiveness of subterminals would vanish. Similarly, reduction in exports would dampen the demand for subterminals. However, neither change might not remove the subterminals as they do provide a valuable storage function.

A second item of policy interest concerns overbuilding a region with subterminals. Our numerical data show that, if all subterminals possible in the region were constructed, compared with no subterminals there would be an annual cost savings of approximately 3 million under high exports or 1.3 million under low exports. Compared with the best combinations of subterminals found, if all nineteen subterminals considered were built there would be a loss of 0.8 million with high exports or 1.8 million with low exports. Thus, overbuilding is a less serious problem than underbuilding, although if export demand is projected to drop overbuilding will be of concern.

The third item of policy interest is the approach itself. The study region considered here is relatively small, and the results are location specific. However, the questions asked are common to many regions and the approach used herein appears to be an attractive way of answering such questions.

[*Received November 1976; revision accepted June 1977.*]

[6] An example of this would be to preclude two subterminals that would serve the same region or to impose an absolute limit upon the number of subterminals constructed.

Appendix

Basic Benders Decomposition

In 1962 Benders developed a mathematical procedure for solving mixed variable programming problems where the variables fall into two sets. A common application of this is mixed integer programming. We briefly review Benders Decomposition below.

The general mixed integer problem can be written in matrix notation as

$$\text{(A.1)} \qquad \min C_1Q + C_2P$$

subject to

$$\text{(A.2)} \qquad A_1Q + A_2P \leq b$$

and

$$\text{(A.3)} \qquad Q \geq 0 \text{ and } P = \text{a vector of nonnegative integers.}$$

This problem may be rewritten as

$$\text{(A.4)} \quad \min \left\{ C_2P + \min \left[\begin{array}{l} C_1Q \\ \text{subject to} \\ A_1Q \leq b - A_2P \\ Q \geq 0 \end{array} \right] \right\}$$
$$P = \text{a nonnegative integer}$$

This version of the problem says that the optimum value of P and Q from equations (A.1) to (A.3) can be found as the simultaneous optimum of C_2P and the optimum value of the bracketed part given P.

Using linear programming duality, the dual of the bracketed part of equation (A.4) is

$$\text{(A.5)} \qquad \max -U'(b - A_2P)$$

subject to

$$\text{(A.6)} \qquad -U'A_1 \geq C_1$$

and

$$\text{(A.7)} \qquad U \geq 0,$$

and equation (A.4) may be reformulated as

$$\text{(A.8)} \quad \min \left\{ C_2P + \max \left[\begin{array}{l} -U'(b - A_2P) \\ \text{subject to} \\ -U'A_1 \geq C_1 \\ U \geq 0 \end{array} \right] \right\}$$
$$P = \text{a positive integer}$$

This reformulation by itself is just a change of variables. Through the duality theory of linear programming, the two problems clearly have the same solutions. The key to Benders Decomposition, which exploits equation (A.8), is the observation that the feasibility (not optimality) of the dual vector in equations (A.5) to (A.7) does not depend on P. Consequently, every possible dual vector is an eligible solution regardless of the setting of the integer variables. Using these facts, the operational Benders procedure involves the iterative solution of two problems.

The master problem is given by

$$\text{(A.9)} \qquad \min C_2P + Z_o$$

subject to

$$\text{(A.10)} \qquad Z_o \geq -U'_l(b - A_2P) \text{ for } l = 1, 2, \ldots, n$$

and

$$\text{(A.11)} \qquad P = \text{a nonzero integer, } Z_o \text{ is arbitrary.}$$

The subproblem is given by

$$\text{(A.12)} \qquad \min C_1Q$$

subject to

$$\text{(A.13)} \qquad A_1Q \leq b - A_2P$$

and

$$\text{(A.14)} \qquad Q \geq 0.$$

The master problem contains the integer variables and an additional variable Z_o, which is constrained by the relation (A.10) to be greater than or equal to the dual objective function value (A.5) obtained from each of the sets of feasible dual vectors.

Thus, Z_o is the predicted best value of the dual objective and the numerical value of equation (A.9) is the best predicted value of the original objective (A.1). The prediction is perfect if one of the dual vectors U_l corresponds to the true optimal solution X in the subproblem. To guarantee this in general would require all possible dual vectors to be present. This is computationally intractable. Thus, the iterative procedure is employed to successively generate dual vectors. Formally, the algorithm is: (*a*) select an initial set of integer variables P, (*b*) solve the subproblem and obtain a dual vector, (*c*) form a constraint (A.10) and add it to the master problem, and (*d*) solve the master problem. Obtain a new set of integer variables and go to (*b*). The algorithm iterates with the master problem, growing by one row at each iteration. The master problem slowly "learns" about the subproblem by building up its stock of information.

At each solution of the master problem, the objective function value (A.9) gives the best solution value that could possibly be found. Over the iterations this forms a monotonically nondecreasing set of lower bounds. At each solution of the subproblem, the actual value of equation (A.1) may be calculated. By taking the minimum value found as the iterations proceed, a monotonically nondecreasing set of upper bounds is obtained. Information is yielded upon the maximum difference from the true optimum at each stage. This provides the user with an easy way to establish a stopping rule and a continual check upon the maximum difference from optimality.

Unemployment Insurance, Estimated Cost Rates, Benefits, and Tax Burden by Type of Farm

Joachim G. Elterich

Unemployment insurance cost rates for newly covered employers and the corresponding tax burden under two sets of tax structures by type of farm are estimated by state. Livestock, dairy, and poultry farmers generally more than support the benefits their workers receive, which is not the case for fruit and vegetable farms. Under experience rating livestock and dairy farms tend to pay the minimum rate in half the states, while the maximum rate applies for fruit and vegetable farms in many states. Benefits received by workers vary also by type of farm and state and tend to be related to the cost rate.

Key words: agricultural labor, benefit payments, costs, unemployment insurance.

The unemployment insurance (UI) system collects taxes on the payrolls of covered employers while employees are working and pays benefits to eligible employees who become involuntarily unemployed.[1] The system is administered cooperatively by federal and state agencies. Federal provisions set minimum basic coverage provisions, qualifying requirements, and taxing procedures. The states' provisions must meet these minimum federal standards to obtain federal assistance and rebates on UI taxes; however, the states are free to exceed federal standards in determining their own particular eligibility requirements and dollar benefit amounts.

Only former employees of covered employers can receive compensation from UI. A covered employer is one who is subject to payment of UI taxes under the Federal Unemployment Tax Act. Covered workers who meet the qualifying requirements are classified as insured workers.[2] However, to receive benefits, a worker must not only meet the qualifying requirements but must have had one or more weeks of compensable unemployment.[3] A worker who meets the qualifications and has at least one week of compensable unemployment is classified as an actual beneficiary. Total actual benefits received by a worker are the product of the weekly benefit amount and the number of weeks of compensable unemployment. Both are subject to limitations and formulae linking employment duration and/or earnings to benefits under the individual state's provisions.

Currently, agricultural workers in all states are temporarily covered under the Special Unemployment Assistance Act of December 1974. Farm coverage was not included in the Employment Security Act of 1970 (PL 91-373). Instead, the Act mandated a "program of research to develop information . . . as to the effect and impact of extending coverage to agricultural labor." The resulting research was undertaken by the Regional Research Committee of NE 58, composed of agricul-

Joachim G. Elterich is an associate professor in the Department of Agricultural Economics, University of Delaware.

Published with approval of the director of the Delaware Agricultural Experiment Station as miscellaneous paper No. 788, University of Delaware, Newark. The author acknowledges with gratitude the critical comments on an earlier draft by Bernard Erven, Ohio State University, Raymond C. Smith and Susan Brodsky, University of Delaware, and two anonymous reviewers. The forereaching assistance by former graduate assistant Daryl K. Petty and Linda Graham, programmer-analyst, is also gratefully acknowledged. The author recognizes the permission to use original survey data for all the states cooperating in the NE-58 project entitled "Economic and Sociological Study of Agricultural Labor in the Northeast States" and its successor NEC-21; both provided the wherewithall for this research.

[1] In New Jersey (along with two other states), workers also pay a 0.25% payroll tax.

[2] A worker is considered insured if he has worked sufficient weeks and/or earned sufficient wages (or specified distribution of them) in covered employment during the record year to demonstrate adequate attachment to the labor force under the states' regulations.

[3] A week of compensable unemployment is a week in which a worker is involuntarily unemployed, is available for work on a job of the same or similar nature to that in which he is usually employed, or is able to work and has made a valid claim for benefits.

tural experiment station researchers in twelve states. This interregional unemployment insurance research project initiated surveys of agricultural employers and employees designed to collect the information necessary to estimate the costs of extending UI coverage to hired agricultural workers in the twelve northeastern states and Ohio, Florida, and Texas.

One of the main reasons mentioned as a source of variation in the cost rates among individual states is the differences in the predominant types of farms among the states. In this article the cost rates by type of farm (congruent with the census definition) are estimated using the data collected in the NE project and the UI provisions in effect in 1971. An objective of this study is to determine the average UI tax burden that a farmer actually would experience. The tax burden is determined on the basis of two sets of tax rates established by the states in 1975: one for newly covered employers and the other based on each farmer's experience rating. In addition, the benefits paid to employees are estimated for 1971.

Methods

The cost rate is defined as the ratio of workers' benefits to their taxable wages. This study uses workers' actual employment histories in 1969–70 obtained from the NE 58 study with the exception of Texas. (For more detail on the survey procedures, see Bauder et al., chap. 1 and appendices I–V.) A worker's benefits are determined based on individual state's qualifying and benefit determination statutes in effect July 1971. Taxable wages are defined as the first $4,200 paid during 1970 to a worker by each covered employer. The benefits and taxable wages of a worker are then allocated to a type of farm in proportion to the wages earned. The total benefits and taxable wages by type of farm for all workers within a state determine the farm-type specific cost rate.

The classification of farms by type used in this cross-section study corresponds to the agricultural census criteria. The types of farm considered are livestock, dairy, poultry, tobacco, fruit, vegetable, cash-grain and other field crops combined,[4] and miscellaneous farms.[5] Considering the number of observations, the basis of some of the cost rates is questionable, and they are not used in this study. This includes all the cost rates for states that are based on less than 100 covered workers.

The cost rates by type of farm are estimated for two alternative coverage provisions. An employer is classified as covered if he hired at least four wage items in at least twenty weeks or had a $5,000 or greater payroll during any calendar quarter of the preceding year (henceforth referred to as "4 in 20 or $5,000").[6] This provision was President Ford's proposal for agriculture and was included in most of the bills receiving serious consideration by Congress in recent years.[7]

This study estimates the cost to farmers using two different sets of tax rates for 1975: (*a*) a standard UI tax rate, which is the rate on taxable payroll that newly covered employers must pay (it applies usually for the first three years) and (*b*) the UI tax rate applicable under experience rating that is bounded by a minimum and maximum rate established in each state (Commerce Clearing House). The standard tax rate and the one under experience rating also include the 0.5% federal tax and a solvency factor applicable in some states (table 1).[8] The tax rates that apply to newly covered employers and minimum and maximum tax rates under experience rating used in this study are the tax rates that were in effect in 1975. They are selected to demonstrate their effects upon the tax burdens that farmers would experience on different types of farms in different states.[9]

[4] Cash-grain and other field crops are grouped into one type of farm, since these farms have similar characteristics and individually none of these classifications have sufficient observations for a meaningful analysis. Henceforth, they are referred to as cash-grain farms.

[5] Miscellaneous farms encompass a host of diverse operations; however, some information about this group is preferable to none.

[6] A wage item (worker) is the employment of one worker by one employer during any part of a year.

[7] The estimates for the "1 in 20 or $1,500" provision in force for nonfarm workers are not reported here, since they are not significantly different from the current "4 in 20 or $5,000", but they may be obtained from the author. However, it would be premature to generalize that insignificant variations in the tax burden would occur under all conceivable coverage provisions. The recently enacted Public Law 94-566 specifies a "10 in 20 or $20,000" provision for coverage, which would reduce the number of covered employers and workers appreciably for some types of farms compared with the "4 in 20 or $5,000" provision.

[8] A solvency factor is not added in a state when it has a positive UI fund balance. However, in recent times the balance of the UI fund has fallen below the desired level in some states, and a solvency factor is used to increase the fund's balance by adjusting the tax rate upward. The value of the solvency factors that were in effect in June 1975 are given in table 1. The procedures employed in the solvency factor adjustments are extremely complicated, and their explanation is beyond the scope of this study.

[9] Estimates of the tax burden based on the 1971 tax rates were

[a] These solvency factors are included in the tax rates.
[b] Data are not statistically reliable as explained in text.

The UI tax rates are subject to annual review and possible revision by the states. The tax rates under experience rating in effect in 1975 are used instead of the less realistic state statute rates. After comparing the two sets of tax rates, it became obvious that the 1975 maximum rate was—with very few exceptions—at or near the maximum statutory rate of the states. On the other hand, only four states approached or were at the statutory minimum rate in 1975. Usually they were at least double the statutory minimum due to fund deficits. Also, for the foreseeable future most states likely will have to charge employers tax rates near the maximum permissible rate in order to replenish their UI fund reserves.[10]

In using the 1975 tax rates, this study assumes the same worker history of farm employers in 1975 as in 1970, since the 1970 survey has not been updated. However, any change that may have occurred since then would change the findings of this study only slightly. Both workers' taxable wages and the UI benefits have increased approximately proportionately. At the same time, the level of employment has remained constant or decreased in most states, and the number of employers with employment sufficient to qualify for coverage has remained constant or increased with the factors involved tending to offset each other. The seasonal employment pattern is judged to have remained essentially unchanged. However, I see no way to judge the changes in employment behavior by both employers and employees since 1971.

The UI costs are the product of the tax rate and the average taxable wage for each type of farm in a state. The average taxable wage per farm is calculated by dividing the total taxable payroll of all farms of a particular type by the number of farms hiring labor, using table 28 of the 1969 *Census of Agriculture* data for commercial farms (U.S. Dep. Commerce). The taxable payroll is the total hired farm labor expense adjusted by a factor. This adjustment accounts for the fact that only the first $4,200 of an employee's wages are taxable. The factor is obtained from the Social Security Administration and varies from state to state and according to the employer's number of workers. The farmers' estimated UI taxes under standard rates and experience rating are expressed as a percentage of production expense and net income (as reported in the 1969 *Census of Agriculture*) and determine the tax burden by farm types and state.

also calculated to assess the variations over time but due to space limitations are not reported here. It is asserted that the tax rates of the two years encompass a wide range of possible outcomes. The 1971 tax rates are available on request from the author.

[10] Under Public Law 94-566 the tax rate increased by 0.2 percentage points for all states on 1 January 1977.

Relationship of Tax Rates to Expenses and Income

Standard Tax Rates

This section analyzes the impact of the UI tax as a proportion of production expense and net income based on the standard tax rates of 1975. The standard tax rates of the survey states range from 1.5% in Florida to 4.4% in Delaware (table 1). For newly covered employers, the tax burden is dependent upon the state's tax rate applicable at the time and the taxable payroll of a particular farm on the one hand and the farm's net income (or production expenses) on the other. In other words, while tax rates vary among states, further variations exist within a state based on net income or production expenses.

Most states would charge dairy, livestock, and poultry farms a higher standard tax rate than needed to maintain the estimated benefits paid to workers on those farms. On the other hand, the standard tax rate (including the 1975 solvency factor) would be insufficient in almost all states to cover the benefits paid on vegetable, fruit, and tobacco farms. The relation between standard tax and cost rate is mixed for cash-grain and miscellaneous farms, i.e., in most states this standard rate is lower than the cost rate, but it is higher in some.

The employers whose cost rates are estimated to be less than the standard tax rate pay a tax that is greater than the cost of providing benefits to their workers under a self-supporting fund. At the same time, the benefits that accrue to workers of those employers whose cost rate is greater than the standard tax rate are subsidized by other employers in their state.

The UI tax burden computed as a proportion of production expense is relatively low for dairy, poultry, and livestock farmers (not exceeding 0.8%) in all states (table 2). The tax as a proportion of net income generally does not exceed 5% for dairy and poultry farms. Though this proportion is considerably higher in some states for livestock farms, it is suspected that farmers on these farms also have off-farm income.

Even though the tax burden for dairy, livestock, and poultry farms is small, these types of farms usually pay a multiple of estimated costs into the UI fund before experience rating can be applied to them. The opposite holds for fruit and vegetable farms in most states and for tobacco, miscellaneous, and cash-grain farms in some states. By paying into the fund under the standard rate—before experience rating affects their cost rate—these farms pay only a fraction of the estimated cost. For tobacco, fruit, miscellaneous, and vegetable farms, the UI tax as a proportion of production expense and net income was relatively high in most states (between 0.5% and 1.8% and 2.3% to over 20%, respectively). The tax in relation to net income was also high in some states for cash-grain farms.

For all types of farms, the variability of the UI tax as a proportion of production expenses among states is small (three- to six-fold); however, it is very high for the proportion of net income, especially for cash-grain, livestock, and tobacco farms (up to thirty-fold).

Experience Rating

This section discusses the tax rate and burden under experience rating by type and state. The employer's estimated cost rate under experi-

Note: The data by states for each farm type are available upon request from the author.

ence rating is limited in each state by established minimum and maximum tax rates. Within these limits, the burden is determined by the cost rate and the taxable payroll of the farm and the specific net income (or production expenses) of the farm. The payroll is farm (type) specific and depends on the level of wages and the size and duration of employment of the work force. Assuming an employer's computed cost rate exceeds the state's maximum tax rate, the excess of his workers' benefits over the employer's contributions is financed indirectly by increasing the tax rate and hence contributions of other employers who pay less than the state's maximum tax rate. Assuming an employer's cost rate under experience rating is below the minimum tax rate, he pays a tax greater than his employees cost the UI program. The employers who have a computed cost rate under experience rating between minimum and maximum tax rate are fully supporting the program.

In 1975 the minimum tax rate under experience rating ranged from 0.5% in West Virginia and Florida to 4.4% in Massachusetts, and the maximum tax rates ranged from 3.8% in West Virginia to 6.7% in New Jersey (table 1). The minimum tax rate applied to at least one type of farm in each state. In Massachusetts, the 1975 minimum tax rate applied to all types of farms, except fruit and vegetable. In Vermont and New York, the 1975 maximum tax rate was greater than the cost rate for all farm types considered.

Under experience rating, the UI tax burden is low for dairy, livestock, and poultry farms, ranging from 0.05% to 1.1% as a proportion of production expenses and generally not exceeding 6.0% as a portion of net income (table 2). Corresponding ranges are higher for miscellaneous vegetable, tobacco, and fruit farms, reaching 3.3% and 21%. However, the lowest proportions for these types of farms may be below 1%. The burden in relation to production expenses is generally low for cash-grain farms but may exceed 20% in relation to net income.

Contributing factors to a low tax burden are year-round employment of covered workers, their earnings level in relation to benefits received, low benefit levels (weekly benefit amount and duration), and a stringent employment or earnings requirement to qualify for benefits. Family farms with zero or only occasional help who do not qualify for UI benefits experience a very low tax burden. Further, if the payroll or UI contributions are a small proportion of net income and/or production expenses, the burden is naturally lower than in the reverse case. Seasonal variations in employment of covered workers, high benefit levels (weekly benefit amounts and durations), and liberal qualifications for benefits increase the tendency for high proportions. Dairy, livestock, and poultry farms usually have a small but year-round work force with high taxable wages but few workers qualifying for benefits. Fruit, vegetable, tobacco, and miscellaneous farms tend to employ a large seasonal work force of which a large proportion collects high benefits. The tax burden is determined largely by the type (and size) of farm and its employment pattern, aside from the state's UI statutes.

Regression analysis indicates that intra- and interstate differences of the cost rates for poultry, miscellaneous, and cash-grain farms tend to be smaller if the states' UI statutes are uniform, since they have equal weight in determining the cost rates with work force characteristics such as earnings, seasonal employment, and farm sales (Elterich and Bieker 1975a, Petty). The cost rate of vegetable, fruit, and dairy farms are much more dependent on work force characteristics than on UI system variables.

Benefit Payments to Agricultural Employees

One of the primary purposes of extending UI coverage to agricultural employers is to reduce individual workers' personal income loss from involuntary unemployment. It also provides an anticyclical effect in case of local or national recessions and stabilizes farm employment. However, the extension of UI coverage to agriculture will undoubtedly have other economic and social implications. Although the exact magnitude of the changes cannot be determined until after the coverage is implemented, some evidence with respect to benefit payments is available.

Table 3 shows the benefit payments in dollars and as a proportion of average earnings for the survey workers by type of farm. The findings indicate that the benefits increase the earnings of workers in some types of farms substantially more than in others. The benefits as a proportion of average earnings of the workers are usually the least on dairy farms, ranging from zero in New Hampshire and West Virginia to 13% in Vermont.

[a] Comparing the benefits with the average earnings of the beneficiaries provides a better social indicator. However, the earnings of the beneficiaries by type of farm are not available. Since the earnings of all the beneficiaries ($2,800) are less than the earnings of all workers ($3,209), the proportions in the table should be adjusted upward slightly. (Benefits shown are per beneficiary.)

[b] Data are not statistically reliable (see text).

The benefits from UI increase the income of the workers with low earnings by a greater percentage than that of the average worker, and a greater proportion of those with low earnings receive benefits. However, the impact of the benefits on workers' welfare varies by the type of farm employing them. Since only about one-fifth of all workers receive benefits (Seaver and Holt, Seaver et al.), UI has an impact on the welfare of this proportion of the worker population. Workers in Connecticut, Maryland, Massachusetts, New Jersey, and Ohio tend to receive high absolute and relative benefit payments (up to $550 or more or over 20% of average earnings, respectively). This is a result of their work histories and the benefit schedules in these states. In Florida, Maine, New Hampshire, and New York, the benefits in absolute or relative terms are low (less than $400 or less than 20% of average earnings).

The fact that coverage provisions are related to the firm's labor force also makes them selective by commodity. Farms having larger labor forces tend to grow fruit, vegetable, nursery products, and other products causing relatively large seasonal fluctuations in labor demand. Under more restrictive coverage provisions, these firms and their workers tend to remain covered (Bauder et al.).

Conclusions

This study investigated some of the economic consequences of covering agriculture with UI. When less inclusive coverage provisions are studied, the differences between coverage provisions are insignificant, since benefits paid out are proportionately reduced with a smaller taxable wage base (Bauder et al.).[11] Similar proportional tendencies apply when the tax burden in relation to its base (production expenses or net income) is considered among the coverage provisions.

In 1975 newly covered employers would have paid a uniform tax rate on wages, regardless of type of farm, ranging from 1.5% to 4.4% depending upon the state. The tax is then a function of the taxable wages paid by an employer, represented here by the average for a farm type in a state. Livestock, dairy, and poultry farms cost rates were usually less than the standard tax rates. The cost rates were higher than the standard tax rate for cash-grain farms in half of the states and for vegetable, tobacco, and fruit farms in nearly every state in 1975. The same tendencies hold when the 1971 standard tax is applied.

Differences between the tax burdens under standard and experience rates are appreciable, since under experience rating state statutes provide for a range of tax rates based on the costs using employers' employment patterns of up to three years. While vegetable, fruit, and tobacco farms traditionally show peaks and troughs, dairy, poultry, and livestock farms have a more even distribution of employment and fewer layoffs and hence the likelihood of a much lower tax burden than the first group of types.[12] The tax rates and burdens were estimated for an "average" farm, and they may vary widely in accordance with the employment pattern of employers. On the one extreme, a covered employer may have no layoffs, or he may hire workers who are not eligible for benefits due to short-term work or nonavailability for work during the rest of the year and hence pay a very low tax under experience rating. On the other hand, if an employer has a seasonally varying employment pattern with many workers drawing high benefits, he will pay a high tax rate on his payroll.

The average UI benefits workers would receive vary in accorance with the cost rates, from insignificant amounts up to $900 or 40% of their average earnings. Workers on vegetable and fruit farms more often receive the highest amounts—due to seasonal employment, while those on dairy and poultry farms receive the lowest, which is to be expected given their tendency to year-round employment. Most workers in Connecticut, Maryland, Massachusetts, New Jersey, and Ohio could expect relatively high absolute benefit payments in relation to their earnings based on their work histories. In Florida, New

[11] This statement does not hold generally. Research presently under way by the author indicates that, for the very restrictive coverage provision incorporated into PL 94-566, the relationship between benefits paid and taxable wage base changes compared with the provisions studied thus far.

[12] In response to a reviewer's comment, I want to stress that the analysis is concerned with empirical findings derived from the existing state rules and rate structures. We do not analyze what the federal government may mandate in the future, namely, uniform rules and rate structure for all states. Assuming farmers of a particular type are competitively adjusted between states before the differing new tax burden affects producers differently in various states (i.e., a state of equilibrium exists between them and they do not reap excess profits), producers in "low tax" states may very well obtain a comparative advantage over like producers in a "high tax" state after the imposition of the taxes.

York, Maine, and New Hampshire the benefits are relatively and/or absolutely low.

Benefit-Cost Analysis of a Nonmetropolitan Prototype for Solid Waste Resource Recovery

Fred Hitzhusen and Mark Luttner

This study focuses on the recovery of energy and materials from solid waste at a coal-burning steam-electric plant located in a nonmetropolitan county in Northeast Ohio. The results of the analysis suggest that the resource recovery prototype involving a new solid waste processing facility and modification of the existing steam-electric plant is an economically feasible investment. This conclusion is substantiated by sensitivity analysis of five key technical and economic parameters under four alternative benefit-cost and internal rate of return criteria.

Key words: materials and energy recovery, nonmetropolitan, Ohio, solid waste.

The utilization of land as a depository for man-made waste concerns many people because of its potential contribution to environmental decay and the loss of valuable (particularly nonrenewable) resources. The negative impacts attributed to land disposal of solid waste—landfilling—include water pollution by landfill leachate, blowing of paper and general unsightliness, creation of methane gas and odors, and loss of recoverable materials and energy. These problems are accentuated by the increase in volume of solid waste generated (Brunner and Keller, Schulz) and the decrease in land available for disposal sites. Developments in the field of resource recovery offer an opportunity for jointly addressing the problems of solid waste management and energy scarcity at the local level.

An increasingly attractive process for the partial resolution of these problems appears to be the utilization of solid waste as a supplementary fuel in electric plant boilers. The potential benefits of this process include: less burning of coal (or other fuels) with resultant savings in coal purchases, less need for landfill space, recovery of materials (e.g., ferrous metals) from the refuse stream, and opportunity for a public or private utility to aid a community in resolving its solid waste management problem.

The importance of energy recovery often supersedes materials recovery. Abert, Alter, and Bernheisel state that "resource recovery is economically viable provided the community has an electric utility which can utilize the organic fraction" (p. 1057). A study by the Midwest Research Institute found that the capital investment requirements for fuel recovery were lower than for any other recovery process investigated. The study further concludes that "the fuel recovery concept has the most favorable overall economics of any investigated" (p. 47).

The scale requirements normally associated with resource recovery are substantially reduced in those systems including the recovery of energy from refuse. Scale economies are further reduced by the commercial availability of systems designed specifically for relatively small communities. For example, the resource recovery system in Ames, Iowa, serves a county population of approximately 60,000. According to data from the National Coal Association and a national survey funded by the U.S. Environmental Protection Agency, there are over 300 coal-burning steam-electric generating plants similar to the Ames plant located in the nonmetropolitan areas of the

Fred Hitzhusen is an associate professor, Department of Agricultural Economics and Rural Sociology and the Ohio Agricultural Research and Development Center, The Ohio State University, and Mark Luttner is an economist with the U.S. Environmental Protection Agency, Washington, D.C.

Approved for publication as Journal Article No. 90-77 of the Ohio Agricultural Research and Development Center, Wooster, Ohio. Based primarily on an unpublished M.S. thesis by Mark Luttner. Helpful comments were received from L. Hushak, L. Forster, F. Walker, and R. Boisvert.

United States (National Coal Association; Tunnah, Hakki and Leonard).

Recent increases in the costs of conventional fossil fuels (coal, oil, and natural gas) provide the greatest incentive for energy and materials recovery systems. Many indicators suggest a sizable increase in future demand for coal resulting from the electric power industry's increasing reliance on coal and its derivatives. This demand is likely to be accentuated in those areas most susceptible to natural gas shortages, i.e., the Midwest, Northeast, and Mid-Atlantic states. Problems in nuclear power development, refinements in coal gasification technology, and projected absolute increases in energy demand all point to increasing demand for coal (with resultant price increases). Increases in the price of coal and other energy sources will make solid waste an increasingly attractive energy source.

The focus of the study on which this analysis is based is a coal-burning steam-electric municipal power plant located in a nonmetropolitan county in Northeast Ohio. The specific objectives of the original study are: (*a*) to ascertain the technical feasibility of converting the existing power plant facility to include an energy recovery system, (*b*) to complete a benefit-cost sensitivity analysis of the proposed resource recovery prototype to evaluate the technical and economic parameters of importance to resource recovery in a nonmetropolitan location, and (*c*) to determine the potential net reduction in external impacts from implementation of such a system.

The Study Area

The area that provides the focus for this analysis is Wayne County, Ohio. Located in the northeastern quadrant of the state, Wayne County has a population of approximately 87,000. Like many other areas, Wayne County is rapidly exhausting its present landfill space. In addition, these current sites are considered suspect in terms of damage to surface and groundwater supplies, negative aesthetic impacts, and generally poor management techniques. Because the county is an important agricultural area of the state, the cost of land for additional disposal sites is relatively high. Residents in the county's population centers oppose the development of new landfills close to these waste-generation centers.

The city of Orrville located in northwest Wayne County owns and operates a 75-megawatt municipal electric plant, a potential site for an energy and materials recovery system similar to that in Ames, Iowa. Two of the four boilers at Orrville Municipal Power (OMP) are side-fired pulverized coal units of modern design capable (with minor modification) of burning refuse in combination with coal. Based on the range of refuse-to-coal firing ratios (15:85 to 27:75), generally recommended for boilers of this type, OMP could burn the combustible portion from 51% to 84% of the solid waste now generated in Wayne County (Smith, Sutterfield).

The prototype recovery system would include a horizontal hammermill to reduce incoming refuse to optimum combustion size, an air classification process (zigzag columnar or elutriative) to separate the refuse into combustible and noncombustible fractions, a magnetic system to recover ferrous scrap material for sale, processed refuse storage facilities, and refuse-fuel transport and firing mechanisms. The entire system (refuse input and processing) would operate in an enclosed building adjacent to the electric power plant. A detailed technical development of the prototype is presented in Luttner.

Methodology

Benefit-cost methodology was selected for the original study (Luttner) primarily because of the a priori evidence of technological external economies (or indirect benefits) associated with the proposed solid waste resource recovery prototype. For example, landfilling of solid waste in the study area appears to be imposing technological external diseconomies (or indirect costs). A priori evidence also suggests that the appropriate discount rate for solid waste resource recovery may not be some estimate of the market rate of interest (Luttner).

Because of the considerable uncertainty regarding values for the discount rate and several other key parameters, sensitivity analysis is used to evaluate the prototype resource recovery facility. Low, medium ("most likely outcome"), and high estimates are made for key technical and economic parameters to determine their relative impacts on economic outcome. The direct economic benefits of resource recovery included in this analysis are the cost savings of reduced landfill activity,

savings from reduced consumption of coal at the power plant, and net revenues from the sale of recovered ferrous metals. Some attempts were made to measure the indirect benefits of decreased leachate induced water pollution due to reduced landfilling and improved air quality due to the use of low sulfur refuse as fuel. Other indirect benefits such as reduced consumption of virgin materials and of the resources required to produce and transport them are not estimated.

The direct costs for the resource recovery prototype include the initial capital outlay for the processing facility and the power plant conversion. Additional costs are the operating costs of the entire recovery facility, operating costs of a small-scale landfill suitable to accommodate that waste not processed and the residuals material (fly ash) from the power plant boilers, transport costs for refuse delivered to the processing facility, and transport costs for excess refuse and fly ash taken to the small landfill.

Physical measures of reduced landfill leachates and power plant emissions are developed, but it was not possible to get reliable monetary estimates of any of the indirect benefits of the solid waste resource recovery prototype. However, there is no a priori evidence of any significant indirect costs associated with the resource recovery process analyzed. Thus, omission of monetary measures of indirect benefits from the benefit-cost sensitivity analysis results *ceteris paribus* in conservative estimates of the discounted present value of benefits and costs estimated for the resource recovery prototype.

The primary criteria utilized to evaluate the prototype are benefit-cost ratio and net benefits.[1] The benefit-cost ratio is generally appropriate for ranking projects under capital rationing. However, it does not provide information on changes in net worth. Determination of the benefit-cost ratio follows the pattern of Seneca and Taussig:

$$B/C = \frac{\sum_{t=1}^{T}\left(\frac{B_t}{(1+i)^t}\right)}{\sum_{t=1}^{T}\left(\frac{O_t}{(1+i)^t}\right) + K},$$

where B is annual benefits resulting from project, O is recurring costs or annual operating and maintenance expenses incurred, T is the time period over which benefits and costs occur, i is the discount rate, and K is capital outlays incurred in the initial year of the project.

The net benefit criteria provides another measure of the economic feasibility of a given investment and provides for determination of changes in net worth. In multiproject comparisons of varying scale, this criterion favors large-scale projects. The net benefit criterion is derived as follows:

$$\text{net benefits} = \sum_{t=1}^{T}\left(\frac{B}{(1+i)^t}\right) - \left[\sum_{t=1}^{T}\left(\frac{O}{(1+i)^t}\right) + K\right].$$

Alternative (low, medium, and high) values are estimated for five technical and economic parameters judged crucial to the resource recovery prototype. The key technical parameter involved is the refuse-to-coal firing ratio utilized in the combustion process. This ratio determines how much refuse can be fired in the boilers, thereby dictating the processing capacity required in the recovery system. The primary economic parameters are the projected coal price levels, rate of discount, and net ferrous revenue per ton of recovered metal scrap. Initial capital investment, a final parameter, tends to have technical as well as economic dimensions. Table 1 presents these parameters and the values developed to demonstrate the sensitivity of the system.

There is some supporting evidence for the parameter projections used (particularly for the medium values) from previous research, historical data, and consultation with authorities in the various areas. For example, firing ratios are based on the demonstrated capabilities of ongoing energy recovery facilities (Sutterfield) and engineering estimates (Smith). The annual coal price increases are based on analysis by the National Coal Association and historical data from Orrville Municipal Power (Williams). The alternative discount rates are based on the Farmers Home Administration loan rate for solid waste projects, the rate of return of U.S. Treasury bonds, and an opportunity cost for capital in the private sector.

The low estimate for capital outlay is based on engineering estimates (Sharp, Smith) and

[1] For comparative purposes, the original study also included the internal rate of return and pay-out period criteria. Internal rate of return is that rate of discount that makes the discounted present value of net benefits equal to the value of the initial capital outlay. The pay-out period criterion measures the number of time periods (usually years) necessary to recoup the initial capital outlay.

Table 1. Summary of Low, Medium, and High Estimates for Technical and Economic Parameters

	Parameter Projection Estimate		
	Low	Medium	High
Refuse: coal-firing ratio	15:85	20:80	25:75
Annual coal price increase	1975–80:10% 1981–94: 4%	1975–80:12.5% 1981–94: 7%	1975–80:17% 1981–94: 8%
Discount rate (%)	5	9	11
Initial investment ($)	3,284,081	4,105,101	5,131,376
Net ferrous revenue per ton ($)	15.00	22.00	29.00

several previous studies and manufacturers' statements (Columbus Division of Electricity and Ohio State Univ.; Black and Veatch, Inc.; Hecht et al.; National Center for Resource Recovery). To allow for contingencies, the medium and high estimates for capital outlay are derived by increasing the low estimate and the resulting medium estimate by 25%, respectively. The net ferrous revenue estimates are derived primarily from analysis done by Abert et al. at the National Center for Resource Recovery (Abert and Zusman) and from discussions with agency and consulting firm staff members (Sharp, Smith). Generally, the evidence is not sufficient to assign probabilities to the array of possible values for each of the key technical and economic parameters. Variations in all parameters may occur, but the medium parameter estimates are assumed to represent the "most likely outcomes."

The discount rate chosen is recognized to be crucial to the outcome of the analysis. The rate indicates if capital provided for any particular project yields as high an economic return as it would among alternative uses. The choice of a discount rate also involves social value judgments about benefits and costs that may accrue to future generations. To minimize subjective argument concerning the validity of using a particular rate of discount, three rates are utilized in the analysis—5%, 9%, and 11%.

Estimates of Benefits and Costs

The medium estimate for initial capital outlay (K) for the processing facility and the power plant conversion is presented in table 2. A detailed description of the resource recovery prototype and the development of the individ-

Total ($)	439,112	429,603	419,093

[a] From detailed budgets developed in Luttner.
[b] Based on replacing 45, 60, and 85 tons of coal per day at $17.30 per ton for 330 operating days per year.
[c] Based on recovery of 9.6, 12.8, and 16.0 tons of ferrous per day at $22.00 net revenue for 330 operating days per year.
[d] Based on estimated operating costs under the 20:80 firing ratio (Luttner). More precise estimates of operating costs will be possible as actual data become available at the resource recovery plant in Ames, Iowa, the first facility of this type and size.
[e] Operating costs decrease with increased firing ratios because less waste is landfilled at higher ratios. Detailed budgets presented in Luttner.
[f] Transport costs increase to the recovery plant and decrease to the landfill with increased firing ratios (Luttner).

ual capital outlay line items is presented in Luttner.

Table 3 presents the estimates of first year (1975) primary or direct benefits and operating costs for the solid waste resource recovery prototype under three refuse-to-coal firing ratios. Coal savings are based on actual coal prices paid by Orrville Municipal Power in 1975 ($17.30 per ton), and ferrous metal net (of transport costs) revenues are based on the medium parameter estimate of $22.00 per ton. The direct benefits and operating costs are not discounted, and initial capital outlay (K) is not included in table 3.

The Green Township landfill operating and transport costs represent the least-cost potential landfill alternative for Wayne County determined from a previous analysis (Hitzhusen and Poling). This proposed site is located in north central Wayne County near the midpoint of waste generation. The resource recovery prototype located near the proposed landfill site would eliminate the need for this proposed landfill and its associated operating and transport costs. Thus, these costs or savings are counted as direct benefits. Some landfilling would still be required with the resource recovery prototype for the solid waste generated in excess of the power plant capacity and for the increased fly ash from the plant boilers. An existing landfill at Mt. Eaton in southeast Wayne County is of adequate size and location for this purpose. Thus, the estimated operating and transport costs associated with this landfill are included as costs of the resource recovery prototype for each of three refuse-to-coal firing ratios.

The foregoing first year budgets are projected for a recovery system plant life of twenty years. Inflationary effects are incorporated into the twenty-year projections based on performance data relevant to each major cost or benefit component over the prior twenty-year period. For example, data from the Bureau of Labor Statistics for 1954–74 are utilized to calculate labor cost increases over the life of the project (Council of Economic Advisors). In estimating the benefits and costs in the period in which each is incurred, it is assumed that the discount factor fully compensates for the rate of inflation (Howe, p. 55).

Results of the benefit-cost ratio and net benefit analysis are presented in table 4 for the medium or "most likely outcome" level of initial capital investment estimate (K). Nine future benefit and cost streams are computed for each of the three refuse-to-coal firing ratios. The low, medium, and high economic parameter projections in table 1 and projected operating budgets for the various direct benefit and operating cost components of the resource recovery system are utilized in computing the discounted present values for each of the future benefit and cost streams.

The data in table 4 indicate the relative impacts of changes in the alternative technical

Table 4. *B/C* and B-C Analysis of Resource Recovery Prototype by Firing Ratio and Alternative Parameter Projections, 1975–95, *K* = $4,105,101

Firing Ratio Parameter Projection	Discount Rate 5%		9%		11%	
	B/C	B-C[a]	*B/C*	B-C[a]	*B/C*	B-C[a]
15:85

High	2.34	17,506	1.95	9,837	1.77	7,309

[a] 1,000 dollars.

and economic parameter values upon the *B/C* and benefit-cost economic criteria at the medium estimate for capital outlay (*K*). For example, given medium values for all parameters, increases in the firing ratio from 15:85 to 20:80 and from 20:80 to 25:75 increase net benefits by $2.758 million and $2.868 million, respectively. Examination of the other data permits the determination of the relative effects of the range in values of the individual technical and economic parameters on economic feasibility. The effect of the low and high estimates for capital outlay can be observed by subtracting $821,020 or adding $1,026,275 to the net benefit values in table 4. These values represent the difference between the low and medium and the high and medium estimates, respectively, for capital outlay (*K*).

Sensitivity analysis is done allowing each of the key technical and economic parameters to vary from its low to high value while holding the remaining parameters at their medium values. Under this type of analysis, the ranking of parameters from largest to smallest impact on net benefits is as follows: (*a*) refuse-to-coal firing ratio, (*b*) project estimates for the coal and ferrous metal price parameters,[2] (*c*) rate of discount, and (*d*) initial capital investment.

Analysis of the resource recovery prototype by the medium parameter estimates represents the "most likely outcome." While somewhat arbitrary, the evidence gathered indicates that the medium parameter projections represent the most plausible values. Analysis of the most likely outcome situation with the benefit-cost ratio and net benefit criteria yields the following criteria:[3] benefit-cost ratio = 1.35 and net benefits = $3,713,000.

These data suggest that the prototype is an acceptable use of resources. Its benefit-cost ratio is well in excess of unity, it provides substantial positive net benefits, it recovers the initial investment in slightly over one-half its expected life, and it provides a rate of return equal to or greater than most measures of the opportunity cost of capital in the private sector.

Monetary measures of the indirect benefits of reduced landfill created water pollution and reduced harmful emissions at the power plant were not possible. However, some attempts were made to get physical measures of these effects.[4] For example, three types of emissions from coal-fired power plants are generally recognized as harmful to humans, animals, vegetation, and structures. They are particulate matter, sulfur dioxide (SO_2), and nitrogen oxides (NO_x) (Council on Economic Advisors Priorities).

By substituting prepared refuse for coal at Orrville Municipal Power, it is anticipated that a reduction in emissions of SO_2 will occur due to the low sulfur content of refuse compared with coal. Particulates and NO_x emissions will probably remain unchanged. A 0.1% sulfur level in the combustible refuse, 3.8% sulfur content in the coal, and a 20:80 refuse-to-coal firing ratio result in decreased sulfur emissions equivalent to 786 tons per year at Orrville Municipal Power. This represents an 18% reduction in the 1975 sulfur emission level of 4,161 tons (Luttner).

Even physical measures were difficult to secure in the case of leachate water pollution from the existing landfills in Wayne County. Discussions with the local Soil Conservation Service (SCS) representative suggest that surface water is probably already being polluted by the current landfills and pollution of groundwater aquifers under or near the landfills is a distinct possibility. However, the monitoring done to date by the SCS and the

[2] Additional analysis reveals that, when the coal and ferrous metal price parameters are considered separately, coal maintains a second-place ranking and ferrous prices rank fifth.

[3] Under the same medium parameter estimates, the pay-out period is 10.7 years and the internal rate of return is 17.9%.

[4] The original study presents a detailed discussion of the probable reductions in landfill leachates and power plant emissions from resource recovery (National Center for Resource Recovery, pp. 76–80, 92–105).

City of Wooster Public Works Department is inadequate to develop precise measures of the exact nature and degree of water pollution (Luttner).

Summary and Implications

The results of the analysis suggest that the resource recovery prototype is an economically feasible investment. This conclusion is substantiated by a majority of outcomes based on sensitivity analysis of five key technical and economic parameters examined under alternative benefit-cost and internal rate of return criteria.

The analysis also reveals the impact of the key technical and economic parameters on the economic feasibility of the prototype. These parameters, in order of importance, are: the refuse-to-coal firing ratio, projection estimates for coal prices, rate of discount, initial capital investment, and net ferrous metal prices.

It was not possible to get monetary measures of any potential external effects from implementation of the resource recovery prototype. However, no technological external diseconomies were evident. Any future efforts to attach monetary values to those technological external economies given physical measures in this analysis (reduced landfill leachates and power plant sulfur emissions) will further enhance the economic feasibility of resource recovery from solid waste.

The primary thrust of resource recovery is to provide an economical, environmentally acceptable method of solid waste management. The recovery of energy and material resources is in itself a secondary goal. Such systems are attractive alternatives to traditional costly waste disposal practices because resource (energy and materials) recovery appears to be potentially a break-even or net benefit alternative.

The Orrville case study provides quantitative support to the position that, given certain conditions, nonmetropolitan as well as metropolitan areas may find resource recovery to be an attractive alternative. Prerequisite conditions appear to include the existence of an electric power plant or industrial boiler capable of burning refuse, the ability of the facilities in question to burn enough refuse (e.g., 100 to 200 tons per day) to justify the expenditures required to convert the plant and construct and operate the solid waste processing facility, and a population base large enough to supply an adequate waste volume (e.g., 100 to 200 tons per day). Rising prices of conventional fuels and a lack of landfill space generally increase the desirability of resource recovery but are not prerequisites to its feasibility.

Secondary data indicate the existence of over 300 coal-burning steam-electric generation plants, and data are currently being collected on industrial plant boilers in the nonmetropolitan counties of the United States. Present evidence on the specific characteristics of these plants and their surrounding waste generation areas is inadequate to make any conclusive statements on their technical and economic feasibility for resource recovery. However, it would appear that substantial potential exists. A regional resource recovery research project currently underway at Ohio State University is assessing this potential for the twelve North Central states.

s been empirically ver- ctor of production in ne, Huffman, Khaldi, eloping agricultures, t so clear. In a study Brazil, Wharton is meaningful relationship performance and educa- esting that the contribu- an early stage developing tain. As for medium-stage ltures, some positive evi- ned by Tang and by Ho in Japan and Taiwan, respec- tudies, however, the contribu- on of farmers is intermingled gricultural research and exten- portance of the contribution of f farmers alone in a medium-stage g agriculture is still an open ques- e present study is an attempt to pro- n answer.

The empirical setting of the study is the transitional farm economy of Taiwan.[1] The sample contains 310 bookkeeping farms in three years (106 in 1964, 117 in 1965, and 87 in 1966) drawn from three mixed farming regions of the island.[2] Agricultural production in Taiwan is mainly carried out by family farms of small size (about 1.2 hectares per farm in 1965; [Taiwan, Provincial Government of 1967c]). A majority of the farm people are formally educated, about 30% having six or more years of schooling (Taiwan, Provincial Government of 1967a); the sample average of educational attainment of farm operators is 6.7 years. The sampled regions are further characterized by rapid technical progress during the study period.[3] This study addressed itself to

Craig C. Wu is an assistant professor of economics, University of Alabama.

The author gratefully acknowledges support received from the Research Committee of the University of Alabama and assistance rendered by the Provincial Government of Taiwan in data collection. He is indebted to I. A. Ghazalah, Cliff Huang, Abbas Mirakhor, and A. M. Tang for helpful comments and suggestions at various stages of development of the paper. He is especially thankful to T. W. Schultz for his inspiring encouragement on the present work. His appreciation is also extended to the editor and three anonymous reviewers of the *Journal*.

[1] Modern agricultural development in Taiwan was initiated at the turn of the century. Active extension of new sources of income streams was largely witnessed after 1955. From 1952 to 1967, real agricultural output grew at a rate of about 6% a year (Shen; Taiwan, Council of International Economic Cooperation and Development).

[2] The three regions are the eastern mixed region, the southwestern mixed region, and the banana and pineapple region. (The other five regions are more or less specialized in growing rice, tea, or sugarcane.) The bookkeeping data for the study period were published in averages by the Provincial Government of Taiwan in its annual *Report of Farm Record-Keeping Families in Taiwan* (1965, 1966, 1967b). Data on individual farms used in the study were collected from bookkeeping records in custody of the provincial government. A feature of the study period is the relative stability of prices. According to the *Taiwan Statistical Data Book, 1968* (Taiwan, Council of International Economic Cooperation and Development), general prices of farm products were about 1% lower in 1965 than in 1964 and about 2% higher in 1966 than in 1965; while prices paid by farmers for productive supplies were 0.8% higher in 1965 than in 1964 and 0.3% higher in 1966 than in 1965. In view of the price stability, it seems legitimate to pool the data in the three years together, treating each year-farm as a data unit.

[3] From 1963 to 1966, the unit yield of banana increased by 60%, sweet potatoes, 55%, pineapple, 32%, corn, 29%, soybean, 26%, etc. (Taiwan, Provincial Government of 1967d). These are the crops mainly grown in the sampled regions.

the question of whether farmers' education of a moderate level can contribute to production in small-scale farming in a medium-stage developing agriculture when there is a rapid technical progress.[4]

The approach of the study is similar to recent studies for U.S. agriculture. This approach investigates the effect of education in terms of technical and allocative efficiencies. The contribution of education to technical efficiency is called a worker effect and that to allocative efficiency, an allocative effect (Welch).[5] The worker effect is usually estimated by incorporating an education variable in the production function. It is when the authors examine the allocative effect that they differ in their empirical models.[6] Both Fane and Khaldi concentrate on efficiency in cost minimization. As noted by Khaldi, "the role of education includes, in addition to cost minimization, the opportunity loss incurred from not maximizing profits" (p. 654). Hence, both studies use a limited or partial optimization model that leaves the problem of optimum or profit-maximizing output untackled. Huffman's model is superior in this respect. He adopts a full profit maximization model, but his empirical examination is confined to a single dimension of allocative effect, the utilization of nitrogen fertilizer. In this study, I adopt a full profit maximization model in which the allocative effect is examined with respect to all variable inputs. If one is interested in knowing the magnitud tion's contribution to allocative eff study provides a more complete

There is another possible eff tion, the importance of which been fully recognized. The Model

The three effects o sented in the context be anticipated output, fixed inputs, X^o a vecto inputs, and E educatio farm operator, where Y^a a in money terms. Assumin the anticipated production written as

$$Y^a = f(Z^o, X^o, E \quad (1)$$

When profit is maximized with ticipated output, the optimu maximizing amount of variable i

$$X^*_j = g^*_j(Z^o, E), \quad (2)$$

and the optimum output is[9]

[4] Rapid technical progress should provide a favorable milieu for education to contribute to production. One may suspect, however, that the significant contribution of education in U.S. agriculture, especially in terms of allocative efficiency, is perhaps due to the complexity of management of large farms. The operation of small farms may leave little room for education to contribute. This is, of course, a question to be answered empirically. Furthermore, in explaining his failure to find a significant effect of education in Brazilian agriculture, Wharton suggests that the "number of years of school completed is an extremely imperfect measure when one is working at the low end of the scale with very few years of schooling completed" (p. 207). Whether the education level in my study area is high enough for me to bypass this difficulty is also something to be decided empirically.

[5] The allocative effect can be decomposed into an effect on optimal use of variable inputs and an effect on optimal allocation of fixed inputs. For lack of data on actual allocation of fixed inputs among competing uses, the allocative effect examined in this study, as in the other studies, is in the former sense.

[6] Only Fane, Huffman, and Khaldi have studied allocative effect. While Miller is primarily concerned with technical efficiency, the empirical part of Welch is a study of total effect. Welch, however, suspects that the worker effect is probably small as compared with the allocative effect (p. 47). This is confirmed for U.S. agriculture by Huffman's estimate of $6.08 for worker effect and $10.40 for allocative effect on the use of nitrogen fertilizer alone. As discussed in note 4, however, the small-scale farming in Taiwan may reduce the relative importance of allocative effect. The importance of allocative effect as compared with worker effect for small farms should also be tested empirically.

[7] Huffman calls this effect a joint worker-allocative (or technical-allocative) effect. His findings show that the dollar value of this effect ($11.20) is about that of the allocative effect ($10.40).

[8] Schultz (p. 164) argues that the adoption of new factors of production depends mainly on profitability. The positive effect of education on technical efficiency normally raises the marginal productivity and, hence, the profitability of new inputs. Therefore, my examination of the scale effect of education with respect to new inputs such as chemical fertilizer may be taken as an indirect test of Schultz's profitability hypothesis.

[9] The word "optimum" is used in this paper to mean "profit maximizing" and a variable with asterisk means the optimum amount of the variable. Likewise, superscript a is used for anticipated amount and superscript o is used for observed amount. Since prices are assumed constant, they do not appear as arguments in equations (2) and (3).

$\ldots Y^* = f^*(Z^o, X^*, E)$.

The second term on the right-hand side of equation (11) implies that, even if E_0 and E_1 are equally allocative-efficient, E_1 can still make a larger π^a because E_1 may have a larger π^* (i.e., $d\pi^*/dE > 0$). To see how E_1 can have a larger π^*, consider equation (8). If the first term on the right-hand side of equation (8), $\partial f^*/\partial E$, is positive, E_1 can produce a larger Y with the same amount of material inputs. This is then the usual definition of technical efficiency or worker effect of education. When $\partial f^*/\partial E$ is positive, E is an argument in equation (2), and E_1 has a larger X^* (i.e., $\partial g^*_j/\partial E > 0$). Accordingly, this term is the scale effect of education.

Substituting equation (8) into equation (11),

$$(12)\quad \frac{d\pi^a}{dE} = \pi^* \frac{du}{dE} + u\frac{\partial f^*}{\partial E} + u\sum\left\{\left(\frac{\partial f^*}{\partial X^*_j} - 1\right)\frac{\partial g^*_j}{\partial E}\right\}.$$

The three terms on the right-hand side of equation (12) successively measure the allocative, the worker, and the scale effect of education. The partial derivatives, $\partial f^*/\partial E$ and $\partial g^*_j/\partial E$, in the last two terms are expressed in terms of optimum quantities. The multiplication of these derivatives by u means that the possible gain from worker and scale effects is a fraction of optimum gain from these effects if u is less than one. In other words, $\partial f^*/\partial E$ is the marginal productivity of E evaluated at optimum quantities of variable inputs (along with given amounts of fixed inputs). The product of u and $\partial f^*/\partial E$ may be interpreted as the actual gain from worker effect, i.e., the marginal product of E evaluated at actual quantities of variable inputs. Likewise, the product of u and $\partial g^*_j/\partial E$ may be interpreted as the actual increase in input j in response to an increase in E. Hence, equation (12) can be operationally expressed as

$$(13)\quad \frac{d\pi^a}{dE} = \pi^* \frac{du}{dE} + \frac{\partial f}{\partial E} + \sum\left\{\left(\frac{\partial f}{\partial X_j} - 1\right)\frac{\partial g_j}{\partial E}\right\},$$

where f and g_j are, respectively, the empirical production function and the empirical factor-demand function for input j, and X_j is the use of input j in accordance with g_j. To test the existence of the effects of education is then to test a positive du/dE, $\partial f/\partial E$, and $\partial g_j/\partial E$.

When the production function is Cobb-Douglas using m fixed inputs and n variable inputs, the anticipated-output function can be written as

$$(14)\quad Q^a = A\left(\prod_i Z_i^{o^{\alpha_i}}\right)\left(\prod_j Q_j^{o^{\beta_j}}\right)\exp[\Psi(E)]$$

for $i = 1, \ldots, m$ and $j = 1, \ldots, n$,

[10] On the assumption that E_0 and E_1 use the same amount of Z^o, which is the basic idea implied in regression analyses, π^* can be the same for E_0 and E_1 if E is not a significant variable in the production function so that it drops out from equation (2), leaving E_0 and E_1 with the same amounts of X^*, C^*, and Y^*.

where Q and Q_j are physical quantities of output and variable input j, respectively, and $\Psi(E)$ is a function of E, the form of which is determined empirically.[11] When output and variable inputs are measured in money terms, the function becomes

$$(15) \quad Y^a = A^\Delta \left(\prod_i {Z_i}^{o^{\alpha_i}}\right)\left(\prod_j {X_j}^{o^{\beta_j}}\right)\exp[\Psi(E)],$$

with

$$(16) \quad A^\Delta = AP\left(\prod_j W_j^{-\beta_j}\right),$$

where P and W_j are prices of output and input j, respectively.

For estimation, the production function for observed output may be specified as

$$(17) \quad Y^o = Y^a \exp(\epsilon),$$

where ϵ is the error term. Once equation (17) is estimated and a statistically better form of $\Psi(E)$ is determined, the test of the worker effect can be conducted by a significance test of the coefficient(s) of $\Psi(E)$.

In order to test the allocative effect by relating u (the allocative efficiency index as defined in equation (9)) to education, π^* and π^a must be estimated. When profit is maximized with respect to anticipated output, the first-order conditions yield

$$(18) \quad Y^* = \left\{A^\Delta \left(\prod_i {Z_i}^{o^{\alpha_i}}\right)\exp[\psi(E)]\right\}^r \left(\prod_j \beta_j^{r_j}\right)$$

and

$$(19) \quad X^*_j = \beta_j Y^*,$$

where $r = (1 - h)^{-1}$, $r_j = \beta_j r$, and $h = \sum_j \beta_j$. From equation (15),

$$(20) \quad A^\Delta\left(\prod_i {Z_i}^{o^{\alpha_i}}\right)\exp[\Psi(E)] \equiv Y^a / \prod_j {X_j}^{o^{\beta_j}}.$$

Substituting equation (20) in equations (18) and (19) yields

$$(21) \quad Y^* = (Y^a)^r \prod_j (\beta_j / X_j^o)^{r_j}$$

and

$$(22) \quad X^*_j = \beta_j (Y^a)^r \prod_j (\beta_j / X_j^o)^{r_j}.$$

It then follows that

$$(23) \quad \pi^* = (1 - h)(Y^a)^r \prod_j (\beta_j / X_j^o)^{r_j}.$$

[11] Four forms of $\Psi(E)$ are specified for empirical fitting, which are given later as equations (40) through (43).

Once the production function is estimated, π^a and π^* can be obtained from equations (6) and (23), using estimated production coefficients. Then, the index u can be calculated by equation (9). To test the allocative effect is to test whether a better educated farmer can bring his u closer to unity. This can be accomplished by relating either u or its squared value to E. If there is a favorable allocative effect, a positive relation between the dependent variable and E should be observed.

Variable u is an overall index of allocative efficiency with respect to all variable inputs. An allocative efficiency index with respect to individual input j can be similarly defined in terms of costs. Since X is measured in money terms, X_j is the cost of input j. The ratio of observed to optimum cost of input j can be taken as an index of allocative efficiency with respect to input j, i.e.,

$$(24) \quad \frac{X_j^o}{X^*_j} = u_j \text{ for } u_j \leqq 1,$$

with X^*_j being estimated from equation (22). When $u_j = 1$, the management of input j is perfect; otherwise, the management is imperfect. The test of the allocative effect with respect to input j can be accomplished by relating the squared value or the absolute value of the logarithm of u_j to E.[12] In the present case, unlike for u, which cannot be greater than one, an inverse relation between the dependent variable and E is expected for a positive allocative effect.

The overall index of allocative efficiency can also be defined in terms of costs as

$$(25) \quad \frac{C^o}{C^*} = u_c \text{ for } u_c \leqq 1.$$

When equation (22) is substituted in equation (5),

$$(26) \quad C^* = h(Y^a)^r \prod_j (\beta_j / X_j^o)^{r_j}.$$

Hence, the test of the overall allocative effect can be alternatively conducted in the way the individual allocative effect is tested. However, while u_c is defined in terms of cost only, u is defined in terms of profit. The estimates of u thus provide a direct means of evaluating the

[12] The dependent variable of the relation can be alternatively defined as $(u_j - 1)^2$ or $|u_j - 1|$ (Khaldi, p. 654). This definition has been used in the empirical fitting and, in general, a poorer result is obtained.

net contribution of overall effect by equation (10).

The optimum demand for input j is given in equation (19). Based on the optimum demand, the empirical demand function for input j may be specified as

$$(27) \quad X_j^o = A'_j \left(\prod_i Z_i^{o\alpha_i'}\right) \exp[\phi_j(E) + v_j],$$

with

$$(28) \quad A'_j = t(P, W),$$

where v_j is an error term, t is a function of P and W, and W is a vector of variable-input prices.[13] The empirical existence of a scale effect with respect to input j can be investigated by a significance test of the coefficient(s) of $\phi_j(E)$.

Taking geometric mean over j on both sides of equation (27), an average demand function for all variable inputs can be derived as

$$(29) \quad \tilde{X}^o = \tilde{A}' \left(\prod_i Z_i^{o\bar{\alpha}_i'}\right) \exp[\bar{\phi}(E) + \bar{v}],$$

where the tilde symbol indicates geometric mean over j and the overbar indicates arithmetic mean over j. Such an average relation can be used to test the "overall" scale effect for all variable inputs. The test of scale effect based on equation (27) or equation (29) only refers to the use of input(s). The net contribution of scale effect should be evaluated in accordance with the last term of equation (13).

Estimation

Production Function and Worker Effect

A preliminary review of the data reveals that total output of the family farms of Taiwan consists mainly of crop output and hog and poultry output (hereafter referred to as poultry output), with crops being the primary line of production (sample average of poultry income is about 15% of crop income). These two lines of production are presumably quite different in nature. Thus, two separate production functions are adopted, the form of which is assumed to be Cobb-Douglas as specified in equation (17).[14] The crop production function includes crop income in New Taiwan dollars (NT$1,000) ($Y_c$) as output;[15] labor in man-days (N_c) and land in NT$1,000 ($L$)[16] as fixed inputs; capital services in NT$1,000 ($K$),[17] fertilizer expenses in NT$1,000 ($F$), and other farming expenses in NT$1,000 ($M$)[18] as variable inputs; and an education variable in years of schooling of the farm operator (E).[19] The poultry production function also has its output measured in NT$1,000 ($Y_p$) and includes in

[13] When input j is employed exactly according to profit-maximizing conditions, $\alpha'_i = r\alpha_i$ and $\phi_j(E) = r\Psi(E)$. If these equalities always hold, there is no need to estimate the demand function insofar as the test of scale effect is concerned because once E is established as a positive factor in the production function, it is a positive factor in the demand function. But, empirically, the farms may not employ input j according to profit-maximizing conditions. In order to see whether there is empirically a scale effect, one must test a positive effect of E in the empirical factor-demand function. By the same token, the better fitted $\phi_j(E)$ function in the factor-demand function need not be of the same form as the better fitted $\Psi(E)$ in the production function.

[14] This assumption is tested for crop production by fitting a Cobb-Douglas function and a constant elasticity of substitution (CES) function of Kmenta's approximate form to data of ninety-three farms whose poultry-crop income ratio is less than 10%. The CES form does not show a significant improvement over the Cobb-Douglas form and, more importantly, more than half of the estimated coefficients of the CES form either are insignificant or carry signs contrary to expectation. CES is thus not a better form than Cobb-Douglas for the data. de Janvry's generalized power production function is also tested and a similar result is obtained.

[15] The foreign exchange rate in the study period was 40 Taiwan dollars for one U.S. dollar.

[16] The land variable includes reported value of farmer-owned land and imputed value of rented land. The officially appraised value of land sold by the government under the land-to-the-tiller program was 2.5 times the value of annual main crops and the maximum land rental was set by the government at 37.5% of main crops (Koo, p. 36). The value of rented land is imputed at 2.5 times (land rental/0.375), which is equivalent to a capitalization of land rental by an interest rate of 15%. Value, instead of area, of land is used for the land variable because the area data do not give a meaningful measure of land input. The reported land area includes paddy land, dry land, and forest land, which are quite different in value productivity.

[17] The capital variable includes 30% (15% for depreciation and 15% for interest cost) of machinery and equipment and 1.075 times expenses on small tools, supplies, and repair, where 0.075 is half of an assumed interest rate of 15% a year.

[18] Other expenses include seed and seedling expenses, farming materials and supplies, pest control expenses, and irrigation expenses. Data on these separate items are available. The reason for aggregating them is that there are too many zero observations when they are treated as separate variables, which are not appropriate for a Cobb-Douglas production function. Also, interest cost is not added to this and other similar variables because a proportionate change of the value of the variable does not affect the estimate of its coefficient.

[19] It is standard procedure to treat land as a fixed input in a short-run model. This is legitimate for the present study because the land-reform regulations of Taiwan restrict transfer of farmland. Labor is also assumed as a fixed input because farm labor is primarily provided by family members. The idea of fixed labor input for family farms is shared by Duloy. Although the number of family members is fixed in the short run, the supply of family labor should depend on the family's utility function. If in the short run the arguments of the utility function such as income-producing resources and tastes remain more or less constant, the supply of family labor also remains more or less constant. Capital is not assumed to be a fixed input because this category mainly includes light equipment and tools. This assumption is nevertheless not of vital importance to the empirical results. In the empirical estimation, capital has been alternatively assumed as a fixed input. This alternative assumption does not substantially alter the conclusion of the findings.

addition to E three inputs: labor in man-days (N_p), inventory of livestock and poultry in NT$1,000 ($I$), and breeding and feed expenses in NT$1,000 ($B$).[20]

In estimating the separate production functions, a problem of data availability is encountered. I have data on total labor input (N), the sum of N_c and N_p, but not on N_c and N_p. The problem is solved by an approximation using Taylor's expansion. The optimal allocation of N between crop and poultry production requires

$$\alpha_c\, Y^*_c/N^*_c = \alpha_p\, Y^*_p/N^*_p, \tag{30}$$

or, equivalently,

$$N^*_p/N^*_c = \rho Y^*_r, \tag{31}$$

where α_c and α_p are production coefficients of N_c and N_p, $\rho = \alpha_p/\alpha_c$, and $Y^*_r = Y^*_p/Y^*_c$, the optimum poultry-crop income ratio.

When equation (31) is solved simultaneously with $N^*_c + N^*_p = N$,

$$N^*_c = (1 + \rho Y^*_r)^{-1}N \tag{32}$$

and

$$N^*_p = \rho Y^*_r(1 + \rho Y^*_r)^{-1}N. \tag{33}$$

Using Taylor's expansion around zero ρ, the log form of equations (32) and (33) becomes

$$\ln N^*_c \doteq \ln N - \rho Y^*_r + 0.5\rho^2 Y^{*2}_r \tag{34}$$

and

$$\ln N^*_p \doteq \ln N + \ln\rho - \rho Y^*_r + 0.5\rho^2 Y^{*2}_r. \tag{35}$$

Before the production functions are estimated, Y^*_r cannot be obtained. The actual poultry-crop income ratio ($Y_r = Y_p/Y_c$) may be used for Y^*_r in equations (34) and (35).[21] If $\ln N_c$ and $\ln N_p$ differ from $\ln N^*_c$ and $\ln N^*_p$ by an error term, ϵ_{c2} and ϵ_{p2}, respectively, then the following approximation of $\ln N_c$ and $\ln N_p$ holds:

$$\ln N_c \doteq \ln N - \rho Y_r + 0.5\rho^2 Y_r^2 + \epsilon_{c2} \tag{36}$$

and

$$\ln N_p \doteq \ln N + \ln\rho + \ln Y_r - \rho Y_r + 0.5\rho^2 Y_r^2 + \epsilon_{p2}. \tag{37}$$

When equations (36) and (37) are substituted in the production functions, the following estimation form in logarithms is obtained

$$y_c = (a_c^\Delta + a_1 Y_r + a_2 Y_r^2) + \alpha_1 n + \alpha_2 l + \beta_1 k + \beta_2 f + \beta_3 m + \Psi_c(E) + \epsilon_c \tag{38}$$

and

$$y_p = (a_p^\Delta + a_1 \ln\rho + a_2 \ln Y_r + a_3 Y_r + a_4 Y_r^2) + \alpha_{p1} n + \alpha_{p2} i + \alpha_{p3} b + \Psi_p(E) + \epsilon_p, \tag{39}$$

where the lower-case letter variables are logarithms of the corresponding capital letter variables, a_c^Δ and a_p^Δ are logarithms of A^Δ defined in equation (16), and $\epsilon_c = \epsilon_{c1} + \alpha_1\epsilon_{c2}$ and $\epsilon_p = \epsilon_{p1} + \alpha_{p1}\epsilon_{p2}$ with ϵ_{c1} and ϵ_{p1} being the error terms of the original production functions.

Since equations (38) and (39) contain all the production coefficients, the estimates of the production functions can be obtained by estimating equations (38) and (39). There is, however, another problem involved in estimating equations (38) and (39). As given in equation (16), A^Δ is a function of prices of output and variable inputs. Prices are assumed to be constant at least within each year-region. For the nine year-regions covered in the sample, eight dummy variables are used for a^Δ to take care of possible price differentials among different year-regions.[22] Finally, four alternative forms of $\Psi(E)$ are adopted, letting the data determine the best fit. They are[23]

$$\Psi(E) = \gamma_1 E, \tag{40}$$

$$\Psi(E) = \gamma_1 \ln E, \tag{41}$$

$$\Psi(E) = \gamma_1 E^{-1}, \tag{42}$$

and

$$\Psi(E) = \gamma_1 E + \gamma_2 E^2. \tag{43}$$

Equations (38) and (39) are estimated by ordinary least squares.[24] The estimates are

[20] Farmland is not assumed to be an input in poultry production because raising hogs and poultry in Taiwan is normally carried out in farm houses and does not compete for land with crop production. No distinction is made between fixed and variable inputs for poultry production, since the allocative and scale effects are not examined on this secondary line of production.

[21] Letting ϵ_{c1} and ϵ_{p1} be error terms in the original production functions and assuming that production errors are not correlated with inputs, $Y_r = Y_p/Y_c = Y^*_p\exp(\epsilon_{p1})/Y^*_c\exp(\epsilon_{c1}) = Y^*_r\exp(\epsilon_{p1} - \epsilon_{c1})$. Hence, to use Y_r for Y^*_r means to ignore $\exp(\epsilon_{p1} - \epsilon_{c1})$.

[22] The dummy variables also capture other differences among year-regions such as weather and topographical variations.

[23] So long as $\gamma_1 > 0$, form (40) gives a positive marginal productivity of education (MPE) that increases at an increasing rate, and form (41) gives a positive MPE that decreases at a decreasing rate. So long as $\gamma_1 < 0$, form (42) gives a positive MPE that first increases as E increases to $0.5|\gamma_1|$ and then decreases as E becomes larger than $0.5|\gamma_1|$. So long as $\gamma_2 > 0$, form (43) either gives an MPE that is positive for all E if $\gamma_1 > 0$ or gives an MPE that changes from negative to positive at $E = 0.5|\gamma_1|/\gamma_2$ if $\gamma_1 < 0$. Therefore, to test a positive worker effect is to find a positive γ_1 in equation (40) or equation (41), a negative γ_1 in equation (42), or a positive γ_2 in equation (43).

[24] Since my model assumes profit maximization with respect to anticipated output, the ordinary least-squares method produces consistent estimates (see de Janvry for a general discussion of

		(0.95)	(0.14)	(0.79)	(1.82)
E^2	γ_2	n.a.	n.a.	n.a.	0.005
					(2.12)
	R^2	0.872	0.872	0.872	0.874

Notes: The estimates are obtained from OLS estimation of equation (38) when only significant dummy variables are included. The estimates for dummy and Y_r variables are not reported for sake of brevity. Figures in parentheses are magnitudes of t-ratios. E^{Δ} equals E in equation (40), $\ln E$ in equation (41), E^{-1} in equation (42), and E in equation (43).

summarized in tables 1 and 2. The coefficients of determination are greater than 0.85 for crop production and greater than 0.90 for poultry production. For a sample size as large as 310, this is a strong indication of good fit. Also, when different forms of $\Psi(E)$ are used, the estimates for other variables remain quite stable. The selection of a statistically better form for $\Psi(E)$ is thus achieved without affecting the estimates of other coefficients.

In all four forms of $\Psi(E)$ except equation (42) for crop production, the estimated coefficients of education carry the expected signs for a favorable worker effect. Equation (43) appears to be a better form for crop production, while equation (40) is better for poultry production. In terms of the better fitted forms, the t-ratio of education coefficient is relatively large (2.12 for γ_2 in crop production and 3.20 for γ_1 in poultry production). The evidence suggests the existence of a favorable worker effect of education in both crop and poultry production in the study area.

For an "average" farm that produces under average conditions and uses material inputs at geometric sample mean values, the worker effect is evaluated on the basis of the better fitted production functions to be NT$357 in crop production and NT$246 in poultry production if the educational attainment of the

consistent estimates obtained by OLS for anticipated-output models).

farm operator is one school year higher than sample average.[25]

Allocative and Scale Effects

Examination of allocative and scale effects is restricted to crop production only.[26] Since land and labor are assumed to be fixed inputs, these effects are studied with respect to capital services (K), fertilizer expenses (F), and other expenses (M).

As outlined before, the estimation of the allocative effect is in general to relate allocative efficiency index to education. The allocative efficiency index is defined either as a ratio of anticipated to maximum profit or as a ratio of observed to profit-maximizing cost. In calculating the anticipated and optimum values, the production coefficients obtained from the better fitted crop production function are used. The relations between allocative efficiency index and education are specified as

$$\theta = d_0 + d_1 E^{-1} \tag{44}$$

or

$$\theta = d_0 + d_1 \ln E, \tag{45}$$

where θ equals $(\ln u_j)^2$ or $|\ln u_j|$ for cost ratios or equals u^2 or u for profit ratio.

The allocative effect is first investigated in terms of cost ratios. The indices of allocative efficiency are calculated by equation (24) for individual inputs or by equation (25) for overall effect. When equations (44) and (45) are fitted, d_1 is expected to be positive in equation (44) or negative in equation (45) for a positive allocative effect. The estimates of d_1 are presented in table 3.

For all the individual inputs, the estimated slope (d_1) carries signs consistent with a positive allocative effect of education. Although the absolute value definition of θ appears better than the squared value definition for K, the t-ratios of d_1 are all less than two. The evidence does not strongly support an allocative effect with respect to K. There is, however, a more clear-cut indication of allocative effect with respect to F. The t-ratios are all greater than two with the absolute value definition of θ in form (44) being the best fit. As for M, the absolute value definition of θ is better than the squared value definition. Under the absolute value definition, the t-ratios are all greater than two. The evidence also suggests a favorable allocative effect with respect to M.[27]

When the overall efficiency index is defined in terms of cost ratio, form (44) appears to be a better fit than equation (45), but the two alternative definitions of θ make no significant difference. The estimated slope coefficient carries expected signs and large t-ratios (ranging

[25] These are equivalent to US$8.93 and US$6.15, respectively. Noting that the average farm size in Taiwan is about 3 acres, the worker effect found is quite substantial as compared with Huffman's finding of $6.08 for U.S. farms with an average size of 55 acres.

The better fitted form of $\Psi(E)$ in crop production implies a change of MPE from negative to positive at $E = 6.36$ (slightly below the sample average of 6.71). A possible explanation can be provided. Suppose that the adoption of new inputs increases with E but that the effective use of them does not begin to improve until a certain minimum level of E is reached. Then, for farms whose E is below that minimum level, the increased use of new inputs intensifies their ineffectiveness in production and, hence, E shows a negative marginal productivity. After that minimum level of E, the effectiveness in using new inputs improves, and E begins to show a positive marginal productivity.

[26] The family farms of Taiwan self-consumed a large portion of poultry output and used a great deal of self-supplied feed. Under these conditions, profit maximization is not an appropriate assumption.

[27] The sample averages of allocative efficiency index for K, F, and M are, respectively, 1.65, 0.47, and 0.45. On the average, the farms overutilized K but underutilized F and M. This study of allocative effect indicates that while the overutilization of K might not be related to education, the situation of underutilization of F and M improved with education.

Table 3. Allocative Effect—Estimates of d_1

Input(s) under Study	Efficiency Index Defined in Terms of	$\theta = (\ln u_j)^2$ or u^2		$\theta = \lvert\ln u_j\rvert$ or u	
		(44)	(45)	(44)	(45)
K	cost	0.772	−0.306	0.657	−0.204
		(0.71)	(1.11)	(1.48)	(1.81)
F	cost	5.418	−1.268	1.324	−0.253
		(2.95)	(2.71)	(2.82)	(2.10)
M	cost	3.850	−0.743	1.594	−0.362
		(1.40)	(1.06)	(2.74)	(2.44)
K, F, M	cost	3.201	−0.659	1.354	−0.277
		(3.70)	(2.97)	(3.69)	(2.95)
K, F, M	profit	−0.290	0.059	−0.197	0.041
		(2.35)	(1.87)	(2.18)	(1.79)

Notes: Estimates are obtained from OLS estimation of equations (44) and (45). Figures in parentheses are magnitudes of t-ratios.

from 2.95 to 3.70). There is a strong indication of overall allocative effect in the study area.

The overall allocative effect is then studied using the profit ratio defined in equation (9). In the present case, as explained earlier, the signs of the slope coefficient (d_1) of relations (44) and (45) expected for a positive allocative effect are opposite to those expected in cost-ratio studies. The estimates of d_1, also reported in table 3, carry expected signs. It appears that u^2 is a slightly better definition of θ than u, and relation (44) gives a better fit than equation (45). Under either definition of θ, the t-ratios are greater than two in equation (44). The result here is similar to, though somewhat weaker than, the conclusions reached for overall allocative effect in terms of cost ratio.[28]

Using equations (10) and (23), the net contribution of the overall allocative effect can be evaluated once the efficiency index (u) is estimated for given levels of education. When the estimates under the u^2 definition of θ in relation (44)—the best fit among the four alternative definitions and forms—are used in this connection, it is calculated that if the educational attainment of the farm operator of an "average" farm is one school year higher than sample average, the net contribution of the overall allocative effect is NT$117.[29] Contrary to Huffman's findings for U.S. agriculture (see note 6), the contribution of allocative effect is smaller than that of worker effect in the study area.

As discussed, the existence of a scale effect depends on a positive derivative of the factor-demand function with respect to education. The empirical demand function is specified in equation (27) for individual input j and in equation (29) as an overall average. In estimating these equations, similar to the estimation of production functions, year-region dummy variables are used for price variables, Taylor's approximation of labor is used for actual labor, and four forms of $\phi(E)$ similar to equations (40) through (43) are fitted. In all these forms of $\phi(E)$, the estimated coefficient of education carries signs consistent with a positive scale effect. While form (41) appears to be a better fit for K, form (43) is better for the others.

Reported in table 4 are the estimates of demand functions with the better fitted form of $\phi(E)$. For the demand for individual inputs, the t-ratio of education coefficient is relatively large for K (2.19) and not very small for F (1.98) and M (1.88). There is at least a weak indication of scale effect of education on utilization of variable inputs. This result becomes more conclusive when the demand function is estimated as an overall average where the t-ratio is as large as 2.96.[30]

Based upon estimates of the better fitted demand functions for individual inputs, the net contribution of the overall scale effect is evaluated according to the last term of equation (13). For an "average" farm, the overall scale effect is calculated at NT$111 if the educational attainment of the farm operator is one school year higher than sample average. The same figure is obtained when the average demand function is used. Similar to Huffman's findings for U.S. agriculture (see note 7), the contribution of scale effect nearly equals that of the allocative effect.

[28] Since the evidence does not show a strong indication of allocative effect with respect to K, perhaps K should better be treated as a fixed input. Under the alternative assumption of fixed K input, the overall allocative efficiency index in terms of profit with respect to the aggregate of F and M gives the following estimates of d_1: −0.326 (2.80) in relation (44) and 0.065 (2.17) in relation (45) for $\theta = u^2$ and −0.218 (2.90) in relation (44) and 0.044 (2.30) in relation (45) for $\theta = u$, where figures in parentheses are magnitudes of t-ratios. The indication here (all t-ratios greater than two) of an allocative effect with respect to F and M in combination is stronger than that with respect to K, F, and M. This is consistent with the findings of the allocative effect with respect to individual inputs. Also, since the profit-ratio study, unlike the cost-ratio study, considers also the revenue side of the problem, this may explain why a weaker conclusion about the overall allocative effect is reached in terms of profit than in terms of cost.

[29] If K is alternatively assumed to be a fixed input, the corresponding overall allocative effect is evaluated at NT$155.

[30] When K is alternatively assumed to be a fixed input, the estimated result gives a weaker conclusion about the scale effect. The t-ratios of education coefficient are 1.57 for F, 1.54 for M, and 2.03 for overall average.

Table 4. Scale Effect—Estimates of Factor-Demand Functions

Variable	Coefficient	K	F	M	Average
N	α'_1	0.721	0.512	0.552	0.598
		(6.57)	(6.80)	(5.90)	(9.18)
L	α'_2	0.332	0.429	0.536	0.435
		(3.81)	(7.27)	(7.51)	(8.54)
E^{Δ}	γ'_1	0.398	−0.936	−1.124	−1.218
		(2.19)	(1.98)	(1.88)	(2.96)
	R^2	0.413	0.566	0.511	0.651

Notes: Estimates are obtained from OLS estimation of equation (27) for demand for individual inputs and equation (29) for the average demand function with significant dummy variables only. Equation (29) is estimated using the geometric mean of K, F, and M as the dependent variable. Estimates for dummy and other variables are not reported for sake of brevity. Figures in parentheses are magnitudes of t-ratios. E^{Δ} equals $\ln E$ for K or equals E^{-1} in the other columns.

Conclusions

For family farms in Taiwan in the mid-1960s, education of the farm operator is a contributor to farm production. Unlike in the United States, the farms are characterized by small size and labor-intensive farming. They nevertheless experienced rapid technical progress during the study period. This study suggests that in a densely populated agriculture where production is typically carried out by small farms, education of farmers of a moderate level (about six years of schooling on the average) is able to contribute to production when rapid development is in progress.

Education contributes to production in several dimensions. This study found a strong indication of worker effect and allocative effect and also an indication of the "overall" scale effect. The profit contributions of these effects per acre are quite substantial. In U.S. agriculture, the allocative effect is more important than worker effect (Huffman). My findings are to the contrary. The contribution of worker effect in crop production is three times as large as the (overall) allocative effect. This suggests that the way by which education contributes to production is quite different for a small-scale, labor-intensive farming than for a large-scale, capital-intensive farming. Another possible explanation is that, with a higher average education for U.S. farmers, they may all possess the basic skills in using modern agricultural inputs, and hence they do not differ to a large extent in technical efficiency. As a result, the worker effect in U.S. agriculture is relatively small. This further suggests that the relative importance of worker effect may decrease with the average level of education.

In theory, when education has a worker effect, it normally raises the marginal productivity and hence the profitability of material inputs. Consequently, a scale effect should exist on the use of variable inputs in the short run or on the size of the farm in the long run. Empirically, the scale effect may not exist because, for example, farmers may all follow the same instructions given by extension workers and thus use the same amount of variable inputs per bundle of fixed inputs. This may also happen if there are certain constraints on the supply of inputs. Although a significant "overall" scale effect was found, the indication of a scale effect with respect to some individual inputs is weak. This shows that, when one studies the scale effect, it should be estimated empirically rather than calculated from the optimum factor-demand function.[31]

The worker effect (or the marginal productivity of education) in crop production was found to change from negative to positive at about 6.4 years of schooling. This may imply that the effective use of certain inputs does not begin to improve until this minimum level of education is reached. If this interpretation is valid, then a minimum level of education is necessary for farmers to learn effective use of modern agricultural inputs. If modern inputs are introduced in a less-developed agriculture without an accompanying increase in education of farmers, it may result in a large degree of ineffective use. The finding that a minimum of about six years of schooling is necessary for learning the effective use of new inputs seems to be consistent with Wharton's failure to find a significant effect of education in Brazilian agriculture where the farmers had very few years of schooling.

There is, on the average, an overutilization of capital input but an underutilization of fertilizer and other modern inputs. While the overutilization of capital input may not be associated with education, the degree of underutilization of fertilizer and other inputs decreases with education. The findings suggest that, if the situation in Taiwan today is not substantially different from that in the study period, to encourage a more intensive use of capital equipment and machinery by the family farms may not be a wise policy. On the other hand, although the farms of Taiwan have used a great amount of fertilizer and other new inputs (Shen), at least in the regions under study, a further increase in the use of these inputs is still profitable. This study further suggests that one way to increase the use of these inputs is to increase the education of farmers, either in terms of formal schooling or in terms of extension education. Needless to say, an elimination of supply constraints or other barriers such as the attitude of risk aversion on the part of the farmers can also increase the use of these inputs.

The total contribution of education is estimated at NT$825, which includes NT$357 for worker effect, NT$117 for overall allocative

[31] Huffman calculated the scale effect or his joint worker-allocative effect from production-function estimates using a formula similar to the last term of equation (12) in which the partial derivative of factor demand with respect to education does not equal zero if education has a worker effect in the production function.

effect, NT$111 for overall scale effect in crop production, and NT$246 for worker effect in poultry production, if the educational attainment of the farm operator of an "average" farm is one school year higher than sample average (about 6.7 years).[32] According to a previous estimate (Wu, p. 93), total costs—including government and private expenditures but not including opportunity costs in foregone income that may not be important in the study period—of one additional year of schooling per student were about NT$2,790 for the seventh year or NT$3,050 for the eighth year. In comparison with the costs of education, the estimated returns to education in terms of farm production are substantial. Since 1968, the government of Taiwan has extended its public education from six to nine years. This might be a profitable move so long as agricultural production is concerned if the economy of Taiwan sustains its pace of development.

[32] As mentioned earlier, because of lack of data the allocative effect in terms of allocating fixed input (labor) between crop and poultry production was not investigated. Moreover, the (employment) allocative effect on poultry production was not investigated either. Hence, the estimate of the total contribution of education is not all-inclusive.

Attitudes Toward Risk among Peasants: An Econometric Approach

Edgardo Moscardi and Alain de Janvry

Attitudes toward risk among peasants in Puebla, Mexico, are derived from survey data in a model of safety-first behavior. The measurements of behavior toward risk obtained are then explained by a set of socioeconomic and structural variables that characterize peasant households. Knowledge of the determinants of attitudes toward risk is, in turn, useful for the purpose of tailoring technological recommendations to particular categories of peasants.

Key words: Mexico, peasants, risk aversion, technological change.

A number of recent studies have evidenced the importance of risk on decision making by peasants (Dillon and Anderson, Wolgin, Wiens) and farmers (Lin, Dean, and Moore; Boussard and Petit). Attitudes toward risk are major determinants of the rate of diffusion of new technologies among peasants and of the outcome of rural development programs. If they are going to be effective, new technologies and rural development programs need to be tailored to the attitudes toward risk of particular categories of peasants. For this purpose, it is important to identify the specific determinants of behavior toward risk and to quantify their impact on decision making.

This paper starts by examining the extent to which risk may be responsible for discrepancies between peasants' demand for fertilizer without risk and actual demand under risky conditions. For this purpose, risk is introduced in a model of economic decision making as a safety-first rule. According to this rule, an important motivating force of the decision maker in managing the productive resources that he controls and, in particular, in choosing among technological options is the security of generating returns large enough to cover subsistence needs. As recent empirical studies of peasant behavior indicate, safety-first criteria tend to be followed whenever the satisfaction of basic needs may be at risk (Scandizzo and Dillon).

Assuming that the safety-first model holds, the degree of risk aversion manifested by individual peasants can be derived from observed behavior. Given a production technology, the risk associated with production, and market conditions, the observed level of factor use reveals the underlying degree of risk aversion. In this fashion, attitudes toward risk can be measured for relatively large samples of peasants. Explanations for differential degrees of risk aversion among peasants can then be sought by relating the measures of risk aversion obtained to a number of variables that characterize the peasant household, its income-generating opportunities, and its position in the political economy.

This indirect approach to the measurement and explanation of risk aversion is introduced as an alternative to the direct approach developed by von Neumann and Morgenstern. In this direct approach the subject is asked to make decisions in reaction to a large number of randomly arranged hypothetical bets and insurance schemes. This approach has serious difficulties resulting from the fact that the subjects have different degrees of utility or disutility for gambling (the very method used to reveal their preferences) and that the concepts of probability are by no means intuitively obvious (Edwards). In addition, the method is very time consuming to administer (Lin, Dean, and Moore). As a result, the measurements of risk aversion thus obtained have been few, and attempts at relating these mea-

Giannini Foundation Paper No. 455. The authors are indebted to Donald Winkelmann and George M. Kuznets for helpful suggestions and to the International Center for Corn and Wheat for financial assistance.

surements to explanatory variables have been unsuccessful (Halter and Beringer, Officer and Halter) or only partially successful (Scandizzo and Dillon).

The indirect approach used here is easy to handle empirically and thus makes it possible to manipulate large samples of peasants. The results, however, are fully conditional on how well the model specified describes peasant behavior. The validity of the results depends upon careful screening of the observations so that all discrepancies between actual and predicted behavior that are not due to risk in production are accounted for by the model.

Allocative Efficiency under Safety First

Alternative specifications of safety-first rules have been given by Roy, Telser, and Kataoka. Following Kataoka, maximize d subject to $Pr(r \leq d) \leq \alpha$, where d is the subsistence or disaster net income level, r is the random net income, and α is the accepted probability of disaster (presumably low). This last variable is postulated to depend upon a vector S of variables that represent the socioeconomic characteristics of the peasant household: $\alpha = \alpha(S)$. Assuming the mean μ and standard deviation σ of r to be known, a certainty equivalent to the above model can be derived by maximizing the upper bound of the disaster level given by Chebychev's inequality (Pyle and Turnovsky). Then the model becomes

$$(1)\quad \max V(\mu, \sigma) = \mu - K\sigma \text{ for } K = K(S),$$

where K is the marginal rate of substitution between expected net income and risk, i.e., the measure of risk aversion suggested by Magnusson. Like α, K is a function of the peasant household characteristics S.

Assume that the randomness of net income derives from yield uncertainty. Assume also that the relationship between inputs (vector X) and yield (Y) is represented by a generalized power production function (de Janvry 1972a, b)

$$Y = A\prod_i X_i^{f_i(X)} e^{u}.$$

For a given production function, a given coefficient of variation of yield ($\theta = \sigma_Y/\mu_Y$), given factor prices (P_i), and a given product price (P), the preference order (1) can be maximized with respect to the input levels. The resulting first-order conditions are

$$(2)\quad Pf_i \frac{E(Y)}{X_i} = \frac{P_i}{1 - \theta K(S)},$$

where f_i is the elasticity of production of the ith input. In equation (2), the left-hand side is the expected value of the marginal productivity of the ith input. On the right-hand side, the price of the ith input is compounded by a risk factor that is a function of the socioeconomic characteristics of the peasant household.

Assuming that this model correctly specifies the peasant's decision-making process, the value of the risk-aversion parameter K can be deduced from the observed levels of product and inputs by solving equation (2):

$$(3)\quad K(S) = \frac{1}{\theta}\left(1 - \frac{P_i X_i}{Pf_i \mu_Y}\right).$$

Equation (3) provides a measure of risk aversion that can easily be derived for each peasant from knowledge of the production function, the coefficient of variation of yield, product and factor prices, and observed levels of factor use.

Since risk aversion is measured as a residual from the behavioral equation (2), it tends to include other sources of discrepancy between optimum and actual resource allocation such as, for example, imperfect market and agronomic information, restricted availability of financial capital and inputs, and high opportunity cost of family labor. In order for the measured K to be a pure measure of risk aversion, the data have to be carefully screened to eliminate observations where such constraints may be effective.

Measurements of Risk Aversion

The data used are derived from the Puebla Project in Mexico (International Center for Wheat and Corn). In this well-advertised rural development project, a package of technological and institutional practices designed to increase corn yields was developed and disseminated among peasants. The package included technical information about fertilizer doses, time of application, and plant density, plus institutional arrangements to facilitate access to credit and fertilizer.

The agronomic information needed to estimate the production function for this new technological package was obtained from the field experiments of corn fertilization carried out by the project agronomists between 1967

and 1971. The data consist of 1,142 observations from twenty-five trials conducted in one of the production systems of the project known as Deep Soils of the Popocatepetl. Each basic observation consists of information on yield (Y) in kilograms per hectare, nitrogen doses (N) in kilograms per hectare, phosphorus doses (PO) in kilograms per hectare, soil organic matter (M) in percentage, soil phosphorus content (P) in kilograms of P_2O_5 per hectare, and soil pH (PH) in units. Due to the existence of high correlations among the exogenous variables, the parameters of the generalized power production function are estimated using ridge regression (Hoerl and Kennard). The results are $\log Y = 0.98 + 0.34 \log N - 0.01M \log N + 0.04 \log PO - 0\,P \log PO + 0.01 \log M + 0.32 \log P + 1.71 \log PH$; $R^2 = 0.6$, ridge parameter = 0.2. The information about fertilizer levels actually used by farmers, as well as location and socioeconomic characteristics of peasant households, was obtained from a random survey conducted in 1971. From this survey, a sample of farm households was selected in order to meet two requirements that would insure that the decision model postulated applies. These requirements are that the farmers knew about fertilizer, had used it in the past, and cultivated maize as their major agricultural activity and had no effective family labor constraint in the sense that the difference between available family working time and time allocated to off-farm, income-generating activities was greater than the labor requirements to grow corn using the economically optimum level of fertilizers. Forty-five of the fifty-five farm households in the survey were retained on the basis of these criteria.

Since nitrogen is agronomically the most important input for increasing yields in the area and is also the largest component of variable costs, its marginal productivity derived from the farm experiments is used to calculate the risk-aversion parameter K for each farm household. This marginal productivity is measured for the particular soil conditions of each peasant and for a level of phosphorus corresponding, on the expansion path, to the observed doses of nitrogen used.

The derived marginal productivity together with the coefficient of variation of yield and product and factor prices for 1971 provide a value of K for each farm household using equation (3). A sample of the results obtained is shown in table 1. The estimated frequency distribution of K obtained from its cumulative distribution function using Schlaifer's fractile rule is shown in figure 1. The results show a distribution of risk aversion highly skewed toward the risk averters and centered around $K = 1.12$. This value is close to that estimated by Scandizzo and Dillon for a similar population of subsistence peasants in northeast Brazil but following the direct approach of von Neumann and Morgenstern.

Since Kataoka's safety-first rule implies constrained optima for values of risk aversion greater than zero, the marginal rates of return associated with diminishing degrees of risk aversion can be calculated. The results are shown in table 2. Clearly, the net benefit curve becomes practically flat for expenditures above \$600 per hectare and the marginal rate of return drops drastically. If one thinks of net benefits as returns for risk taking and defines a risk premium as the percentage amount that a farmer requires before exposing himself to a variable income, such a premium is very high for an average farmer (K being about 1), thus discouraging nitrogen fertilization rates beyond some 60 kilograms per hectare.

Table 1. Economic Optimum, Farmers' Use of Fertilizer, and Risk-Aversion Measure, Puebla, 1971

Farmer Identification	Economic Optimum		Farmers' Use		Risk Measure
	N	P_2O_5[a]	N	P_2O_5[a]

Determinants of Attitudes Toward Risk

Three classes of variables are used to define the socioeconomic characteristics of the peasant households: the nature of the household, its income-generating opportunities, and its access to public institutions. An explanation for the differential degree of risk aversion among peasant households can be sought from these characteristics.

Age and years of schooling of the household head and family size are included in the first class of variables. It is generally assumed that, other factors being the same, older farmers tend to be less prone to take risks than younger ones. This should be particularly true in subsistence agriculture where age can hardly imply greater on-the-job experience (which may be thought to be positively associated with risk bearing), since, on the one hand, the ability to farm under these conditions does not require a lot of experience and, on the other, opportunities to develop informally new types of skills and to use them profitably are not easily available. As table 3 shows, the average age of the household head is quite high: fifty years.

Higher levels of education have generally been associated positively with risk taking. In the area under study, the average number of years of schooling is, however, very low—2.4 years—indicating attendance at elementary school without graduating. Due to this low level of education, the impact of schooling on risk taking can be expected to be positive but not of great importance.

Two opposing interpretations can be given to the relationship between risk taking and family size. One is that, the larger the size of the family, the higher the subsistence consumption needs and, given a fixed amount of land, the lower the willingness of the farmer to assume risks. In this case, family size reflects the consumption needs of children. Another interpretation is that family size reflects the labor capacity of the peasant household. A larger family implies greater availability of labor on the farm, which is particularly important at harvest time when there is a labor shortage in the region and a greater capacity to generate off-farm income. As a result, the capacity of the farmer to assume risks increases with family size. The data support this second interpretation: most family members are actually engaged in productive activities. Average family size is 5.4 members with only 1.5 members below ten years of age.

The income-generating opportunities of the peasant household are represented by the total amount of land under its control and the level of off-farm income. Total land under control is the amount of land cultivated by the peasant independently of the type of land tenure. According to a benchmark survey conducted in 1967, some 40% of the farmers had a combined private and *ejido* holding, while 30% were pure *ejidatarios* and 40% were pure private small holders. Land tenure differences do not have an impact on economic behavior. The average land under control for the sample under study is 2.9 hectares, including 0.15 hectares under irrigation. The hypothesis here is that having more land under control permits the farmers to bear higher risks. This hypothesis is consistent with both Pratt and Arrow's formulation of decreasing absolute risk aversion for increasing wealth as well as with the recent findings of Wiens regarding peasant risk aversion. Following the logic of safety first, this results from the fact that the risk-aversion constraint becomes less effective as income rises beyond subsistence requirements. In addition, more land makes it possible to spread out risks by cultivating more than one crop or the same crop under different technologies; also, more land often implies different plots at various locations on different kinds of soils and under different climatic conditions.

Off-farm income can be assumed to have an important impact on risk taking. In the sample under study, 65% of the households earned off-farm income, generating some 40% of total family income. This part-time agricultural system is typical of subsistence agriculture in Latin America (Barraclough). The importance of off-farm income as a component of family income increases as farm size is smaller, family size larger, and agronomic conditions more marginal. In the Puebla area, which is fairly urbanized, off-farm earnings are obtained from wages in domestic, commercial, and industrial employment in nearby cities. With rather stable employment opportunities, the hypothesis is that the higher the off-farm income, the higher the capacity of farmers to assume risks in agricultural production.

Only one variable is used to account for the integration of the peasant with public institutions—membership in a "solidarity group." The creation of such groups was induced by the Puebla Project to allow peasants to have access to credit not as individuals but as groups of five to twenty members. In this way transaction costs are reduced for both farmers and banks; technical assistance by the Puebla Project can be provided more effectively; and many farmers who do not have legal title to their land can thus obtain credit as long as at least one member of the group has legal title. Some 30% of the farmers in the sample are members of solidarity groups. What is not known is whether the farmers joined the groups because they wanted to follow the technological recommendations of the Puebla Project or whether they were already using high fertilizer doses but wanted to have easier access to credit. If the latter condition applies, there would be no relationship between risk taking and membership in a solidarity group. If the former applies, as can generally be expected, a farmer in a solidarity group is better able to sustain risks.

A discriminant analysis was conducted to

explore quantitatively the relation between risk aversion and the household characteristics defined above. This multivariate technique is more adequate here than regression analysis for two reasons. First, the interval of variation of K is truncated between 0 and 2 for the behavioral condition (1) to be satisfied with a coefficient of variation of yield of 0.5. Second, it is useful for the design of rural development programs to classify peasants into groups with similar attitudes toward risk and identify the defining socioeconomic characteristics of those groups.

The risk parameter K has been used to classify peasants into three groups: low-risk ($0 < K < 0.4$), intermediate-risk ($0.4 \leq K \leq 1.2$), and high-risk aversion ($1.2 < K < 2$). The general hypothesis that a systematic relationship exists between attitude toward risk and the socioeconomic characteristics of peasant households, as well as the particular hypothesis on each variable discussed above, is rejected or accepted to the extent that the discriminant function estimated assigns the peasant households to the same groups as does the classification variable K. Table 3 shows the mean and standard deviation of the socioeconomic variables for the three groups defined in terms of attitude toward risk. Particularly remarkable is the association between risk taking and off-farm income, land under control, and membership in a solidarity group.

Table 4 makes it possible to compare the classification obtained by discriminant analysis with that established on the basis of risk aversion. Of the total number of observations assigned to each group on the basis of risk aversion, 83% remained in the risk-neutral group, 86% in the low-risk group, and 82% in the high-risk group. No reclassification occurred between the extreme groups. This analysis was repeated on a sample of thirty-one peasant households in another area of the Puebla Project with results essentially similar to those presented here (Moscardi).

For predictive purposes, a regression equation was run between risk aversion and the same socioeconomic variables characterizing peasant households using a combined sample of seventy-six cases from two regions. As can be seen from table 5, the results also support the hypothesis that the risk-bearing capacity of peasants can be explained by their socioeconomic and structural characteristics. Particularly significant for that purpose are the extent of land under control, off-farm income, and membership in a solidarity group.

Conclusions

Estimation of risk aversion for a relatively large sample of farmers, following the indirect method outlined above, shows that risk aversion is indeed responsible for substantial differences between the demand for fertilizer without risk and actual demand. Risk premiums are high, discouraging the use of high rates of fertilizer under safety-first behavior.

Knowledge of the value and distribution of K is important for the construction of models of peasant behavior and of aggregate supply response. Particularly interesting is the fact that, following the much less data-demanding indirect method, results similar to those obtained by direct use of the von Neumann-Morgenstern technique have been obtained.

Beyond random discrepancies, it is possible to establish a systematic relationship between risk aversion and a number of socioeconomic variables that characterize peasant households, their access to income-generating opportunities, and their relation to public institutions. Knowledge of attitude toward risk for particular categories of peasants defined by these socioeconomic variables makes it possi-

Notes

Price Incentive versus Irrigation Investment to Achieve Food Self-Sufficiency in the Philippines

Yujiro Hayami, Eugene Bennagen, and Randolph Barker

Barker and Hayami, using rice in the Philippines as a case, evaluate product price support and input subsidies as policy alternatives to achieve food self-sufficiency in developing countries. The analysis shows that the input subsidy is more efficient in terms of social benefit-cost criteria when the subsidy is applied to modern inputs, such as fertilizers, that are used below optimum level. However, the self-sufficiency goal can probably be achieved more efficiently in the long run through the improvement in physical and institutional infrastructure for food production.

In this note, the policy comparison includes government investment in irrigation systems so that the social benefits and costs associated with the construction of production infrastructure and the provision of price incentives are compared as alternative policies for achieving food self-sufficiency. As in the previous paper, the analysis is applied to the rice economy in the Philippines.

Methodology and Data

A major problem in comparing price policy with infrastructure development policy is the difference in the distribution of benefits and costs over time. A constant flow of annual government expenditure is required for supporting product prices or subsidizing input prices if a level of output increased by the price incentives is to be maintained. Resulting benefits of producers and savings of foreign exchange also flow in constant streams.

In contrast, if the same amount of output is to be increased by government investments in irrigation systems, a large capital cost (with a certain foreign exchange component) is involved during the construction period. The benefit increases gradually as the major hardware is built and the subsidiary laterals and ditches are constructed. The full benefit emerges when a farming system in the command area is completely adjusted to the irrigation system. The benefit stream can be maintained with a flow of operation and maintenance expenses until the end of a usable life. The government can plow back a part of benefit by charging irrigation fees for the service rendered to farmers in the command area.

In order to compare price policy with irrigation development policy as alternatives to achieve food self-sufficiency, it is necessary to convert their benefits and costs into the same time dimension. The methodology adapted here is to capitalize all benefits and costs associated with an irrigation development project from its initiation to the end of usable life into present values at the time of initiation. Then, using a standard rate of interest, the capitalized values of benefit and cost are converted into infinite annual streams, which are compared with the annual benefit and cost associated with the product price support and the input price subsidy.

Simplifying assumptions for the capitalization of irrigation costs and benefits are the following. (*a*) The whole capital cost is spent in the median year of the construction period. (*b*) No benefit is produced until the construction of the irrigation system is completed. However, the full benefit of the systems in the form of increases in farm output (rice) with corresponding increases in inputs emerges from the next year of completion of government construction project and is maintained until the end of usable life.[1] (*c*) Both the cost of operation and maintenance and the collection of irrigation fee per hectare of command area per year is fixed throughout the period of usable life. (*d*) Government policy is such that an increase in domestic rice output substitutes for an equal reduction in import, thereby resulting in no change in domestic rice supply and prices. An additional amount of fertilizer required to increase domestic output in the expanded area under irrigation is procured from overseas.

The capitalized present values of government costs, farm producers' benefits, and net foreign exchange savings associated with the policy of developing irrigation infrastructure to achieve food self-sufficiency are calculated as follows:

Yujiro Hayami is a professor of economics, Tokyo Metropolitan University, Eugene Bennagen is a research assistant and Randolph Barker is an agricultural economist, International Rice Research Institute.

This study was conducted at the International Rice Research Institute.

[1] Usually the benefit begins to emerge even before the completion of whole construction and increases gradually for a number of years after its completion as farmers adjust their production to the irrigation system. The assumption of a constant benefit stream throughout the usable life of the system may tend to bias the benefit estimate upwards. In order to avoid such a possibility, a conservative estimate of benefit flow is used.

$$\text{Government cost} = \frac{c}{(1+i)^m} + (o - w)\frac{[(1+i)^n - 1]}{i(1+i)^{h+n}},$$

$$\text{Producers' benefit} = (\Delta qp - k\Delta xp_f - \Delta zp_z - w)\frac{[(1+i)^n - 1]}{i(1+i)^{h+n}},$$

and

$$\text{Net foreign exchange saving} = -\frac{e}{(1+i)^m} + (\Delta qp_w - k'\Delta xp_{fw})\frac{[(1+i)^n - 1]}{i(1-i)^{h+n}},$$

where Δq is the increase in rice output required to achieve self-sufficiency (220,000 tons of milled rice), c is the capital cost of building irrigation systems to increase rice output by Δq, e is the foreign exchange component in c, o is the operation and maintenance cost, w is the irrigation fee, Δx is the increase in nitrogen input to produce Δq, Δz is the increase in labor input to produce Δq, p is the domestic producer price of rice, p_w is the import price of rice ($200 per ton of milled rice), p_f is the nitrogen price paid by rice producers ($400 per ton of N), p_{fw} is the import price of nitrogen ($340 per ton of N), p_z is the farm wage rate ($0.85 per man-day), k is the ratio of the total cost of current inputs, capital interest, and depreciation to the cost of nitrogen input for rice production, k' is the ratio of the foreign exchange cost of current inputs, capital interest, and depreciation to the cost of nitrogen input for rice production, h is the period of irrigation construction, m is the median of the construction period, n is the period of usable life of irrigation systems, and i is the interest rate.

The data used are for 1975, so that the benefits and costs of developing irrigation systems are comparable with those of the rice price support and fertilizer subsidy programs estimated in Barker and Hayami.

The specification of data for irrigation costs and benefits depends critically on the type of irrigation system assumed. In this study, a gravity system of the National Irrigation Administration (NIA) is used. However, there is a wide spectrum of technical standards within NIA systems in terms of water supply and control capabilities. On the average, the actual rate of irrigation in the systems command area is low—an estimate shows that actual irrigated areas are only 75% and 33% of total command area, respectively, for wet and dry seasons. Average capital cost per hectare commanded by the NIA systems for which the construction was completed for 1972–75 was 4,600 pesos (Philippines) ($650) at 1975 prices.[2]

However, recent large-scale projects such as the Upper Pampanga River Project (UPRP) have a much higher technical standard at a much higher cost. Such projects have larger foreign exchange components than the traditional small-scale projects. The "UPRP standard," which is used as a yardstick to the future irrigation development plans, assumes that a capital cost per hectare of command area at 1975 prices is 10,000 pesos ($1,430) for flat land and 12,000 pesos ($1,700) for rolling land and that the rates of irrigation in the command area are 100% and 60%, respectively, for wet and dry seasons. The foreign exchange component is assumed to be about one-half of the total capital cost.

The collection of water fees depends on the standard of the system. The NIA rate of water fee is 2 cavans of paddy for wet season and 3 cavans for dry season (1 cavan = 44 kilograms, about 50 pesos per cavan). The collection rate depends on how the command area is irrigated. The UPRP standard system, which has better water control and supply capacity, should be able to collect a larger amount of irrigation fee than the NIA average system.

The operation and maintenance cost per hectare of NIA command area is assumed to range from about 100 to 150 pesos ($15 to $20). The low standard systems tend to be more easily damaged and require frequent repairs. It seems reasonable to assume that the low standard system needs equal or even larger maintenance cost compared with the high standard system if it is to be maintained for the same period of usable life.

Based on the information as summarized above, the two standard systems for NIA irrigation construction are specified (table 1) as "NIA average," which corresponds to the systems for which construction was finished in 1972–75, and "UPRP standard," which corresponds to large-scale projects in NIA future development plan.

Increases in rice output and production costs corresponding to a hectare increase in irrigation systems command area are estimated by assuming that the conversion of a paddy field from rainfed to irrigated conditions accompanies both a shift from traditional varieties to modern high-yielding fertilizer responsive varieties and a shift from a wet-season single cropping to double cropping of rice. Functions estimated by Hayami et al. are used as representing the responses of paddy output to nitrogen:

High-yielding varieties in irrigated fields:

$$Y = 2{,}150 + 18N - 0.08N^2,$$

Traditional varieties in irrigated fields:

$$Y = 1{,}610 + 11N - 0.13N^2,$$

and

Traditional varieties in rainfed fields:

$$Y = 1{,}238 + 8N - 0.1N^2,$$

where Y and N are, respectively, paddy yield and nitrogen input per hectare in kilograms.

It is assumed that the conversion from the rainfed

[2] The official peso/dollar exchange rate in 1975 was about 7 to 1.

Table 1. Data Assumptions Associated with Different Specifications of Irrigation Systems in the Philippines

	Specification	
	NIA Average	UPRP Standard
Averages per hectare of command area		
Capital cost		
Total ($)	650	1,500

Dry season	0.33	0.6
Increase in rice output per year (tons of milled rice)	1.5	2.8
Increase in nitrogen input per year (kg.)	60	90
Increase in labor input per year (man-days)	50	80
Operation and maintenance cost per year ($)	20	20
Collection of water fee per year ($)	15	20
Period of usable life (years)	50	50
Construction period (years)	3	5
Total requirements to achieve self-sufficiency		
Increase in command area (1,000 ha.)	147	79
Capital cost		
Total ($ million)	96	118
Foreign exchange component ($ million)	38	59

to the irrigated field accompanied both the shift from the third to the first response function and the increase in nitrogen input from 5 to 60 kilograms per hectare. Resulting increases in rice output (in milled rice terms converted from paddy by a factor of 0.7) and nitrogen input per hectare of crop area for dry and wet seasons are multiplied by irrigation rates and added together to arrive at the estimates of output and input increases per hectare of command area per year. The response function used for irrigated fields corresponds to an average irrigated condition in the Philippines, which is inferior even compared with the NIA average. The yield per hectare assumed for the UPRP standard is 30% to 40% higher than the response function implies. Here, we very conservatively adjust the yield estimates produced from the function upwards by 10% for the UPRP.

The nitrogen cost is assumed to be one-half of the cost of current inputs, capital interest, and depreciation for rice production, of which 80% is supplied from abroad ($k = 2$ and $k' = 1.6$). Further, it is assumed that labor input per hectare of crop area increases from 65 to 90 man-days in the wet season, corresponding to the shift from the rainfed to the irrigated condition, and 0 to 90 man-days corresponding to the one-hectare increase in dry season crop area due to irrigation.

Another critical variable in benefit-cost analysis of irrigation investment is the interest rate, which is assumed to reflect a social discount rate. A standard interest rate for the loans to government-assisted development projects in the Philippines is 12% per year. However, 15% is a commonly used discount rate in the project evaluation by a planning agency (National Economic and Development Authority). In this analysis, we use 12% and 18% as the boundary estimates of the effective rate of interest in development planning.

Policy Comparison

The capitalized present values of benefits and costs associated with government investments in NIA irrigation systems to achieve self-sufficiency in rice in the Philippines are estimated for four different cases (table 2). Case A assumes NIA average standard and 12% interest rate; case B assumes NIA average standard and 18% interest rate; case C assumes UPRP standard and 12% interest rate; and case D assumes UPRP standard and 18% interest rate.

The present value of capital cost for the UPRP standard is about 10% higher than for the NIA average standard, but because the collection of irrigation fee is higher in the UPRP standard, the total government cost is almost the same for both systems. Corresponding benefits for rice producers are about 20% lower for the UPRP standard primarily because of a longer gestation period. The difference in net foreign exchange savings between the two standards of systems is about 20% to 30%, but the difference between different interest-rate assumptions is almost 100%.

The capitalized values of government cost, producers' benefit, and foreign exchange savings for irrigation investment are converted into infinite an-

(8) Producers' benefit = (4) − (5) − (6) − (3)	169	96	149	76
(9) Foreign exchange savings $= -\frac{e}{c}(1) + \frac{p_w}{p}(4) - \frac{k'}{k}\frac{p_{fw}}{p_f}(5)$	333	172	261	123

[a] See text for definitions of alternatives.

nual streams by applying the interests assumed in the capitalization, which are compared with annual benefits and costs associated with rice price support and fertilizer subsidy programs to achieve self-sufficiency (table 3).[3]

In terms of annual flows, the government cost required for the support of rice prices is almost ten times higher than for irrigation development; for the subsidy on fertilizer prices, it is almost five times more expensive. On the other hand, the price support and fertilizer subsidy programs produce larger benefits to rice producers primarily in the form of income transfer from government (taxpayers) to producers.

The calculation of social benefit-cost ratios (assuming the premium on foreign exchange is 5%) shows that irrigation investment is a more efficient means to achieve rice self-sufficiency except for case D, which assumes a higher cost project and a high interest rate. If the social discount rate is high and few possibilities exist for low-cost projects, the fertilizer subsidy program becomes more advantageous to irrigation development project in efficiency criteria.

[3] The fertilizer subsidy program in this comparison corresponds to plan A in Barker and Hayami, in which the subsidy applies only to the rice sector. It was shown that the efficiency of the program can be increased by extending the subsidy to the sugar sector and, at the same time, raising the rate of the sugar export tax (plan C). This plan is not compared here, partly because the plan has never been contemplated actually by policy makers but more importantly because to be compared with plan C a variation of the irrigation development policy should be designed (e.g., to extend the government irrigation investment to the sugar sector and tax away the benefit).

Conclusion

The results in this study show that, despite its large initial capital cost, irrigation investment imposes less financial burden on the government than the manipulation of product and input prices in the long run. In terms of the social benefit-cost ratio, the irrigation development is clearly more efficient than

Table 3. Benefits and Costs Associated with Alternative Policies to Achieve Self-Sufficiency in Rice, Philippines, 1975

[a] See text for definitions of alternatives.

rice price support. But it becomes inferior to fertilizer subsidy if a high discount rate is applied to a large-scale high-cost project.

In the Philippines, even though the real cost of irrigation construction is rising as the easier sites that can be covered by small-scale low-cost projects are exhausted, areas still exist that can be irrigated by relatively low-cost systems comparable with or even less costly than the NIA average. The average benefit-cost ratio for irrigation development on a scale to achieve self-sufficiency in rice would be close to the NIA average. Considering the high opportunity cost of government funds, the irrigation investment is probably more efficient as a means to achieve rice self-sufficiency in the Philippines in the long run than the use of fertilizer subsidy, even though the conventional benefit-cost ratios are comparable.

However, the social rate of discount for government investment can be higher than assumed in the analysis. The rate of discount for future rice output corresponding to the investment may rise to a very high level in years of rice shortage. In such years, the discount rate for future output conceived by policy makers would become extremely high because it is the rice supply of this year rather than several years later that determines the social stability and, hence, their political position. Therefore, in years of rice shortage, it could become rational for the policy makers to adopt short-run price policies to increase domestic output, despite the long-run inefficiency involved.

Estimating Agricultural Production by the Use of Satellite Information: An Experiment with Laotian Data

Richard Hooley, Roger Hoffer, and Stanley Morain

Accurate estimates of agricultural output are particularly important in less developed countries (LDC's) because of the large relative size of the agricultural sector. In most LDC's, estimates of national product are hardly useful to the analyst unless the data on agricultural production can be taken as a reasonably accurate measure of the volume of agricultural activity.

Two common ways of measuring value added in agriculture are from the production side and from the income side. The first requires data on agricultural production, intermediate goods used, and, for net value added, an estimate of capital consumption. The second method requires data on income, rents, taxes and subsidies, and estimates of capital consumption. A presumed advantage of estimating agricultural production within the framework of a system of national accounts is that independent estimates of value added are made from both the production and income side. The accounting framework provides an internal check on the consistency of data, since estimates by either method must necessarily be equal.

In fact, however, independent estimates made from both the production and income side are the exception rather than the rule. The United Nations found that only one-third of sixty countries it surveyed have sufficient data on wages and salaries paid in agriculture to make an independent estimate from the income side. The remaining two-thirds make the estimate of output from the production side alone. When classified by income level, the same survey shows that 89% of countries with a gross domestic product per capita of less than $500 rely exclusively on estimates from the production side, compared with only 43% for countries with a gross domestic product per capita of over $1,500 (United Nations 1969). Fiscal systems are not highly developed in LDC's, and taxes on wages and salaries rarely cover the rural population to any significant degree. Moreover, the rural work force is engaged in a variety of occupations, including service, with significant seasonal swings, making it difficult to determine wages and salaries paid for agricultural, as distinct from rural, production. It is precisely in the poorer countries where agriculture contributes in a major way to aggregate output that the dependence on accurate production data is most decisive.

In most cases, agricultural output consists primarily of crop output. The general method of measurement of crop production is well known. It consists of measuring area under cultivation and multiplying the result by an estimate of crop yield, usually obtained by cutting a swath of the standing crop on a sample basis. With proper stratification by geographic area and by type of crop (at least for major crops), this method can produce reasonably accurate results.

Accurate estimates of cultivated area are particularly important in measuring long-run changes in production. This is particularly true in LDC's where farmers often work with traditional technology and expand output along with inputs, including land. The measurement of cultivated area presents serious problems in LDC's because it requires at least one benchmark estimate based on a complete count.[1]

The difficulties of making accurate estimates of cultivated area are of two kinds: problems of establishing an accurate benchmark and those associated with actual measurements of land area. In spite of the efforts of the United Nations, some LDC's still have not taken an agricultural census. For these countries, a benchmark area estimate is still unavailable. For a number of others, training interviewers, reaching areas made inaccessible by topography, and monitoring performance of census interviewers have proved so intractable that the results of the census are of dubious value. Add to this the difficulties of updating such a benchmark periodically, and one can understand why dependable estimates of agricultural land area in use are often difficult to obtain.

A second group of problems concerns area measurements themselves. A number of the poorest

Work on this paper was supported by funds from the Asia Foundation. The authors alone assume responsibility for the views expressed.

[1] It is possible to utilize sampling procedures to estimate year-to-year variation in area planted, but this information is obviously of little use if there is no benchmark estimate on which to construct an initial estimate of total cultivated area.

LDC's still do not have well-functioning land title systems. In these cases, there is no record of farm size. Consequently, any attempts at a census are bound to be based on what the farmer or census enumerator "guesses" the area of a particular farm to be.

In view of the serious—in many cases overwhelming—difficulties involved in measuring crop production in less developed countries, the possibility of measuring cultivated area by the use of satellite imagery should be seriously considered (Cheosakul, Food and Agricultural Organization, Frey, Heydt and McNair, Park, United Nations 1972). The use of satellite data for estimating production of specific crops has been successfully tried in some developed countries (Baumgardner and Henderson, Morain and Williams, Wigton and Von Steen), but we are unaware of similar works of a comprehensive nature in LDC's, where the potential contribution of the new techniques appears even more promising.

Satellite imagery has been obtained for most of the earth's surface through the LANDSAT-1 and LANDSAT-2 satellites launched in 1972 and 1975, respectively. These data are available to anyone at a nominal cost. The imagery usually utilized is a very small scale—1:1,000,000. Two wavelength bands in the visible (green and red) and two wavelengths in the reflective infrared portion of the spectrum are available. These can be color coded and combined to produce a "color-infrared" composite on which the vegetation appears as tones of red or pink and water features appear in tones of black and blue, thereby facilitating the interpretation. Each frame of data is identified according to latitude and longitude, facilitating the location of areas of interest. Because each frame covers an area of 10,000 square kilometers, these data offer an efficient and economical method of obtaining reasonably up-to-date imagery showing land use patterns in a manner never before possible.

To investigate the feasibility of utilizing such satellite data for the measurement of crop area, we experimented with the available data for Laos, a country of 256,000 square kilometers, approximately two-thirds the land area of Japan. Although the techniques utilized in this case were not very sophisticated (as compared with the techniques currently available), valuable insights into the capabilities and limitations of such an approach were obtained. The lack of "ground truth" data was a particular challenge in this investigation. The procedures and methods followed and the results obtained and costs incurred in satellite data are reported. The results of this survey using only the satellite data are compared with results obtained from ground surveys. Some suggestions are included concerning how the method used in this study can be combined with existing methods now in use to produce more accurate information, much faster, and at far less cost for other developing nations.

Application of Satellite Sensing Techniques to Laos

We began the interpretation with a general understanding of agricultural practices in the region and a good knowledge of the way in which different earth surface features and cover types would appear on Landsat imagery. The best available images were obtained, and the dates of these images were in general accord with the crop calendar for rice as we perceived it. While conditions in Laos were not optimum for a test of satellite interpretative techniques, they were adequate for a general evaluation of the utility of these data.

A complete set of satellite images for the study area was obtained from the U.S. Department of Interior, the distributing agency for Landsat imagery. In all, 187 images of Laos were recorded by satellite between October 1972 and May 1973. Imagery varied in degree of cloud cover and general quality. Hence, of the original 187, approximately 40 images were ordered and processed into diazochrome transparencies.[2] From this latter group, a final selection of twenty-four transparencies was made on the basis of quality and concordance with crop calendars. We were fortunate in obtaining images of a number of agricultural areas on more than one date, which gives a somewhat better basis for interpretation. The image frames were then fitted into a 1:1,000,000 scale transparent overlay map of Laos. By this process, the portion of each image that fell within the national boundaries was defined. In other words, the portion of each image frame to be interpreted was delineated both on overlays of the individual frames and on the overlay of the national map. By this procedure, thirty-eight data measurement areas were delineated on seventeen Landsat images.[3]

A fundamental need for reliable image interpretation is reference data that can be utilized in conjunction with the process of interpretation. In this case, we had nothing to work with aside from our general personal experience in the area. In this first phase of the work, we therefore proceeded without specific reference data but with a general knowledge of the tonal appearance of rice and cropland, as gathered from previous work in Thailand and in the upper Mekong River Basin.

In general, four tonal colors of agricultural land (representing four spectral categories) were visually recognizable on the diazochrome composites. We interpreted each of these tones to be indicative of different types of agricultural land: (*a*) dark-toned

[2] The diazochrome process enables three individual spectral bands obtained in the form of black and white transparencies to be color coded. The color-coded images are then overlaid to form a false color composite. In this form, reflective properties of ground areas can be determined from variation in colors. A map of Laos indicating Landsat image overlays is available upon request from the authors.

[3] Of the twenty-four image frames used for interpretation, seven were obtained over the same areas but on different dates from those required for the Laos mosaic.

to black areas—interpreted as flooded riceland; (*b*) white or nearly white, highly reflective areas—indicative of bare soil or stubble; (*c*) light-toned red or pink areas—when occurring in lowlands may indicate areas cultivated to rice and/or other crops; and (*d*) medium-toned red areas—when occurring in lowlands may indicate orchards; when in uplands indicate forests and other lush vegetation but not grain or vegetable crops.

It is at this point that data from supporting ground observations become critical to the precision of the results. We are reasonably confident after reviewing the imagery and on the basis of on-site field experience that our interpretation of tones (*a*) and (*d*) is correct; that is, dark-toned areas indicate flooded riceland and medium-toned red areas indicate forest or similar lush vegetation. It is much less certain, however, how much of the area in tones (*b*) and (*c*) is correctly interpreted. Highly reflective surfaces, as in tone (*b*), could be indicative of either crop stubble or patches of bare, possibly laterite soil. Light-toned areas, as in tone (*c*), may indicate rice (or other crops) in nonflooded cultivated areas. In some cases rice is difficult to distinguish from nonlush vegetation such as dry, tall grass.

The initial interpretative effort consisted in having two experienced interpreters make completely independent estimates of cultivated areas from the twenty-four data frames described earlier.[4] Both interpreters used the same technique, but since they were working independently in this phase of the study, each used a different definition of cultivated land. The first used a definition encompassing tone categories (*a*) and (*b*) and those portions of tones (*c*) and (*d*) that fell in lowland areas. The second interpreter defined cultivated area conservatively to include only tones (*a*) and (*b*). As a result, two different estimates of cultivated area were obtained: a "conservative" estimate of 743,000 hectares and a broader estimate based on a "liberal" definition of 3,673,000 hectares. The divergence between these two estimates indicated a need to refine our concept of cultivated area by focusing more intensively on regional topographical features.

The second phase of analysis began with a comparison of these independent estimates. As province totals were compared, it became evident that differences between the estimates were highly sensitive to treatment of the light red and pink tones included in tone category (*c*). It became increasingly clear, as preliminary results were compared, that the inclusion or exclusion of tone (*c*) was much more critical in lowland than in upland areas. With this in mind, a second interpretation of the imagery was made, adopting the following definitions for use by both interpreters. Minimum lowland cultivated area is lowland area that was either flooded at the time the image was obtained or was interpreted as stubble. This represents essentially tonal categories (*a*) and (*b*), as earlier defined. Minimum upland cultivated area is all valley bottom land in mountainous areas displaying tone categories (*a*), (*b*), and (*c*). In short, wherever the tone was not bright red (i.e., in the forest) the land was defined as cultivated. This definition works here but not in lowland areas. Laterite and similar terrain are easily confused with tone (*b*). Potential lowland cultivable area is all lowland (valley land) in tonal categories (*a*) through (*d*). This definition includes some lowland that may not have been cultivable because of absence of water or other qualities.

Our estimate of "minimum cultivated area" for the country would, therefore, consist of the sum of the first two definitions. It was necessary to adjust the definition of tonal categories included within the various crop areas when considering upland and lowland area. In general, the lowland areas are characterized by large areas of laterite and other highly reflective soils. These are also areas that support sparse vegetation that can sometimes be mistaken for crops in their early stages of growth. In upland areas, however, exposed laterite soils occur so rarely that any break in forest cover can safely be assumed to be under cultivation.

In reviewing various estimates of crop area, the need for regional crop calendars becomes clear because Laos spans some rather different climatic regimes, particularly when both lowland and upland crops are considered. Furthermore, there seems to be a fair degree of flexibility in planting and harvesting times for some individual crops. Under these conditions, it becomes difficult to use the same image dates for the whole country. Interpretation of the imagery is facilitated if the appropriate dates for imagery are identified in each area based on specific dates for flooding, planting, and harvesting.

Results

With the above considerations in mind, revised estimates of cultivated area were prepared. For reasons explained earlier, an estimate of minimum cultivated area is the most useful. In addition, an estimate of the maximum cultivable lowlands was prepared.

The estimates of minimum cultivated cropland in table 1 represent the best estimates possible at this time utilizing 1:1,000,000 scale Landsat data and unaided visual interpretation techniques; that is, our estimates are conservative approximations of cultivated agricultural area. We relied heavily on identifying tonal groups (*a*) and (*b*). Pink tones (*c*), which were probably areas of at least some crop production, were excluded altogether, since cultivation on small-sized plots was undoubtedly excluded due to satellite resolution constraints.

[4] The estimates were independent both in the sense that each interpreter worked without knowledge of the other's results and also without having ever seen estimates of cultivated area produced from other (nonsatellite) data sources.

Table 1. Cultivable Area Estimated from Landsat Imagery and from Ground Reports, Selected Provinces, 1973

	Landsat: Minimum Cultivated Area (1,000 Ha.)	Ground Survey: Cultivated Riceland (1,000 Ha.)	Landsat as Percentage Ground
Flood plain provinces			
Vientiane	54	52	
Xiang Khoung	28	59	
Borikhane	16	13	
Kahmmouane	59	70	
Savannakheet	141	151	
Wapik Kanthong	37		
Champassak	36	122	113
Sithandone	24		
Sedone	25		
Saravane	32	27	
Subtotal	452	485	93
Mountain/valley provinces			
Luang Prabang	20	38	
Houa Khong	19	27	
Phong Saly	6	15	
Subtotal	45	80	56
Totals for flood plain and mountain/valley provinces	497	565	88
Provinces with poor imagery			
Sayaboury (some images missing)	8	15	
Haua Phouang (cloud covered)	1	25	
Attoupeu (poor quality images)	1	45	
Subtotal	10	85	12
Grand total, all provinces	507	650	78

Source: Commission General of the Plan.

In several areas the diazochromes were of low quality. The imagery over Hua Phong contained too much cloud cover to yield good results. That over Attopeu contained defects in printing and, in addition, was a poor selection in terms of the agricultural calendar; one frame over Sayaboury was unavailable. While significant for the provincial totals, these defects and omissions have little effect on the estimate of the national total because none of these three provinces is a major agricultural producer.

It is not entirely clear how close the satellite-derived estimate should actually be to the existing ground estimates. We estimate minimum cultivated area and not "most probable" area. We set out to measure all cultivated cropland, while existing estimates measure only riceland. However, at least in provinces lying along the Mekong River, and to a somewhat lesser extent in mountain provinces, most cropland is in fact planted to rice, so that the two estimates should be comparable.

Our estimates are compared with those taken by ground sampling methods in table 1. The total minimum estimate for the entire country is 507,000 hectares when measured by satellite, as compared with 650,000 as reported by ground methods. However, when the three provinces having poor quality or missing data are omitted, the total for the thirteen remaining provinces as determined by satellite becomes 497,000 hectares. This compares with 565,000 hectares for ground estimates, or a difference of only approximately 12%.

In the flood plain provinces our estimates are close to or above existing ground estimates. For most of the flood plain provinces, the difference is 7% or less between ground estimates and those made by satellite. In the mountain provinces, however, our estimates consistently fall short of ground estimates by a considerable margin. One reason for this is that the Landsat images available and the method of interpretation undoubtedly cause small areas of cultivated land located on the mountainsides to be overlooked. Nevertheless, the differences are substantial. During the period covered by these estimates (1972–73), there was a considerable movement of refugees into and out of the mountain provinces. Provincial ground-based estimates may be more subject to error than is commonly supposed.

These results demonstrate the usefulness of Landsat imagery as a source of data for estimating cultivated area. We emphasize the words "a source" because we do not at this time or in the near future foresee satellite sensory techniques replacing existing ground sampling methods. Rather, remote sensor imagery (and digital data) is a valuable supplement to the existing, but sometimes fragmentary, information available to agricultural economists from ground surveys.

Two impressive features of remotely sensed data

are its relatively rapid availability and low cost. With an earth resources satellite passing over an area every eighteen days, even with delays in gathering, recording, and processing transparencies, data can be available to analysts within a few months. With ground sampling techniques and reporting systems in use of many LDC's, time lags between sample design and the first draft of estimates often amount to a year or longer.

Satellite techniques also contain a distinct attraction from a cost standpoint. The estimates prepared for this report represent an average cost of 0.6¢ per hectare of area estimated. This figure includes start-up costs involved in developing appropriate definitions and in delineating the measurement areas that would not be present in an ongoing project. In an operational project, start-up costs would not be present, although there would be additional costs involved in obtaining ground truth. Over the longer term, therefore, we anticipate the presence of overall economies of size that would make possible an estimate of substantially improved accuracy than that presented here at an average cost per hectare probably below that shown here.

Concluding Remarks

Developing countries need information on the level and composition of agricultural production. Existing methods of measuring the level of agricultural activity leave much to be desired when applied to LDC's. The use of satellite data can make an important contribution to the speed with which data on area under cultivation are available, to improved cost effectiveness, and hence to a shortening of the length of the reporting period. Relatively simple, manual interpretation techniques can be utilized to provide many LDC's with methods that are relatively cheap and that do not require the availability of very highly specialized computer processing capabilities. Where possible more detailed analysis of selected areas is recommended using a stratified, multilevel sampling approach involving aircraft and ground data obtained at the same time as satellite data for specified areas. Efforts to improve methods of interpretation should be focused on a regional basis with the object of developing estimates of area under cultivation separately for each region, making possible more accurate, useful, and more cost-effective results.

There is a need for much more detailed information on crop calendars by region. Cloud-free imagery should be obtained that is coincident with critical dates by crop and by region. There is also a critical need for additional ground truth, especially with respect to the characteristics of vegetation suggested by tone category (c) in both lowland and mountainous regions. When additional ground truth is obtained, consideration should be given to employing of computer-aided analysis techniques for improved accuracy in acreage estimates.

Finally, satellite data may not always present an advance over traditional methods of measurement. It seems reasonable that in many countries the best results will be achieved by an integration of old methods of measurement along with those suggested here. Measurements that can be made effectively by satellite should release skilled manpower, which then can be reallocated to measurement tasks in which its marginal productivity is higher.

A Note on the Measurement of Technological Progress and Experience in Production

Yakov Amihud

A general way to represent "technological progress" in a single product production function is $Y = F(X_1, X_2, \ldots, X_k, T)$, where Y is output, F is the production function, X_i $(i = 1, \ldots, k)$ are the input factors, and T is a "vector of parameters, each value of which corresponds to a different level of technology. It is natural to think of T as changing in time . . . as knowledge accumulates; in this case, F should be a nondecreasing function of T" (Solow, p. 28).

In many empirical studies, T is represented by time, implying that experience, learning, and knowledge are a function of time and directly induce technological progress, which then leads to an increase in output for any given set of inputs. A frequently used model is $Y = F(X_1, \ldots, X_k)e^{bt}$. In particular, researchers often use the Cobb-Douglas (C-D) production function (see, e.g., Eisner, Evans, Bridge, Barkai and Levhari):

$$Y = A \prod_{i=1}^{k} X_i^{a_i} \cdot e^{bt},$$

where A, a_i $(i = 1, \ldots, k)$, and b are constants, and t is an increasing arithmetic series (e.g., 1, 2, 3, . . .). Then, when researchers estimate the constants and find b to be positive, they conclude that time has a positive effect on production through technological progress, increased experience, and efficiency. This interpretation was made regardless of whether the data are from time-series or from cross-section observations.[1]

The purpose of this note is to suggest that the conclusions of such studies should be regarded with caution, since they do not necessarily follow from the statistical results. The fact that b is significantly greater than zero may have nothing to do with experience. It may result from the fact that the factors' elasticities (a_i) are not constants but random variables, and the quantities of those factors generally increase in time. (Alternatively, it maybe that there is an experience effect, but it is confounded.) A possible caveat in the reported studies is the assumption that the form of the relationship between Y and X is unchanged, i.e., that the production function is constant either through time or across the various producing entities. This assumption is relaxed and replaced by a less restrictive one: the relationship between Y and X may change randomly from one observation point to another, but the expected relation remains unchanged; that is, the distribution of the a_i's is stationary (the moments are constant) throughout the analyzed sample.

The factors' elasticities may vary from one observation point to another in a manner that may be considered by the observer as purely random. As pointed out by Nerlove, in estimation of a cross-section C-D production function with observations taken from various firms' production data, the exponential parameters may be considered random variables that differ from one firm to another.[2] Evans (pp. 250–51) suggests that in estimating the C-D function from time series, the values of the exponential coefficients fluctuate due to the differences in capacity utilization in every period. Sidhu finds that the exponential coefficients (the factors' elasticities) fluctuate through time due to changes in methods of production.

Assuming the distribution of the elasticities in a Cobb-Douglas production function is a truncated normal probability density function,[3] where $E(a_i) = \bar{a}_i$, output can be expressed as approximately a multivariate normal random variable with the following expected value:

$$(1)\quad E(Y_t) = E\left[A \prod_{i=1}^{k} X_{it}^{a_i}\right] = E[\exp(\ln A + \sum_{i=1}^{k} a_i \ln X_{it})]$$

$$= \exp\left[\ln A + \sum_{i=1}^{k} \bar{a}_i \ln X_{it}\right.$$

Yakov Amihud is on the Faculty of Management, Tel-Aviv University, Israel.

[1] For example, Eisner concludes that "there is an upward movement of output of some 2% to 5% per annum not explained by the utilization, capital and employment variables" (p. 451). Barkai and Levhari claim to have found in their study that experience has contributed significantly to the growth of productivity in kibbutz farming (p. 63). Eisner uses time-series and Barkai and Levhari use cross-section data.

[2] Ulveling and Fletcher, observing these differences in the value of the elasticities across firms, attribute it to differences in managerial ability.

[3] A somewhat different approximation, which maintains the results of this note, can be obtained by a Taylor expansion of $E(Y)$ about $\bar{a}_i$ (all i) and truncating it after the second derivative on the assumption that the series converges fast or that the distribution of the a_i's can be well approximated by their first two moments (e.g., that the variance of a_i is sufficiently small relative to its expected value).

$$+ \tfrac{1}{2}\sum_{i}^{k}\sum_{j}^{k} E[(a_i - \bar{a}_i)(a_j - \bar{a}_j)]\ln X_{it}\ln X_{jt}\Big]$$

$$= A\prod_{i=1}^{k} X_{it}^{\bar{a}_i}\exp\Big\{\tfrac{1}{2}\sum_{i}^{k}\sum_{j}^{k} E[(a_i - \bar{a}_i)(a_j - \bar{a}_j)]\ln X_{it}\ln X_{jt}\Big\}.$$

Assume that the quantity of the production factors is increasing in time and that older producing entities (e.g., the firm, the industry, the national economy) are generally larger than the younger ones. This is generally true when estimation is based on time series of a single producing entity that undergoes a certain process of growth. The assumption applies in many cases to cross-section data as well, where the greater the age of the producing entity, the greater its level of labor, capital, and maybe other major factors.[4] Then $X_{it} = f(X_{i0}, T_t, z_i)$, where $f(\cdot)$ is an increasing function of T_t,[5] the age of the producing entity, or merely a time index at period t, X_{i0} is the initial quantity of factor i, and z_i is its growth parameter. Equation (1) above may be rewritten as

$$(2)\quad E(Y_t) = A\prod_{i=1}^{k} X_{it}^{\bar{a}_i}\exp\{g[f(X_{i0}, T_t, z_i), E((a_i - \bar{a}_i)(a_j - \bar{a}_j))]\},$$

and then the only variable in $g(\cdot)$ is T_t, which increases every period t. If $E((a_i - \bar{a}_i)(a_j - \bar{a}_j)) \geq 0$ for $i \neq j$ (for all $i, j = 1, \ldots, k$), then $g(\cdot)$ is an increasing function of T, while if the above inequality is reversed and applies strictly, the sign of $\frac{\partial g(\cdot)}{\partial T}$ is not unambiguously defined. In addition, the OLS estimate of A is biased, while that of the elasticities is unbiased but inefficient.[6]

Sometimes it is argued that technological progress is increasing at a decreasing rate, i.e., that time has a decreasing positive marginal productivity. For example, Barkai and Levhari suggest a model

$$Y = A\prod_{i=1}^{3} X_i^{a_i}e^{b_1T+b_2T^2},$$

where $b_1 > 0$, $b_2 < 0$, and the other variables are as before. This implies that, for these values of b_1 and b_2, $\frac{\partial Y}{\partial T} > 0$ and $\frac{\partial^2 Y}{\partial T^2} < 0$. They find that b_1 is significantly greater than zero and b_2 is negative in all the periods they study, although hardly significantly different than zero.

For some growth patterns of the production factors and for some values of their initial quantities, growth rates, and the moments of the joint distribution of their elasticities, it is possible to obtain $b_1 > 0$ and $b_2 < 0$, even if experience has no effect on output. To illustrate, consider the case of two factors, X_1 and X_2 (labor and capital). Then, by equation (1),

$$(3)\quad E(Y_t) = AX_{1t}^{\bar{a}_1}X_{2t}^{\bar{a}_2}\exp\{\tfrac{1}{2}[\sigma_1^2(\ln X_{1t})^2 + \sigma_2^2(\ln X_{2t})^2 + 2\mathrm{cov}(a_1, a_2)\ln X_{1t}\ln X_{2t}]\},$$

where $\sigma_i^2 = E(a_i - \bar{a}_i)^2$ and $\mathrm{cov}(a_i, a_j) = E[(a_i - \bar{a}_i)(a_j - \bar{a}_j)]$. Assume further that

$$(4)\qquad X_{it} = X_{i0}\exp(z_iT_t^{\frac{1}{2}}),$$

so that $\ln X_{it} = \ln X_{i0} + z_iT_t^{\frac{1}{2}}$, which is an ordinary growth formulation, and the square root of T implies that the rate of growth is declining for older producing entities. Then, applying equation (4) to equations (2) and (3) gives

$$\begin{aligned} E(Y_t) &= E\{AX_{1t}^{a_1}X_{2t}^{a_2}\} \\ &= E\{A[X_{10}\exp(z_1T_t^{\frac{1}{2}})]^{a_1}[X_{20}\exp(z_2T_t^{\frac{1}{2}})]^{a_2}\} \\ &= AX_{1t}^{\bar{a}_1}X_{2t}^{\bar{a}_2}C_1\exp(C_2T_t + C_3T_t^{\frac{1}{2}}), \end{aligned}$$

where C_1, C_2 and C_3 are constant and take the following values: $C_1 = \exp[\frac{1}{2}\sigma_1^2(\ln X_{10})^2 + \frac{1}{2}\sigma_2^2(\ln X_{20})^2 + \mathrm{cov}(a_1, a_2)\ln X_{10}\ln X_{20}]$, $C_2 = \frac{1}{2}\sigma_1^2z_1^2 + \frac{1}{2}\sigma_2^2z_2^2 + \mathrm{cov}(a_1, a_2)z_1z_2$, and $C_3 = \ln X_{10}z_1\sigma_1^2 + \ln X_{20}z_2\sigma_2^2 + \mathrm{cov}(a_1, a_2)(\ln X_{10}z_2 + \ln X_{20}z_1)$. When $\mathrm{cov}(a_1, a_2) \geq 0$, then $C_1 > 0$, $C_2 > 0$, and $C_3 > 0$, and

$$\frac{\partial E(Y_t)}{\partial T_t} = C_2 + \tfrac{1}{2}C_3T_t^{-\frac{1}{2}}E(Y_t) > 0,$$

but

$$\frac{\partial^2 E(Y_t)}{\partial T_t^2} = [(C_2 + \tfrac{1}{2}C_3T_t^{-\frac{1}{2}})^2 - \tfrac{1}{4}C_3T_t^{-1.5}]E(Y_t),$$

whose sign is not unambiguously defined and depends on the magnitude of the moments and the variables. Clearly, for some values of C_2 and C_3, it is possible to obtain a negative second derivative, which implies $b_2 < 0$ in the Barkai-Levhari model. When $\mathrm{cov}(a_1, a_2) < 0$, even the sign of the first derivative is not unambiguously defined. Of course, these conclusions depend on the formulation of the assumed growth function, but as long as $\mathrm{cov}(a_1, a_2) \geq 0$, the sign of the first derivative of $E(Y_t)$ with respect to T_t is always positive.

In conclusion, I have shown that attributing an increase in output to time is correct, but it may be a result of an estimation problem and not due to technological progress or experience. Indeed, the hypothesis that these factors increase the productivity (possibly at a decreasing rate) cannot be rejected, but it is questionable whether we can "accept" it without further refinement of the suggested model,

[4] An anonymous referee pointed out to me that some of the smallest and marginal producing units are the oldest. The paper suggests that in any case where there is a systematic relation between the size of the firm and its age, the conclusions regarding "productivity" and "experience" should be regarded with caution. Clearly, the analysis is confined to economies where the assumption holds.

[5] To illustrate, $X_{it} = X_{i0}e^{z_iT_t}$ for $0 < z_i < 1$, or $X_{it} = X_{i0}T_t^{z_i}$ for $0 < z_i < 1$, or $X_{it} = X_{i0}z_iT_t$. Even in the latter case of linear combination of the X_i's and T, there is no problem of multicolinearity, since the factors are transformed to their logarithm.

[6] The estimation of random coefficients is treated in Theil (p. 622) and Hildreth and Houck and applied to the Cobb-Douglas production function with random elasticities in Amihud.

which should isolate the effect of randomness in elasticities from the age of the producing entities.

Using the Consumer Price Index as Part of the Index of Prices Paid by Farmers: An Evaluation

James P. Houck and Mary Smaciarz

Beginning January 1977, the Statistical Reporting Service made a major change in its monthly *Index of Prices Paid by Farmers* (USDA 1976a).[1] The subgroup index of prices paid for family living items (FLI), computed within the U.S. Department of Agriculture, was replaced by the national consumer price index (CPI), computed by the Bureau of Labor Statistics (USDA 1977). The FLI contained about 150 regularly priced items, while the CPI covers about 400 goods and services. Collection and publication of price data for farm family living items was discontinued in the USDA after January 1977.

This particular change was presaged in May 1976 by a revision that introduced two CPI subgroup price indexes into the FLI (USDA 1976b). These were the indexes for medical and health care and for education, recreation, and other. These revisions broadened the FLI to include components of family living expenditures not previously covered. The subsequent adoption of the full CPI in place of the FLI reflects the general view that economic and social differences between family life on the farm and in the city have dwindled sufficiently so that a separate index for farm families is unnecessary. Furthermore, adoption of the CPI significantly reduces data collection and handling costs within the USDA. With the CPI, the family living component of the total prices paid index (PPI) remains at 30.4%. The balance of the PPI includes production items, interest, taxes, and farm wage rates.

The purpose of this note is to present some background analyses related to this change.[2] First, the historical statistical relationship between the CPI and the FLI is presented. Second, the simulated effect of using the CPI in the PPI over the historical period is analyzed along with implications for the parity ratio and some representative parity prices. Technical differences between the CPI and the FLI in their coverage and computation are not discussed here nor are the administrative, legal, and other complexities that attended dropping the FLI in favor of the CPI.

Comparing the FLI and the CPI

The analysis used official monthly data on various indexes over the eleven-year period, January 1965 through December 1975 (USDA 1976b, U.S. Dep. Labor). The May 1976 revision of the major agricultural price indexes fixed January 1965 as the link date with the previous weighting regime. All pertinent indexes and subgroup indexes were officially revised back to that link date. The indexes used in this study were expressed on the current official base (1967 = 100).

The relationship between the FLI (as revised in May 1976) and the CPI is illustrated in figure 1 for the 132-month period, January 1965 to December 1975. Because they measure essentially the same phenomena, the two indexes move closely together. The published CPI increased steadily over the period, but the FLI decreased from time to time. Also, neither the FLI nor the CPI increased faster than the other over the entire period. If the rate of increase is considered, the main discernible pattern occurs in the most recent two to three years when the FLI increased more rapidly than the CPI. Before mid-1973, the CPI was higher than the FLI and, for the three previous years, remained a rather stable two to three points above it.

Simple correlation analysis between the FLI and the CPI reveals that, over the eleven-year period, 99.1% of the monthly variation in the FLI is associated with variation in the CPI. This regression equation with the estimated standard errors of the coefficients in parentheses is

$$(1) \quad FLI = \underset{}{-7.22} + \underset{(1.09)}{1.062}\ CPI;\ r^2 = 0.991. \qquad (0.009)$$

The proximity to 1.0 of the estimated coefficient on the CPI suggests that, on a 1967 base, the two indexes are virtually interchangeable insofar as month-to-month changes are concerned. (However, the extremely high correlation between the two indexes makes the difference between the estimated coefficient and 1.0 statistically significant at the 1% level.) The regression coefficient slightly greater than 1.0 indicates that observations in the 1974–76 period, when the FLI was higher and ac-

[1] The official title of this index is "The Index of Prices Paid by Farmers for Commodities and Services, Interest, Taxes, and Farm Wage Rates." When expressed on the 1910–14 base, it is also known as the "Parity Index."

[2] The authors conducted this research in 1976 as consultants to the Statistical Reporting Service, USDA, but remain solely responsible for the contents of this note.

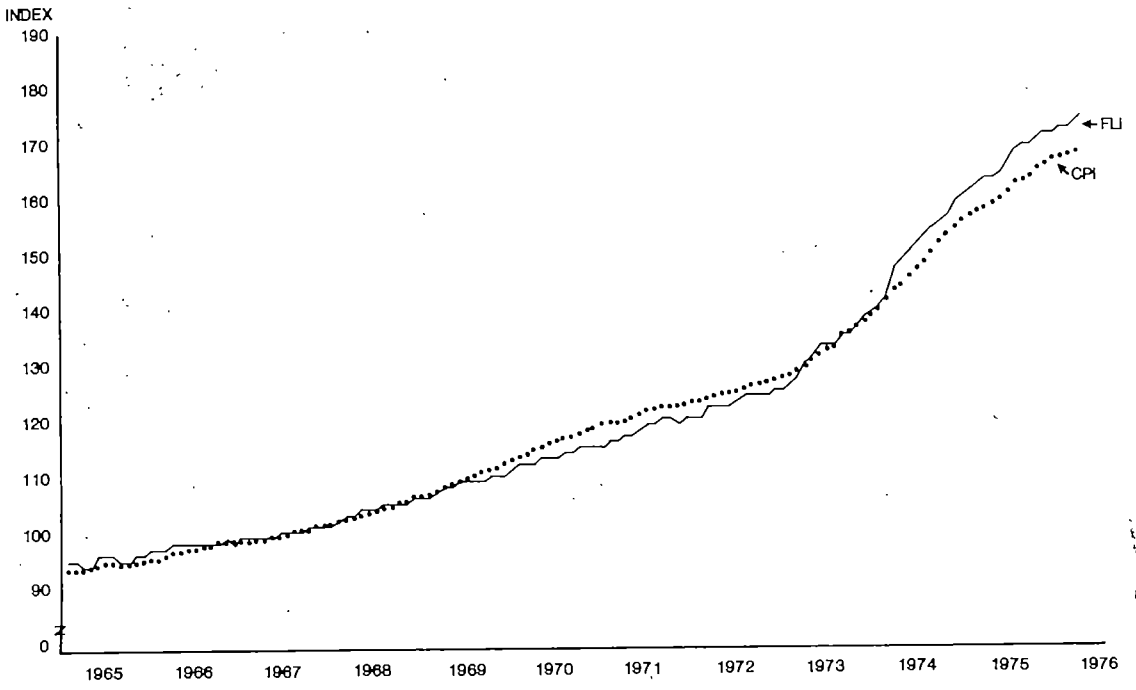

Figure 1. The consumer price index (CPI) versus the family living index (FLI) (1967 = 100)

celerating faster than the CPI, statistically dominate those of the preceding years when the CPI was higher.

The fidelity of the two indexes in registering month-to-month price level changes also is of interest. First differences of the two indexes from January 1965 to January 1976 were analyzed with simple regression. The estimated equation is

$$(2)\quad \Delta FLI = -0.706 + 1.191\ \Delta CPI;\ r^2 = 0.388. \quad (0.093)\ \ (0.134)$$

The standard errors are in parentheses and Δ denotes first differences. As expected, r^2 dropped dramatically since, with first differences, trend effects are reduced. This estimated coefficient also indicates that a one-point change in the CPI is associated with an approximate one-point change in the FLI. In this case, the difference between the estimated coefficient and 1.0 is not statistically significant. Although the overall correlation of first differences is not very high, actual versus estimated values of first differences of the FLI over the sample period using equation (2) show very few reversals or opposite movements. In only three of 132 observations did the estimated value of the FLI, based on changes in the CPI, move opposite to the actual change.

Under current practice, the agricultural price indexes are computed and published late in the same month to which they apply. However, the CPI for any given month is not available until the middle of the following month. Consequently, the one-month lagged value of the CPI (denoted CPI_{t-1}) is now being used to compute the index of prices paid by farmers.

The simple correlation between the FLI and CPI_{t-1} is also very high with about 99% of the variation in the FLI associated with variation in CPI_{t-1}. The relevant regression equation is

$$(3)\quad FLI_t = -8.343 + 1.076\ CPI_{t-1};\ r^2 = 0.990. \quad (1.145)\ \ (0.009)$$

The estimated coefficient on CPI_{t-1}, equation (3), is very nearly the same as that on the CPI, equation (1). It is clear that, over the historical period, either CPI_t or CPI_{t-1} could be regarded as a proxy for FLI_t with little loss of information.

Simulated Effects

The PPI was recalculated monthly over the January 1965 to December 1975 period using CPI_{t-1} instead of FLI_t. The simple coefficient of determination (r^2) between the actual and simulated PPI is 0.9995. The largest discrepancy is less than half of 1% of the average value of the PPI. Thus, almost nothing was altered by using a one-month lagged value of the CPI in the computation of the full prices paid index.

The parity ratio is the ratio of the index of prices received by farmers to the index of prices paid. The parity ratio, adjusted for government price support payments to farmers, is a traditional statistical yardstick by which farmers' economic welfare is gauged. Figure 2 illustrates how the historical ad-

Table 1. Parity Prices: Actual and Computed Using Estimated Values of the PPI

Item	November 1976			December 1976		
	Actual Parity Price	Computed Parity Price[a]	Difference	Actual Parity Price	Computed Parity Price[a]	Difference
Cotton: upland (¢/lb.)	78.84	78.00	−0.84	79.44	78.60	−0.84
Wheat ($/bu.)	4.86	4.80	−0.06	4.89	4.84	−0.05
Milk ($/cwt.)	12.10	11.96	−0.14	12.20	12.05	−0.15
Beef cattle ($/cwt.)	56.80	56.22	−0.58	57.30	56.66	−0.64
Hogs ($/cwt.)	52.20	51.68	−0.52	52.60	52.07	−0.53
Soybeans ($/bu.)	7.23	7.15	−0.08	7.28	7.21	−0.07
Peanuts (¢/lb.)	27.3	27.0	−0.3	27.5	27.2	−0.3

[a] In the computations, the FLI was replaced by CPI_{t-1}. Actual parity prices are from USDA 1976a.

justed parity ratio was affected by substituting CPI_{t-1} for FLI_t in the prices paid index. Only very small differences occur between the actual and the calculated values of the adjusted parity ratio. There are no reversals of turning points, and actual differences are barely discernible.

Parity prices are specific calculations applying to individual commodity prices. At any given time, they reflect the level that prices would have to achieve in order to give units of that product the same purchasing power, when sold, as they enjoyed in some designated base period. The PPI plays an important role in the formulas used to compute all parity prices. Hence, any changes in the PPI will have a potential impact upon parity prices and, by extension, on any farm price and income programs that are linked to parity.[3]

Table 1 contains some recent actual parity prices and those that would have occurred if CPI_{t-1} had been used in the calculation of the PPI. The items were selected to be representative of important commodity classes. The actual and computed parity prices in the table are directly comparable. All of the computed differences for these two months are about 1% of actual parity prices. Similar calculations for other months in 1976 show almost identical results. The conclusion is clear; the replacement of the FLI by CPI_{t-1} would have had very little effect on either the index of prices paid by farmers or parity calculations.

[3] Under current legislation, target price adjustments are linked to an index of prices paid for production, interest, taxes, and farm wage rates. Consequently, this substitution would not affect target price levels.

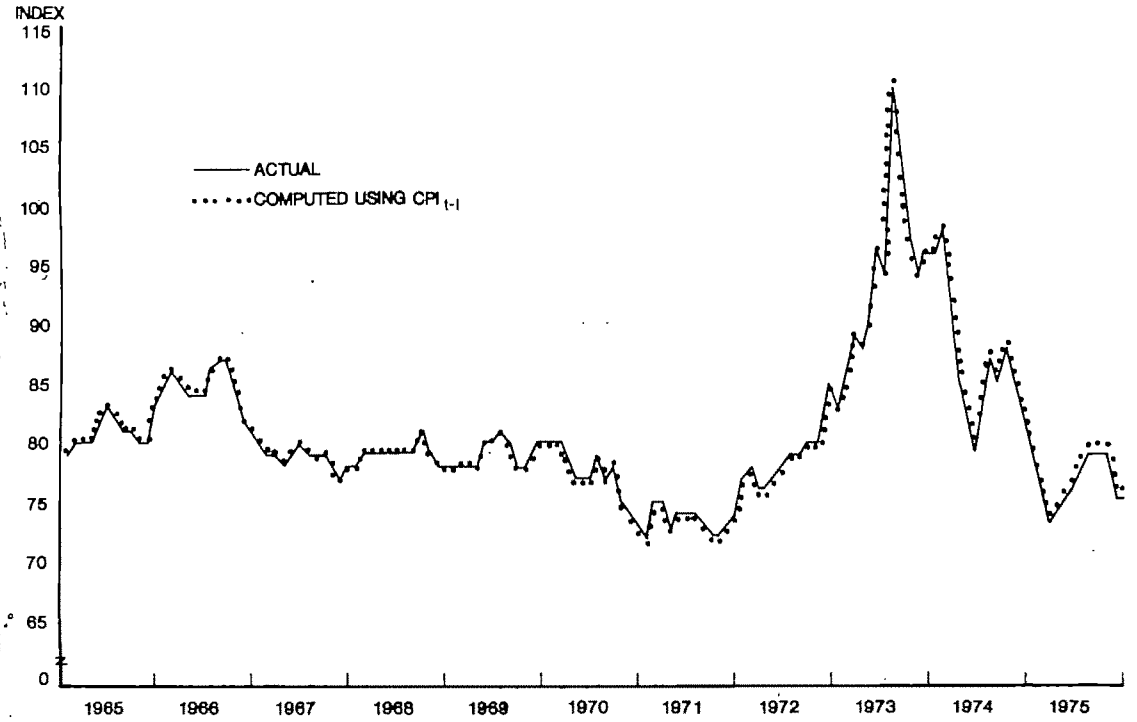

Figure 2. Adjusted parity ratio (1967 = 100)

The Linking Process

The actual transition from the FLI to the CPI in January 1977 was accomplished by a chaining computation that compensates for different levels of the two indexes. Consequently, the PPI, parity ratio, and all parity price levels in January 1977 are unaffected by the changeover. No official revisions of earlier PPI data are envisioned by the USDA. For measuring prices paid for family living items, the FLI is the official subindex until January 1977, and the CPI is the official subindex from that month onward.

The Elasticity of Foreign Demand for U.S. Agricultural Products

Paul R. Johnson

Not unexpectedly, the upheavals in world agricultural markets in recent years have led to an increased interest in international trade problems in the agricultural economics literature. In order to quantify our analytical insights into these problems, we need empirical estimates of a host of basic relationships. Data problems and identification problems plague the international trade researcher. These problems are well known and are not pursued here. Their presence, however, has led to the adoption of some useful devices to reduce the empirical burden and to utilize existing estimates of various parameters. One such device is the subject of this note.

The quantity demanded of any one country's exports of a commodity is identically equal to the quantity demanded in the rest of the world minus the quantity supplied by the rest of the world. When this identity is differentiated with respect to price, the well-known elasticity of excess demand can be derived:

$$\eta_X = \eta_R \frac{D_R}{X} - \epsilon_R \frac{S_R}{X}, \tag{1}$$

where η_X is the elasticity of excess demand, η_R is the demand elasticity in the rest of the world, ϵ_R is the corresponding supply elasticity, D_r and S_R are rest of the world consumption and production, and X is the quantity of exports of the country in question. This kind of elasticity only requires estimates or knowledge of the demand and supply elasticities and normally available information on quantities. An estimate such as equation (1) is often useful in its own right for analytical purposes. It also can be combined with estimates of the domestic elasticity to find the elasticity of demand for the total output of a particular commodity in a nation.

Tweeten (1967) uses a relation like equation (1) in an attempt to estimate the elasticity of demand for all U.S. farm output. His basic goal is to aggregate across all farm commodities and both domestic and foreign markets. His use of the excess demand formulation is to add the foreign component to his domestic analysis, where in the latter he utilizes some of his own empirical results. Tweeten's recognition of the foreign demand component for U.S. farm output and the necessarily "large" magnitude for its elasticity is important. Unfortunately, his estimation technique for the foreign (or excess) demand component is substantially in error.

The reason for my concern with the error in calculating the foreign demand elasticity is that the estimate may get institutionalized in the agricultural economics literature. I have seen the elasticity referred to recently in several different contexts. For instance, Lopes and Schuh utilize it in an analysis of the effect of the exchange rate on agriculture. Tweeten (1975) himself has defended the estimate as a unique and important contribution. There is a danger, then, that this estimate might, through repetition, become a datum for analysis of certain agricultural policy problems. The danger, strangely enough, is mitigated by the fact that the number itself is not in error. As I show below, one can get a number in the same neighborhood as Tweeten's but with a correct procedure. I raise the issue only so the unwary will understand that the technique is the problem.

Tweeten (1967, p. 361) proposes to calculate "the price elasticity of demand for U.S. food and feed exports . . ." from the following expression (his equation (61)):

$$E_{ef} = \sum_{i=1}^{n} \left[E_{di} E_{pi} \frac{Q_{di}}{O_{ef}} - E_{si} E_{pi} \frac{Q_{si}}{O_{ef}} \right], \tag{2}$$

where E_{di} and E_{si} are the domestic price elasticities of supply and demand in country i, E_{pi} is an elasticity of prices in i with respect to U.S. market prices, Q_{di} and Q_{si} are quantities demanded and supplied in i, and O_{ef} is U.S. farm exports. E_{pi} is set equal to one and can be ignored. Tweeten then adopts previous calculations of demand or supply elasticities for foreign countries and calculates an excess demand elasticity for each of eleven countries or regions. By equation (2) he adds them up. His sum is equal to -15.85. He concludes that the coefficient is too large and proceeds to scale it down by various procedures to get a long-run elasticity of -6.42, which he then uses as his long-run demand elasticity for U.S. agricultural exports.

The source of the error is clear. The elasticity for a market with many participants is equal to the quantity weighted average of the various participants and not the sum. This piece of price theory is available in Stigler among other places.

A correct procedure for this kind of calculation can be found in Floyd and in Johnson. In order to

Paul R. Johnson is a professor in the Department of Economics, North Carolina State University.

Paper 5331 of the Journal Series of the North Carolina Agricultural Experiment Station, Raleigh.

gauge the magnitude of the number Tweeten was seeking, I have made some very rough calculations. To make these calculations, one must take into account two kinds of aggregation problems. Farm output (or less generally, food) is an aggregate of many commodities. The market for U.S. exports is an aggregate of many national markets. Tweeten avoids for the most part the first aggregation problem by looking at the foreign demand for the composite good. His treatment of the country aggregation problem is the source of his measurement error. My approximation to equation (1) is based on assuming that domestic demand and supply elasticities for individual commodities are the same in all countries that import U.S. agricultural commodities. This assumption would not appear to be too much at variance with the real world, and it avoids altogether the aggregation problem across regions. I do consider, however, the aggregation across commodities. There is a large stock of estimates of elasticities for various commodities that could properly be termed consensus estimates. These elasticities for major exports can be used for calculating commodity excess demand elasticities and then aggregated into an export demand elasticity for U.S. agricultural products as a whole.

The basic information for this calculation is shown in table 1. The domestic demand elasticities everywhere are taken to be −0.2 for wheat and cotton, −0.4 for feed grains and soybeans, and −0.1 for tobacco. All supply elasticities are taken to be 0.2. These elasticities are all taken to be net of cross price relationships between groups, e.g., wheat and cotton. The second column in table 1 shows the percentage of world supply represented by U.S. exports for each commodity. The third column is calculated by a slight variant of equation (1). The reciprocal of each element in the second column is the weight on the supply elasticity. This weight plus one is the weight for the demand elasticity.[1] The third column shows the implied elasticity for U.S. exports of each commodity. The last column is the weight of that commodity in the 1970 export market basket. The weighted average of all the elasticities is shown in the last row of the table and is calculated to be −6.69.

Table 1. Market Shares, Individual Elasticities, and the Total Elasticity of U.S. Farm Exports

Commodity	U.S. Exports as Percentage of World Supply (%)	Implied Elasticity	Weight
Wheat	6.14	−6.72	0.18
Feed grains	6.14	−10.18	0.37
Soybeans	25.14	−2.8	0.26
Cotton	7.59	−5.5	0.09
Tobacco	6.24	−4.9	0.10
Total elasticity		−6.69	

This estimate is, of course, subject to reservations of its own. However, it is in line with other estimates and what is known about the world. Thus, I would surmise that the Tweeten estimate is in the right ball park. That estimate, it must be remembered, is not the basic estimate from his procedure but a scaled-down estimate. If one takes the 1970 weights of 0.86 for domestic use and 0.14 for exports of total farm, and a domestic elasticity of −0.25, one gets an elasticity of demand for total farm output of −1.15. This last estimate compares with Tweeten's long-run estimate of −1.11. His conclusion concerning the elasticity of farm output being greater than one is in fact vindicated.

The Elasticity of Foreign Demand for U.S. Agricultural Products: Comment

Luther Tweeten

I greet with sincere approbation Johnson's contribution to the professional literature on the elasticity of foreign demand for U.S. agricultural products. This elusive but highly important parameter has been neglected too long. Although his calculations lend credence to my estimate, I suggest caution in accepting our estimates as final or exact parameters to be used by the profession. Perhaps our efforts will motivate the profession toward refinements in procedures and data to provide more reliable estimates of the parameter.

Despite this overall acclaim for Johnson's contribution, it is necessary to clear up several misconceptions. He states, "Tweeten . . . himself has defended the estimate [of the foreign demand elasticity] as a unique and important contribution" (1977). I made no such assertion. Johnson apparently was referring to my statement that "Perhaps the most used, single parameter in our profession is the price elasticity of demand for farm output at the farm level. Despite its central importance to farm policy, only one estimate exists of the parameter to my knowledge" (1975, p. 183). Here, I refer to the importance of the price elasticity of demand for farm output and not to the reliability of my specific estimate of that parameter. I state, "the results are by no means exact and . . . a sizable upward bias could be present" in the export demand elasticity (1967, p. 365) and that the elasticity of demand for farm output "is highly sensitive to the choice of export demand elasticities—parameters that are not known with much reliability" (1967, p. 366). Later I write that "The exact magnitude of the elasticity of demand for farm products is unlikely ever to be known with a high degree of certainty, especially because of the difficulties in estimating foreign demand. The above [my own] estimates are highly controversial" (1970, p. 203).

Johnson states, "Unfortunately, his [Tweeten's] estimation technique for the foreign (or excess) demand component is substantially in error" (1977). The "error" to which Johnson refers is my alleged failure to properly weight respective elasticities by country or region in summing them, where the sum of the weights is equal to 1.0 (see Johnson 1970, p. 165).

It is instructive to derive my equation (see equation (2) in Johnson's note) for the elasticity of demand for U.S. exports, leaving out E_{pi}, which Johnson agrees to ignore. U.S. exports O_{ef} are the sum of the excess of demand quantity Q_{di} over supply quantity Q_{si} in region or country $i = 1, 2, \ldots, n$:

$$(1) \quad O_{ef} = (Q_{d1} - Q_{s1}) + (Q_{d2} - Q_{s2}) + \ldots + (Q_{dn} - Q_{sn}).$$

The derivative with respect to U.S. price, P, assumed also to be the world price, is

$$(2) \quad \frac{dO_{ef}}{dP} = \left(\frac{dQ_{d1}}{dP} - \frac{dQ_{s1}}{dP}\right) + \left(\frac{dQ_{d2}}{dP} - \frac{dQ_{s2}}{dP}\right) + \ldots + \left(\frac{dQ_{dn}}{dP} - \frac{dQ_{sn}}{dP}\right).$$

The elasticity of demand for exports is

$$(3) \quad \frac{dO_{ef}}{dP}\frac{P}{O_{ef}} = \left(\frac{dQ_{d1}}{dP}\frac{P}{Q_{d1}}\cdot\frac{Q_{d1}}{O_{ef}}\right) + \left(\frac{dQ_{d2}}{dP}\frac{P}{Q_{d2}}\cdot\frac{Q_{d2}}{O_{ef}}\right) + \ldots + \left(\frac{dQ_{dn}}{dP}\frac{P}{Q_{dn}}\cdot\frac{Q_{dn}}{O_{ef}}\right).$$

Letting $\frac{dO_{ef}}{dP}\frac{P}{O_{ef}} = E_{ef}$, $\frac{dQ_{di}}{dP}\frac{P}{Q_{di}} = E_{di}$, and $\frac{dQ_{si}}{dP}\frac{P}{Q_{si}} = E_{si}$, then equation (3) can be expressed as

$$(4) \quad E_{ef} = \sum_{i=1}^{n}\left(E_{di}\frac{Q_{di}}{O_{ef}} - E_{si}\frac{Q_{si}}{O_{ef}}\right).$$

In table 12 of my 1967 article, the heading "U.S. export demand elasticity imputed to" refers to the terms $E_{di}\,Q_{di}/O_{ef}$ and $E_{si}\,Q_{si}/O_{ef}$ for foreign demand and foreign supply, respectively. From equation (4), it is appropriate merely to sum these weighted quantities to estimate E_{ef}. The error to which Johnson refers does not exist.

I choose to aggregate commodities including feed grains, food grains, and soybeans, which are close substitutes in production and consumption, into a single food and feed category before using equation (4) to aggregate across countries and regions. Johnson, however, chooses the approach of aggregating elasticities across commodities rather

Luther Tweeten is Regents Professor in the Department of Agricultural Economics, Oklahoma State University.

Journal Article 3324 of the Oklahoma Agricultural Experiment Station, Stillwater. Reviews by Milton Hallberg and Marc Johnson are much appreciated.

than across regions to derive E_{ef}. This approach has serious pitfalls. Define U.S. exports of commodity a as O_{ea}, foreign domestic demand quantity of commodity a as Q_{da}, foreign domestic supply quantity of commodity a as Q_{sa}, and price of commodity a as P_a along with similar notation for substitute commodities represented by b. Then elasticities are defined as follows:

$$E_{ea} = \frac{dO_{ea}}{dP_a}\frac{P_a}{O_{ea}}, \quad E_{da} = \frac{\partial Q_{da}}{\partial P_a}\frac{P_a}{Q_{da}},$$

$$E_{dab} = \frac{\partial Q_{da}}{\partial P_b}\frac{P_b}{Q_{da}}, \quad E_{ba} = \frac{dP_b}{dP_a}\frac{P_a}{P_b},$$

$$E_{sa} = \frac{\partial Q_{sa}}{\partial P_a}\frac{P_a}{Q_{sa}}, \quad \text{and} \quad E_{sab} = \frac{\partial Q_{sa}}{\partial P_b}\frac{P_b}{Q_{sa}}.$$

It can be shown that

$$E_{ea} = (E_{da} + E_{dab}E_{ba})\frac{Q_{da}}{O_{ea}} - (E_{sa} + E_{sab}E_{ba})\frac{Q_{sa}}{O_{ea}}.$$

If prices of food and feed move in harmony, then $E_{ba} = 1$, and that term can be dropped from the equation. E_{ef} is a weighted average of elasticities E_{ea}, E_{eb}, etc. Although it is not clear from his note, Johnson appears to have omitted from his equations the substitution effects represented by cross elasticities E_{dab} and E_{sab}. But whether he did or did not omit these terms, the profession should be aware of this potential conceptual trap in using his technique. Because of opportunities for substitution among, for example, wheat, corn, and soybeans in consumption as well as production, the weighted sum of the component own price elasticities is likely to be greater than the aggregate price elasticity for food and feed.

In summary, it is gratifying to note that the commodity disaggregation procedure used by Johnson provides an export elasticity similar to mine. Our basic methodology is quite similar. My procedure is not in error and conceptually is superior to Johnson's. A fruitful line of additional research may be direct estimates of demand equations for U.S. agricultural exports. Parameters generated thereby could improve estimates of the elasticity of demand for U.S. farm output.

Some Welfare Implications of the Adoption of Mechanical Cotton Harvesters in the United States

Marshall A. Martin and Joseph Havlicek, Jr.

The role of technological innovation in agricultural development has been a topic of considerable interest among agricultural economists (e.g., Hayami and Ruttan). Several studies have examined the welfare consequences for society that have occurred as a result of technological change in the agricultural sector (Bieri, de Janvry, and Schmitz; Schmitz and Seckler; Martin). Although in many cases the benefits to society from technological change may be substantial, costs are often imposed on certain groups in society.

The technology used in cotton production in the United States has changed dramatically since World War II. The rate of substitution of mechanical cotton harvesters for hand labor was quite rapid. In 1950 less than 10% of the cotton crop was mechanically harvested. By 1970 virtually all cotton produced in the United States was picked by machine. The socioeconomic ramifications of the adoption of this new technology have been complex and far reaching. This note focuses on only one aspect of the economic impacts of adopting mechanical cotton pickers: the potential economic welfare gains to the producers and consumers of cotton in the United States.

The Economic Welfare Model

The concept of producers' and consumers' surplus has been dealt with extensively in the literature (e.g., Currie, Murphy, and Schmitz). Hence, the discussion in this section is primarily concerned with the specification of an appropriate analytical model for U.S. cotton production.[1] Since cotton fiber produced in the United States is consumed domestically, exported, and stored by the Commodity Credit Corporation, the model must reflect these three demands for U.S. cotton. Two demand functions are required: domestic demand and export demand.[2] A "storage rule" to account for the Commodity Credit Corporation activities is also incorporated into the model.

Total demand (D_t) is defined as the sum of domestic demand (D_d) and export demand (D_x) (figure 1). Since there was a net increase in the Commodity Credit Corporation inventories during the period analyzed (1952–69), this quantity is added to total demand to obtain the effective demand function (D) for cotton fiber produced in the United States.[3]

As the cost per pound for mechanical harvesting fell relative to hand picking, farmers tended to adopt the new technology. Hence, the adoption of the technology shifted the individual firm's cost curves downward, and the industry supply function shifted to the right.[4] The notation S_b and S_a is used to denote the supply function before and after the technological change.

In the absence of government intervention, the before and after free market prices (P_b and P_a) are determined by the intersection points of the respective supply functions (S_b and S_a) with the total demand function (D_t). If the free market prices P_b and P_a are below acceptable levels, the Commodity Credit Corporation stores cotton in order to maintain the support prices (P_b' and P_a'). This shifts D_t to the right toward D by the amount of the net addition to inventories. The quantity consumed

Journal Article No. 6419. The authors are indebted to Robert L. Thompson, T. Kelley White, Glenn Nelson, the *Journal* editors, and anonymous *Journal* reviewers for helpful comments on an earlier version of this manuscript.

[1] Although a general equilibrium model would theoretically be more appropriate, econometric model specification and computational limitations forced the authors to use a partial equilibrium framework to empirically estimate the economic welfare effects.

[2] Since the United States has been the largest single world producer and exporter of cotton, the United States is assumed to possess some world market influence. Hence, the export demand for U.S. cotton would be expected to be less than perfectly elastic. For the period analyzed, the United States was responsible for one-third of the total world production and for one-third to one-fifth of the total world cotton trade.

[3] The Commodity Credit Corporation is treated as a residual buyer that absorbs that portion of cotton produced but not consumed domestically nor exported in a given market period.

[4] It is important to distinguish between the effects of biochemical and mechanical innovations. Both shift the supply function to the right. However, the former is predominately a consequence of an output effect (increased yield per acre), while the latter is largely the result of a cost saving effect (lower cost per unit of production with no increase in yield per acre). An attempt is made to distinguish the effects of mechanical innovations from those of biochemical innovations in the U.S. supply function in the econometric model. However, it may not be statistically possible to entirely separate the effects of those biochemical inputs, e.g., defoliants and new varieties, that were adopted to facilitate the mechanical harvesting from the direct cost saving effect of the adoption of the mechanical harvesters.

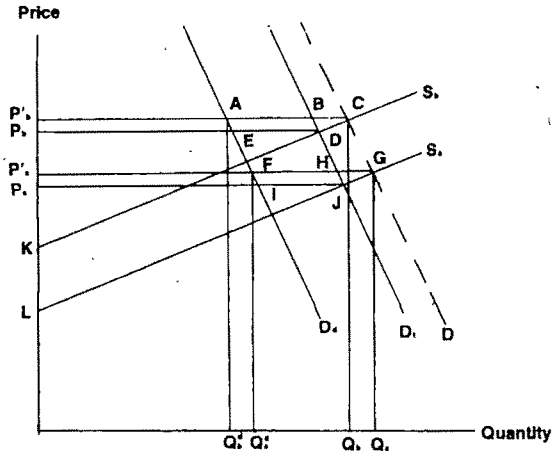

Figure 1. The consumers' and producers' surplus areas for the U.S. cotton market

domestically (Q_b^d and Q_a^d) is determined at the point where the domestic demand function (D_d) intersects the appropriate support price (P_b' and P_a'), respectively.

The gain in consumers' surplus in the United States is represented by the area $P_b'AFP_a'$ (figure 1). Consumers of cotton exported by the United States gain a consumers' surplus indicated by the area $ABHF$. The area $BCGH$ is a government consumers' surplus that is a potential gain to foreign or domestic consumers, depending on whether or not the Commodity Credit Corporation releases its inventories in the export or domestic market.

The producers' surplus gain is the difference between the after and before technological change in the producers' surplus areas. The producers' surplus areas for after and before technological change are $P_a'GL$ and $P_b'CK$, respectively. The gain to producers is $P_a'GL$ minus $P_b'CK$. The net welfare gain to the entire U.S. society is the sum of the gain in U.S. consumers' surplus ($P_b'AFP_a'$) and producers' surplus ($P_a'GL - P_b'CK$).

Econometric Model

To estimate the economic surplus, several price elasticities must be known. To obtain them, a supply and demand model for cotton fiber produced and consumed in the United States and the rest of the world is specified and estimated.

The model of the world cotton market contains five behavioral equations and two identities. All variable definitions are found in table 1. The market clearing identities are the U.S. market clearing condition:

$$(1) \qquad Y_1 + Z_{21} + Y_4 = Y_3 + Z_{19} - Z_{20},$$

and the rest of world market clearing condition:

$$(2) \qquad Y_6 - Y_4 + Z_{21} = Y_7 + Z_{22} - Z_{23}.$$

The five behavioral equations are a supply and a demand equation for the United States, a supply and a demand equation for the rest of the world, and an export linkage equation. Since the supply equations contain only one endogenous variable, they are estimated by ordinary least squares (OLS). The other structural equations (U.S. demand, rest of the world demand, and the export linkage) form an overidentified, simultaneous system of equations. These three equations are estimated by two-stage least squares (2SLS). All statistical equations are estimated in the log-linear form.[5]

The U.S. demand equation is

$$(3) \quad \log Y_1 = -86.168 + \underset{(16.474)}{26.470 \log Z_1} + \underset{(1.260)}{1.574 \log Z_2} + \underset{(0.311)}{0.103 \log Z_3} - \underset{(15.985)}{29.555 \log Z_4} + \underset{(0.500)}{0.148 \log Z_5} - \underset{(0.701)}{0.892 \log Y_2}.$$

The positive signs of the coefficients for the population (Z_1) and income (Z_2) suggest that, *ceteris paribus*, an increase in either of these variables increases demand, while the negative sign of the coefficient for trend (Z_4) indicates that over time demand declines. Although the coefficient for man-made fibers (Z_3) does not reflect a substitution of synthetic fibers for cotton fibers, there has been a substantial increase in the use of synthetic fibers in the United States in recent years.

The estimated price elasticity of demand is -0.89. Brandow and Blakley's estimates of the U.S. price elasticity of demand for cotton are -0.40 and -0.86, respectively.[6] Hence, based upon these various estimates of the U.S. price elasticity of demand for cotton, it appears to be inelastic and in a range from -0.4 to -0.9.

The U.S. supply equation is

$$(4) \quad \log Y_3 = -2.953 + \underset{(2.055)}{1.647 \log Z_6} + \underset{(0.422)}{1.287 \log Z_7} + \underset{(1.476)}{0.921 \log Z_8} - \underset{(0.578)}{0.463 \log Z_9}$$

[5] The standard errors are enclosed in parentheses under their respective regression coefficients. For the equations estimated by 2SLS, the R^2 and the Durbin-Watson statistic d are not strictly valid and are not reported. Although the rest of the world supply equation is estimated by OLS, it contains the dependent variable as a lagged independent variable, and the Durbin-Watson statistic is not reported.

[6] A distributed lag model of the type suggested by Nerlove was also estimated, but the lagged endogenous variable had a negative sign that contradicts the assumed market adjustment process over time. Thus, it was not possible to estimate a long-run price elasticity of demand. Blakley also encounters this same difficulty with some of the distributed lag models specified in his study. In an effort to reduce the effect of multicollinearity among several variables in the U.S. cotton demand equation, a per capita Nerlovian distributed lag model was also estimated. In this case the short-run price elasticity of demand was found to be -0.38 with an elasticity of adjustment of 0.78. These coefficients provide for a long-run per capita price elasticity of demand of -0.49. Based upon the elasticity of adjustment, *ceteris paribus*, it would take two years to remove 95% of an initial disequilibrium.

Table 1. Variable Definitions

Endogenous variables

Y_1 = Quantity of cotton fiber consumed in the United States excluding imports (million lbs.)[a]
Y_2 = Cotton fiber price (15/16"M) at 14 selected markets in the United States (¢/lb.)
Y_3 = Quantity of cotton fiber produced in the United States (million lbs.)
Y_4 = Quantity of cotton fiber exported by the United States (million lbs.)
Y_5 = "World" cotton fiber price (1'M), Liverpool (¢/lb.)
Y_6 = Quantity of cotton fiber consumed outside the United States (million lbs.)
Y_7 = Quantity of cotton fiber produced outside the United States (million lbs.)

Predetermined variables

Z_1 = U.S. population
Z_2 = Disposable income in the United States
Z_3 = Quantity of man-made fibers on a cotton equivalent basis produced in the United States (million lbs.)
Z_4 = Trend, 1952 = 52, 1953 = 53, etc.
Z_5 = Price index of broad woven cotton cloth (1947–49 = 100)
Z_6 = Price index of commercial fertilizer in the United States (1947–49 = 100)
Z_7 = "Support price" as announced by U.S. government (¢/lb.)
Z_8 = Composite wage rate for cotton producing states (1947–49 = 100)
Z_9 = Price of soybeans lagged one year (¢/lb.)
Z_{10} = Percentage adoption of mechanical cotton harvesters (base year 1945)
Z_{11} = Level of adoption of biochemical technology, measured as the percentage increase in cotton yields per acre (base year 1945)
Z_{12} = Quantity of man-made fiber produced outside the United States (million lbs.)
Z_{13} = Y_5 lagged one year
Z_{14} = Y_7 lagged one year
Z_{15} = "World" price of #2 corn, United Kingdom, lagged one year (¢/lb.)
Z_{16} = "World" price of soybeans, United Kingdom, lagged one year (¢/lb.)
Z_{17} = "World" price of wheat, United Kingdom, lagged one year (¢/lb.)
Z_{18} = Export subsidy paid by U.S. government to exporters (¢/lb.)
Z_{19} = Beginning year cotton inventory, United States (million lbs.)
Z_{20} = Ending year cotton inventory, United States (million lbs.)
Z_{21} = Quantity of U.S. imports (million lbs.)
Z_{22} = Beginning year cotton inventory, outside United States (million lbs.)
Z_{23} = Ending year cotton inventory, outside United States (million lbs.)

Note: All variables are measured on a crop year basis and in real terms. The deflators used were the U.S. wholesale farm price index and the U.S. prices paid by farmers index (1947–49 = 100). The year 1952 was selected as the initial date since by 1952 all states mechanically harvested at least 1% of their cotton production. This date also avoids the major market disturbances resulting from World War II and the Korean War. By 1969 the adoption of mechanical harvesters was virtually complete. Data are found in the USDA and United Nations publications.

[a] Imports are excluded so that the surplus areas correspond only to cotton grown in the United States. The U.S. imports only about 1% of its total mill consumption.

$$+ \underset{(0.233)}{0.343} \log Z_{10} - \underset{(0.148)}{0.336} \log Z_{11};$$

$$R^2 = 0.77 \text{ and } d = 1.84.$$

The coefficients for the price of fertilizer (Z_6) and labor (Z_8) have signs opposite those expected a priori and are not significantly different from zero. Apparently, there are some problems of data aggregation and specification of a supply equation that is capable of separating the substitution effect from the output effect. The coefficient of the price of soybeans (Z_9), although not statistically different than zero, has a negative sign, suggesting some substitution of soybeans for cotton.

The coefficients of the mechanical (Z_{10}) and biochemical (Z_{11}) technologies have relatively small standard errors. The positive sign of the coefficient of the mechanical technology is consistent with an increasing rate of adoption of cotton harvesters over the period. The negative coefficient of the biochemical technology suggests that, although the absolute yield per acre of cotton tended to increase as biochemical inputs were adopted, the rate of increase declined throughout the period. The short-run support price elasticity of supply is 1.29, indicating that U.S. cotton producers are quite price responsive in the short run.[7]

The export linkage equation is[8]

[7] A supply equation was also estimated with Y_3 lagged one time period. The coefficient of the lagged endogenous variable, however, was not statistically different from zero. An adjustment elasticity of one for the U.S. cotton supply function probably reflects government intervention in the form of acreage allotments, diversion payments, and related supply-control policies. A supply equation using the market price lagged one year in place of the support price produced a price elasticity of supply of 0.9. Cotton producers apparently respond more readily to the announced support price than to the previous year's market price.

[8] In those years when the world cotton price was less than the domestic price, the U.S. government paid an export subsidy to encourage cotton exports in an effort to maintain the U.S. share of the world cotton export market. Rather than estimate an export demand function, it was hypothesized that an export linkage equation would more adequately account for the U.S. policy-induced

$$(5)\quad \log Y_4 = -5.043 - \underset{(1.107)}{1.071}\log Y_2 + \underset{(1.452)}{3.799}\log Y_5' + \underset{(1.379)}{2.281}\log Z_4.$$

The results indicate that a 10% increase in the domestic price (Y_2) reduces the quantity exported (Y_4) by approximately 11%, *ceteris paribus*, while a 10% increase in the world price including the export subsidy (Y_5') increases the quantity exported by 38%. Apparently, the export subsidy substantially encouraged U.S. exports. The positive sign of the coefficient for trend (Z_4) reflects a net tendency to increase the quantity exported over time.

The rest of the world demand equation is

$$(6)\quad \log Y_6 = 1.770 + \underset{(3.808)}{1.671}\log Z_4 - \underset{(0.350)}{0.124}\log Z_5 - \underset{(0.526)}{0.051}\log Z_{12} - \underset{(0.599)}{0.031}\log Y_5.$$

The positive sign of the coefficient for trend (Z_4) is indicative of a long-run increase in the quantity demanded. Although the magnitude of the coefficient for man-made fibers (Z_{12}) is small, the sign does suggest some substitution of man-made fibers for cotton.

The short-run world price elasticity of demand is −0.03.[9] Blakley estimates a world price elasticity of demand of −0.07. Although based on rather weak statistical results, the rest of the world demand function for cotton is apparently even more inelastic than that for the United States.

The rest of the world supply equation is

$$(7)\quad \log Y_7 = -0.163 + \underset{(0.663)}{1.228}\log Z_4 + \underset{(0.199)}{0.089}\log Z_{13} + \underset{(0.314)}{0.472}\log Z_{14} + \underset{(0.265)}{0.257}\log Z_{15} - \underset{(0.195)}{0.140}\log Z_{16} + \underset{(0.213)}{0.098}\log Z_{17};$$

$$R^2 = 0.97.$$

Heterogeneity of land types, different local input prices, and divergent levels of technologies make this supply function extremely difficult to specify. Due to these problems, Blakley assumes the supply function for cotton for the rest of the world to be perfectly price inelastic. In this study, the price elasticity of supply is not significantly different from zero even at the 0.30 level; thus, the rest of the world supply function is considered perfectly price inelastic.

The parameters from the rest of the world supply and demand equations are not required for the calculations of the economic surplus areas for the United States. These two equations are mainly specified in order to close the system of equations in the world cotton model. Unfortunately, both equations give rather weak statistical results.

The Economic Surpluses

When collapsed on the geometric means of all variables except cotton price and quantity, the U.S. demand equation is

$$(8)\quad \log Y_1 = 4.954 - 0.892 \log Y_2.$$

As indicated in the discussion of the economic model, the domestic demand function (D_d) must be shifted to the right to obtain the effective demand function (D). This is done by adding the geometric means of the domestic quantity demanded (Y_1) and the quantity exported (Y_4) to the net additions to Commodity Credit Corporation inventories to get the total quantity effectively demanded ($\bar{Y}$). The consequence of this adjustment is to shift the intercept of the domestic demand function:

$$(9)\quad \log \bar{Y} = 5.130 - 0.892 \log Y_2.$$

In a similar fashion, evaluating the U.S. supply function at the geometric means of all variables except cotton price, quantity produced, and mechanical technology yields

$$(10)\quad \log Y_3 = 1.284 + 1.287 \log Z_7 + 0.343 \log Z_{10}.$$

In order to estimate the benefit stream generated by the adoption of harvesting technology, the supply function is assumed to shift one year at a time along the static effective demand function (D) by the mechanical harvesting technology variable (Z_{10}). By substituting in the observed level of adoption of mechanical cotton harvesters one year at a time, eighteen different intercept terms for the U.S. cotton supply equation can be derived. By solving simultaneously each of these eighteen supply equations with the static effective demand equation, eighteen before and after *ceteris paribus*, equilibrium price-quantity pairs are obtained.[10]

Formulas developed by Hertford are utilized to calculate the surplus areas.[11] The benefit stream

distortion between the domestic and world market prices, especially the influence of export subsidies and how they affected U.S. cotton exports. Therefore, the U.S. export price (Y_5') is equal to the world price (Y_5) plus the export subsidy (Z_{18}).

[9] A distributed lag model of the Nerlove type was also estimated. The short-run price elasticity of world demand was found to be −0.10 with an elasticity of adjustment of 0.36. The long-run price elasticity of world demand would be −0.28. The world market would require about four years to remove 95% of some initial disturbance.

[10] For purposes of solving the respective pairs of equations, it is assumed $Z_7 = Y_2$ and $Y_3 = \bar{Y}$. The average support price for the eighteen-year period was only slightly greater than the market price. Total U.S. cotton production is equal to U.S. mill consumption plus exports plus net changes in inventories. These two assumptions have only a relatively minor impact on the surplus areas.

[11] Change in consumers' surplus is

$$\left[\left(\frac{P_b - P_a}{P_a}\right)P_aQ_a\right]\left[1 - \tfrac{1}{2}\left(\frac{\epsilon\eta(P_b - P_a)/P_a}{\eta + \epsilon}\right)\right].$$

over the eighteen-year period is then discounted to a present value at a 6% rate of interest. The gain in total consumers' surplus in 1947–49 dollars was approximately $350 million with about $230 million going to U.S. consumers and $120 million to consumers outside the United States. The net increase in Commodity Credit Corporation inventories over the eighteen-year period was minimal.[12] Hence, the government consumers' surplus was negligible.

Based on the average quantity of U.S. produced cotton consumed in the period, this represents a savings to all consumers in real terms of about 5¢ per pound. In terms of the average U.S. population for 1952–69, this is a savings of approximately $1.25 per capita for consumers in the United States.

The producers' surplus gain in 1947–49 dollars was about $309 million. Based upon the average yields and number of acres harvested in the period, this represents a savings in harvesting costs in real terms of approximately 4.5¢ per pound of lint cotton or $20.00 per acre. The cost data reported in Maier's study of the adoption of mechanical cotton pickers suggest that from 1952 to 1966 the real cost per pound of lint cotton mechanically harvested relative to hand picking fell about 3¢ per pound. His study looks only at the direct substitution of mechanical harvesters for hand picking. The coefficient of mechanical technology in this study may also be reflecting other aspects of adopting mechanical pickers such as more timely harvesting and the use of defoliants. Moreover, since this study covers the period 1952–69 and since real hand picking costs continued to increase relative to mechanical harvesting costs throughout the period, one expects the cost savings to be slightly higher in this study than in the Maier study.

Cost of production data for the Mississippi Delta (USDA 1970, 1971) indicate that real labor costs for all production activities fell $28 per acre from 1960 to 1970, while real machinery costs remained virtually unchanged. Hence, a cost savings of about 4.5¢ per pound or $20.00 per acre from the adoption of mechanical cotton harvesters for 1952–69 does not seem to be unreasonable.

Conclusions

Both consumers and producers in the United States have benefited from the adoption of mechanical cotton harvesters. U.S. consumers received the larger portion of the economic welfare gains, approximately $230 million or about $1.25 per capita in 1947–49 dollars. The cost savings to the U.S. cotton producers as a result of the adoption of the harvesting technology was approximately 4.5¢ per pound of lint cotton (1.4¢ per pound of seed cotton).[13] This cost savings is about 15% of the average real price received by farmers for lint cotton during 1952–69.

The welfare gains from the adoption of mechanical cotton harvesters reported in this note are based on a partial equilibrium framework and do not reflect the direct impacts on the labor market. Although the benefits to consumers and producers were substantial, the adoption of the labor-saving technology contributed to the disequilibrium in the labor market in the South. Further research on this labor market disequilibrium should provide additional insights into the total magnitude of the social costs and benefits of the adoption of cotton harvesters.

[*Received May 1976; revision accepted June 1977.*]

Change in producers' surplus is

$$\left[\left(\frac{Q_a - Q_b}{Q_a}\right) P_a Q_a\right]\left[1 + \tfrac{1}{2}\left(\frac{Q_a - Q_b}{Q_a/(\eta + \epsilon)}\right)\right],$$

where P is the price, Q is the quantity, a and b "after" and "before" technological change, respectively, η is the price elasticity of demand, and ϵ is the price elasticity of supply.

[12] In the late 1950s and early 1960s, the Commodity Credit Corporation inventories were relatively large. However, by the end of the period, government inventories were nearly depleted.

[13] Based on a USDA conversion factor of 3.26 pounds of seed cotton, including trash, per pound of ginned cotton.

Impact of Rail Abandonment upon Grain Elevator and Rural Community Performance Measures

John J. Miller, C. Phillip Baumel, and Thomas P. Drinka

Historically, businessmen located on rural branch rail lines have strongly opposed rail abandonment. They have argued that the loss of their branch rail lines would substantially increase their costs and make it more difficult—and perhaps impossible—for elevators and farmers to market their grain and to obtain production inputs. Community leaders maintain that the very existence of their towns will be threatened if their rail lines are abandoned.

Congress also has been concerned with the impact of rail abandonment on rural communities. The Railroad Revitalization and Regulatory Reform Act of 1976 provides up to $360 million of financial assistance to states for "transitional continuation of service on light density rail lines that are necessary to continued employment and community well-being throughout the United States."

The available research on the impact of rail abandonment on rural businesses and towns is inconclusive. The studies addressing this question generally are of three types. One type attempts to project the potential impact of abandonment on communities and elevators that have rail service. Studies by Poth (1975a,b) and by Fink and Goode forecast large losses of income and/or employment from potential rail abandonment.

A second set of studies measures changes in communities and counties before and after abandonment. Due measures employment and population in two Oregon counties before and after abandonment of a branch line. Allen measures population growth, transportation costs, and firm adjustments within ten communities before and after abandonment. Due and Allen conclude that the short- and long-run effects of abandonment were relatively small.

A third set of studies compares the growth of firms and counties affected by abandonment with the growth of nearby firms and counties that continued to have rail service. Bunker and Hill measure the impact of rail abandonment on agricultural production and on associated grain-marketing and fertilizer-supply firms located on two abandoned rail lines by comparing the growth of the firms located on the abandoned lines with the growth of nearby firms. The chief impact was on fertilizer dealers. There was no clear indication that abandonment had any significant impact on employment.

Sloss, Humphrey, and Krutter attempted to measure the overall effects of rail abandonment on the development of nine test counties that had lost a major portion of their rail mileage. These nine counties were compared with nine control counties that had either no abandonment or relatively little abandonment. They find no significant impacts attributable to abandonment using economic indicators such as changes in total bank deposits, changes in total value added by farm products, changes in number of employees in manufacturing, etc. Measures of total economic activity on a county basis, however, may be too aggregative to measure accurately the impact of rail abandonment on individual businesses and communities.

Many communities already have lost their rail lines. Thus, it should be possible to measure statistically the effect of rail abandonment on performance measures of businesses and communities by comparing the change in performance measures over time of the businesses and communities that have lost their rail service with the change in these performance measures of similar businesses and communities located on branch rail lines. It should then be possible to determine if significant statistical differences occur in the change in performance measures of the two groups of businesses or communities. This note compares certain performance measures of cooperative elevators and incorporated towns in Iowa that lost their rail lines before 1974 with the performance measures of cooperative elevators located on all rail lines in Iowa and of incorporated towns served exclusively by seventy-one Iowa branch rail lines recently studied for possible upgrading or abandonment (Baumel, Miller, and Drinka 1976, 1977). These seventy-one branch lines, which generally serve rural areas in Iowa, are considered as potential candidates for abandonment.

The towns on these seventy-one branch lines were chosen as the control group because of their similarity in size and type of economic activity with the towns already abandoned. The major difference between the control and treatment groups is that almost all of the communities on the seventy-one lines

have vigorously opposed abandonment and have worked aggressively to generate additional traffic to justify keeping the rail line. Some of the communities and shippers have raised private funds that, combined with state government funds, have been used to upgrade their rail lines. Most of the upgraded lines generate very large volumes of rail shipments. The upgraded lines as well as the lines with shippers who are successful in increasing the rail traffic are likely to remain in operation.

Methodology

According to Steiner, the major criteria used by the Interstate Commerce Commission to evaluate individual rail abandonment petitions are (*a*) historical levels of carloadings, (*b*) historical levels of railroad profits or losses from the line, (*c*) availability and cost of alternative transportation, and (*d*) other considerations such as rail line rehabilitation costs or previous commitments to shippers. The criteria weighted most heavily by the Interstate Commerce Commission are the level of railroad profits or losses from the line and the historical volume of traffic on the line. Therefore, rail lines serving communities and shippers with small volumes of freight are more likely to be abandoned than are rail lines serving communities and shippers with large volumes of freight. Thus, an analysis of absolute values of performance measures of communities and shippers is likely to lead to the conclusion that railroads serving communities and shippers with small freight volume are more likely to be abandoned than are lines serving communities and shippers with large freight volume. To avoid the "chicken-egg" issue of whether rail lines affect community and elevator size or whether community and elevator size affect the presence of the rail line, this analysis is based on percentage changes in the performance measures of communities and elevators located on abandoned rail lines compared with communities and elevators located on rail lines; that is, this analysis determines whether the rates of change of the performance measures are different between the communities and elevators with and without rail service. These effects can be termed the "secondary effects" of rail abandonment.

An analysis-of-variance model was used to test the null hypothesis of no significant differences in the yearly percentage change of each of the measures between the cooperatives or towns that had already lost rail service and the cooperatives located on rail lines or towns still served by the seventy-one branch lines studied. The model used is

$$Y_{ijk} = u + \alpha_i + \beta_j + \alpha\beta_{ij} + \epsilon_{jk},$$

where Y_{ijk} is the performance measure for the kth individual in the jth year and ith group, u is the grand mean, α_i is treatment effects ($i = 1$ = abandoned rail line towns and $i = 2$ = towns on the seventy-one study lines), β_j is replication effects (j = index of years), $\alpha\beta_{ij}$ is the interaction between the treatment and years, and $\epsilon_{jk} = v_k + e_{jk}$, where v_k is the random error associated with the kth individual and e_{jk} is the random error associated with the jth measurement for the kth individual. The random errors v_k and e_{jk} are assumed independently distributed with zero means and with variances σ_v^2 and σ_e^2, respectively, where $\sigma_v^2 \geq 0$ and $\sigma_e^2 > 0$. This model is the one-fold, nested-error type (Fuller and Battese). The covariance structure of the random errors ϵ_{jk} in this model is expressed by

$$\begin{aligned} E(\epsilon_{jk}\epsilon_{j'k'}) &= \sigma_v^2 + \sigma_e^2 \text{ if } k = k' \text{ and } j = j', \\ &= \sigma_v^2 \quad \text{if } k = k' \text{ and } j \neq j', \\ &= 0 \quad \text{if } k \neq k'. \end{aligned}$$

The estimation procedure for the model consists of two steps. First, the variance components (σ_v^2 and σ_e^2) are estimated by the fitting-of-constants method (Searle). If $\sigma_v^2 > 0$, the Fuller and Battese method is used to compute a matrix of transformed variables for the estimates of the variance components. Least squares is then applied to the matrix of transformed variables to obtain least-square estimates. If $\sigma_v^2 = 0$, then least squares is applied to the original variables. A two-tailed F-test is used to test the null hypotheses that $\alpha_1 = \alpha_2, \beta_1 = \beta_2 = \ldots = \beta_n$, and $\alpha\beta = 0$.

Results

The cooperative elevator performance measures (the alternate Y_{ijk}'s) used in this study include total sales, return on investment, total assets, grain sales, and fertilizer sales for the years 1969–74. The sample of elevators analyzed consists of cooperatives audited by a regional grain cooperative. Financial data were obtained from the audited financial reports of cooperative elevators that had lost rail service and from cooperative elevators still located on rail lines (Farmers Grain Dealers Association of Iowa). The cooperatives in the group with rail service include only the 138 cooperatives audited by the regional cooperative each year from 1969 to 1974.

The group of cooperatives that had lost rail service include only those that had no facilities with access to rail lines; cooperatives were added to this group the year after abandonment of the rail line. The number of cooperatives in this group ranged from five in 1969 to twelve in 1974.

The unweighted average yearly percentage changes in total sales, grain sales, fertilizer sales, and total assets and percentage return on investment for the two groups of cooperatives are presented in table 1. The data in table 1 are unweighted average percentage changes, where n is the number of cooperative elevators in the previous year. Because the return on investment measure was automatically adjusted for elevator size when total earnings were divided by total assets, this measure was not converted to an annual percentage change.

Table 1. Unweighted Average Percentage Change in Selected Performance Measures of Two Cooperative Elevator Groups, Iowa, 1969–74

Performance Measure	1969	1970	1971	1972	1973	1974
Total sales[a]						
On abandoned lines[b]	—	22.7	27.3	−0.8	51.6	51.0
On existing lines	—	32.6	17.2	1.6	53.7	59.6
Grain sales[a]						
On abandoned lines[b]	—	35.0	31.4	2.0	73.4	65.7
On existing lines	—	45.3	23.0	1.0	65.4	73.5
Grain sales (bu.)[a]						
On abandoned lines[b]	—	25.7	13.6	1.1	37.1	10.7
On existing lines	—	35.2	6.1	1.0	30.6	22.4
Fertilizer sales[a]						
On abandoned lines[b]	—	6.9	59.4	1.0	26.8	78.5
On existing lines	—	11.5	23.2	−4.1	37.6	92.8
Total assets[a]						
On abandoned lines[b]	—	26.0	15.6	11.0	32.6	26.7
On existing lines	—	13.4	5.4	14.5	36.9	13.4
Return on investment						
On abandoned lines	11.1	10.5	6.6	7.5	12.9	20.4
On existing lines	6.1	7.0	6.5	6.8	10.8	18.5

[a] Percentage change from previous year.

[b] Based on number of cooperative elevators in the previous year.

The computed *F*-statistics and degrees of freedom from the analysis of variance of the cooperative data are presented in table 2. The computed *F*-statistics for years indicate significant differences for all measures at the 99% confidence level. The computed *F*-statistics for the treatment (rail service) and the interaction terms indicate no significant differences between the two groups of cooperatives.

The high level of significance among years for all measures is largely a result of the rapid growth in the export demand for feed grains and soybeans during 1969–74. The growth in exports was caused primarily by widespread drought in many parts of the world combined with the devaluation of the U.S. dollar. This growth in the demand for feed grains resulted in increased sales and earnings for almost all cooperatives.

The lack of significance of the treatment (rail service) and interaction terms seems reasonable given the data in table 1. Only small differences exist in the rate of growth of the two groups of cooperatives. These results suggest that cooperatives located on abandoned rail lines do not die but rather continue to grow. A similar conclusion can be drawn from the average percentage return on investment data. While the cooperatives located on abandoned rail lines experienced slightly higher rates of return on investment than did the cooperatives with rail service, the average return on investment of the two groups followed similar patterns of change over the six-year period.

According to the managers of the cooperatives located on abandoned rail lines, the abandonment of their rail line induced them to completely reevaluate

Table 2. Analysis of Variance Results for Percentage Change in Performance Measures of Cooperative Elevators, Iowa, 1969–74

Performance Measure	Computed *F*-Statistics and Degrees of Freedom		
	Year	Treatment (Rail Service)	Interaction
Total sales	$94.41^{a}_{(4,713)}$	$0.39_{(1,713)}$	$0.39_{(4,713)}$
Grain sales	$72.60^{a}_{(4,711)}$	$0.01_{(1,711)}$	$0.26_{(4,711)}$
Grain sales (bu.)	$11.16^{a}_{(4,707)}$	$0.05_{(1,707)}$	$0.18_{(4,707)}$
Fertilizer sales	$46.24^{a}_{(4,684)}$	$0.002_{(1,684)}$	$0.49_{(4,684)}$
Total assets	$31.90^{a}_{(4,713)}$	$1.84_{(1,713)}$	$0.83_{(4,713)}$
Return on investment	$41.66^{a}_{(5,862)}$	$1.49_{(1,862)}$	$0.19_{(5,862)}$

[a] Significant at the 99% confidence level (Snedecor and Cochran).

Table 3. The Analysis of Variance Results for the Community Performance Measures

Growth Measure	Computed F-Statistics and Degrees of Freedom		
	Years	Treatment (Rail Service)	Interaction
Population	$4.29_{(1,557)}$	$0.04_{(1,557)}$	$0.89_{(1,557)}$
Retail sales	$62.11^{a}_{(4,583)}$	$0.04_{(1,583)}$	$1.81_{(4,583)}$
Bank demand deposits	$79.96^{a}_{(8,1414)}$	$0.81_{(1,1414)}$	$1.47_{(8,1414)}$
Bank loans and discounts	$13.44^{a}_{(8,1414)}$	$0.05_{(1,1414)}$	$0.37_{(8,1414)}$
Bank surplus, reserves, and undivided profits	$26.63^{a}_{(8,1414)}$	$0.0002_{(1,1414)}$	$0.52_{(8,1414)}$

[a] Significant at 99% confidence level (Snedecor and Cochran).

the operations of their cooperatives. This, in turn, led to the elimination of unneeded labor and equipment, to improved marketing practices, and to a search for new product lines and enabled them to continue to grow in sales, assets, and earnings. Therefore, the calculated F-statistics combined with an evaluation of the raw data on the growth of the performance measures of the cooperatives suggest that the null hypothesis of no significant differences in the performance measures of the two groups of cooperatives should not be rejected.

The performance measures (Y_{ijk}'s) of incorporated towns located on abandoned rail lines and of incorporated towns located on the seventy-one study lines include population and retail sales. In addition, data on bank demand deposits, bank loans and discounts, and bank surpluses, reserves, and undivided profits were obtained for state banks located in each set of towns. Bank demand deposits and bank loans and discounts can be interpreted as gross measures of income in the communities. Bank surpluses, reserves, and undivided profits are approximate measures of bank profitability. Employment data are available only by county and, therefore, were not used in this analysis. All towns included in the abandoned groups had lost their rail lines before the beginning of each time period.

Table 3 presents the analysis-of-variance results. The computed F-statistics for years indicate significant differences among years in the performance measures. Evidently, the significant difference was caused primarily by a rapid growth in agricultural output and, hence, rural income during the years included in the analysis. The computed F-statistics for the treatment (rail service) indicate no significant differences in the five performance measures between incorporated towns and banks located on abandoned rail lines and the incorporated towns and banks located on the study rail lines. The computed F-statistics for interaction indicate no significant differences in the effect of abandonment on the performance measures among years.

Conclusions

The results indicate that, contrary to popular opinion, cooperatives located on abandoned rail lines do not die but rather continue to grow. When the performance measures were converted to percentages to adjust for elevator size, the data indicate no differences in rate of growth in the performance measures. If additional explanatory variables were considered in the analysis-of-variance model, a larger proportion of the total variation might be explained; however, the raw data suggest that the treatment F-statistics would likely show little change. With respect to community measures, no significant F-statistics existed for treatment (rail service) or for interaction. The results of this statistical analysis tend to confirm the conclusions of case studies that suggest minor or negligible impacts of rail abandonment on rural towns and elevators.

Recreation Program Development Impacts: A Dynamic Regional Analysis

Nicholas Brown and James A. MacMillan

Controversy exists with respect to the effectiveness of outdoor recreation programs in contributing to regional development. According to Garbacz, recreation may be the major economic opportunity for revitalizing some rural areas. In contrast, Meyer observes that past studies do not confirm the common assertion that tourism-recreation has the potential for stimulating the economies of distressed areas. The lack of adequate data on regional impacts of concern to local, provincial, and federal interest groups in Canada (as well as the United States) has delayed the construction and development of national parks proposed to preserve unique ecological landscapes or to create new recreational opportunities (MacMillan, Lyon, and Brown; Clawson and Knetsch).

Analysis to date has not compared recreation with other development programs and has been limited to measuring the importance of visitor expenditures (Beyers, Hinman). Critical issues that have been neglected include the impacts associated with park construction, operation, manpower training, visitor expenditures, and income distribution. The primary purpose of this note is to compare impacts of a recreation program relative to agricultural development programs utilizing a dynamic regional economic model developed by Tung, MacMillan, and Framingham. This note is organized into three sections: (*a*) inclusion of recreation in a regional model, (*b*) an assessment of recreation versus agricultural development programs, and (*c*) development policy implications. The results indicate a low level of recreational impacts relative to agricultural program benefits. Thus, recreation may often be oversold as a stimulus for regional development.

Inclusion of Recreation in a Regional Model

Development of outdoor recreation resources stimulates regional growth primarily from the "demand side," generated from the exogenous increases in the final demand sector associated with government capital, and operations and maintenance expenditures and visitor expenditures by recreationists attracted to the region.[1] In the model described here, these impacts are calculated in three stages. First, economic impacts are simulated in the model without recreation programs to determine base values for economic development indicators. The effects of the recreation program are then included in a rerun of the model. Second, distributional impacts are estimated. Third, recreation impacts are compared with those generated from other development programs.

The recreation impact estimation developed here is based upon a modification of a dynamic regional input-output system estimated by Tung, MacMillan, and Framingham. This model is modified to incorporate the recreation program expenditures by sector with the addition of four vectors to the initial final demand vector in year t, including park capital expenditures, total nonwage operations and maintenance expenditures, regional household expenditures resulting from wage and salary payments in operations and maintenance and manpower training programs, and visitor expenditures due to the park. The elements of the household expenditures vector associated with wage, salary, and trainee payments are derived from proportional allocation to sectors of commodity group expenditures estimated by Engel functions.[2] The elements of the visitor expenditure vector are estimated by proportional allocation by sector of estimated day-use and camping party expenditures. The 1976–78 visitation projections are based on average annual growth rates of 37%, 27%, and 11%, respectively, to approximate rapid increases in initial years and a gradual decline to the provincial average growth rate.

The distributional impacts involve estimation of the impact of the recreation program on low-income households. There are three dimensions to the distributional impacts. First, the recreation facility is used primarily by high-income visitors from outside the rural region. Second, the park facility construction was used as a training project for low-income unemployed rural residents. Third, seasonal jobs associated with visitor expenditures primarily in the personal service sector are relatively low-wage occupations. Recreation impacts in low-income households are realized primarily in the construction phase of the project.

Nicholas Brown is a research associate and James A. MacMillan is a professor in the Department of Agricultural Economics, University of Manitoba, Canada.

[1] Tourism generally involves all travel for whatever reason when the trip made is not part of a daily routine, whereas outdoor recreation at parks relates solely to those trips made voluntarily during leisure time.

[2] Engel functions have been estimated for eleven commodity groups in the Interlake Area (Tung, pp. 209–18).

An Assessment of Recreation versus Agricultural Development Programs

The recreation program examined in this study was developed as part of an area rural development plan in the Interlake Area of Manitoba. The program is jointly funded by the Province of Manitoba and the Canada Department of Regional Economic Expansion. The broad objectives of the rural development plan are to increase income and employment opportunities and standards of living. Other development programs include education, drainage, land clearing, manpower training, and fisheries adjustment. The objectives of the recreation program are to enhance and complement the Manitoba recreational areas within 100 miles of Winnipeg along the west shore of Lake Winnipeg and to provide construction, training, and service jobs.

The park is 90 miles north of Winnipeg on Hecla Island in Lake Winnipeg. A small campsite existed prior to park development, and development of hotel facilities has occurred after the study period. Hecla Provincial Park will serve an existing and increasing recreational demand for day trips, sightseeing, camping, and cottage facilities. Recreation's share of the development expenditure in the Interlake Area rural development plan (1967–77) approximates $4 million or 5% of the total budget of $85 million. During 1968–77, the outdoor recreation development program at Hecla Provincial Park (including provincial expenditures in addition to the development plan) involved the following expenditures: (*a*) $5.1 million capital construction, (*b*) $0.7 million manpower training corps, and (*c*) $2.6 million operations and maintenance. Land acquisition expenditures analyzed by Friesen are not included.

Data on capital expenditures, operations and maintenance expenditures, and wage and salary payments and training allowances obtained from analysis of government records were used to estimate consumption expenditures. The projected sectoral allocation of expenditures by visitors to Hecla Provincial Park was obtained through a visitor survey of 626 day-users and 415 camping parties conducted at the park during the summer of 1975 (Brown, Lyon, and MacMillan). Nonresponse tests and confidence intervals on day-use and camper average party expenditures indicate that data quality is not a problem.

The overall impact of the recreation program at Hecla Provincial Park in terms of the regional economy appears small, but the effects are much greater in some sectors than others. The largest impacts occur in the nonagricultural service sectors of the economy. The construction phase provides the bulk of the employment impact early in the project in the construction sector (92 man-years or 0.6% of projected employment of 15,729 in 1971), while at later stages government operations, maintenance expenditures, and visitor expenditures provide most employment in the government and service sectors (43 man-years or 0.3% of projected employment of 15,374 in 1976). Although the overall employment and income impact may appear low, much of the expenditure is concentrated in one municipality within the region (the rural municipality of Bifrost), which creates a significant local effect.[3]

The distributional effects of the primary output of outdoor recreation development are negligible. Over 77% of day-users and campers from Manitoba visiting Hecla Provincial Park in 1975 had 1974 family incomes in excess of $10,000. This is three times the proportion of Manitobans with individual 1974 incomes in this bracket (a group that contributed approximately 74% of individual tax revenue in the province) and suggests that the income class that receives the largest share of benefits from visiting the park pays the largest share of park costs (Brown).

The economic impacts in terms of income and employment generation also appear to have little effect on low-income groups and are concentrated in the urban sectors of the regional economy. The stable jobs that are created in Hecla Provincial Park tend to be in the higher income occupation categories, but the small number of seasonal jobs associated with visitor expenditures are in low-wage occupations. For instance, the average 1968 household income in Bifrost was $5,666 (Framingham, MacMillan, and Sandell), and those with occupations in the management, professional, laborer, and craftsman categories (the people employed in the Hecla project) had above-average incomes. The only tangible contribution of the recreation project to low-income families is the employment and training opportunities provided through the Canada manpower program in the construction phase.

An evaluation undertaken for agricultural development programs involving drainage (Norton and

[3] Subregional impact estimates are calculated using an input-output table (MacMillan and Lu). The rural municipality of Bifrost borders on the entrance to Hecla Provincial Park and contains the two towns nearest to the park, Riverton and Arborg. Because many of the personnel now employed at the park reside in the municipality, the impact of the creation of the park on this local economy is significant. The direct sales impact of the Hecla development program on the municipality is estimated to average $114,000 per annum over the construction phase of the program and $144,000 per annum over the operational phase. The majority of this impact derives from the local hiring of trucking firms during the construction phase and from local purchases and wage and salary payments during the operational phase. In total, the Hecla project is estimated to have generated average annual total sales in the municipality of $153,900, increased household income by $77,200, and provided employment for sixteen persons over the 1970–74 period. These annual impacts should increase to average $182,700 in sales, $163,500 in income, and employment for twenty-nine persons each year thereafter.

These impacts are significant in terms of the local economy. Although the effect on gross output is small (1.1% in 1976), the income and employment generated is more substantial. Income in the municipality is estimated at $5.36 million in 1976, to which the program will add $163,500 or 3.1%, concentrated in the government sector. Similarly, employment generation in 1976 of approximately twenty-nine persons adds 2.6% to the 1968 municipal employment level of 1,109.

MacMillan), land clearing (Pareek), and farm management training (MacMillan, Bernat, and Flagler) permits an assessment of the relative effectiveness of recreation versus other programs in achieving regional development objectives. Approximate capital costs for the Interlake Area drainage, land clearing, and farm management training programs were $6.8 million, $4.4 million, and $0.9 million, respectively (1968 dollars). The objective of the drainage program was to increase agricultural production by increasing the quality and quantity of agricultural land, and the capital expenditure over the 1968–73 period resulted in the reclamation of 123,885 acres, 75% of this being on livestock farms. The land clearing program was designed to stimulate the expansion of cultivated acreage in the Interlake Area by subsidizing clearing costs incurred by farmers. Over the 1967–73 period, 126,346 acres of land had been cleared, with an estimated 114,027 acres being in production in 1977. The farm management training program was specifically aimed at increasing the management skills of farmers in the Interlake Area through attendance at five-month courses. During 1967–73, 466 trainees graduated from the program, the majority being farmers having low gross receipts.

It is essential in any comparison of these programs that the capital and development phases of the program impacts be separated because it is not possible to sort out the short-term versus the long-term development implications for policy based on the aggregate results presented by Tung, MacMillan, and Framingham. Some types of program expenditures may have high initial regional impacts but minimal continuing effect on the local economy, and although average impacts may exceed those of an alternative program, the latter may well be preferable for reasons of capacity constraints in the economy and long-term stability. Average annual program impacts per million dollars of capital expenditure relative to regional economic development indicators are therefore shown in table 1 under two classifications—"capital phase" and "development phase."

Recreation impacts are below the impacts of agricultural programs in most categories, but the results clearly demonstrate that there is no single "best" program to achieve regional development policy objectives. Each type of resource development has its particular advantages depending on the priority assigned to target variables. For instance, drainage has the highest initial impact on household income, but farm management training has a larger ongoing effect. The latter also generates the largest impact on employment. Both the land clearing and outdoor recreation development programs appear to have relatively smaller impacts on the indicators listed than drainage or farm management training, but outdoor recreation has a larger impact than land clearing on nonagricultural household income and employment.

With respect to the longer term relative impacts (over a ten- and twenty-year horizon), a few preliminary observations can be made. If outdoor recreation visitor expenditures increase at an average of 10% per annum, the magnitude of impacts from this source will be fourfold the initial level in fifteen years. Conversely, drains in an agricultural program may well have silted up over a similar time span and drainage program impacts become negligible. Outdoor recreation impacts will, therefore, increase markedly over time, and while an evaluation of alternative programs over a five-year period may reject outdoor recreation as a means of achieving certain policy goals, the positions and rankings may be more comparable or even reversed if the evaluation were longer term. The results indicate the need for a critical assessment of long-term versus short-term recreation impacts.

The ongoing regional impact of outdoor recreation development programs arises from two components: operations and maintenance expenditure at the park and local expenditures by visitors to the park. In the two operational years of Hecla Provincial Park (1976 and 1977), the operational expenditures generate 74%, 94%, and 92% of the impacts in regional gross output, household income, and employment opportunities. This is because a large proportion of these expenditures are for salaried staff and wage earners, and these payments represent direct inputs into the household sector. Clearly, the proportion of impact attributable to operational expenditures will decline over time given that average visitor growth rates of approximately 10% per annum are exceeding projected annual increases in these expenditures. However, if operational expenditures grow at 5% per annum, it would not be until 1997 that the magnitude of regional impacts would be equally attributable to both operational expenditures and visitor expenditures.

A final critical factor in determining the magnitude of regional income and employment impacts generated by visitors to a newly established park is the substitutability between the park and other recreational sites in the region. The 1975 Hecla Provincial Park survey found that nearly 50% of the park visitors would have come to the Interlake Area even in the absence of the new park. Therefore, although the gross impact on the regional economy from expenditures by all visitors to the park may be significant, the net impact from the development of the new site will be much reduced. An extension of the analysis to include impacts associated with parks having alternative recreation activities would permit park planners to design parks consistent with development objectives (Craven, Framingham, and Capel).

Development Policy Implications

This study suggests that, with development such as is occurring with Hecla Provincial Park and the

Impact on low-income farms[f]								
Distribution of benefits (%)	36		70		87		0	

[a] Capital expenditure on the drainage program totaled $6.79 million during 1968–73, all incurred by the government.

[b] Capital expenditure on the land clearing program totaled $4.39 million during 1967–73, of which $0.707 million was government expenditure and $3.68 million was clearing costs incurred by farmers.

[c] Costs of the farm management training program totaled $0.88 million of government expenditure during 1967–73.

[d] Capital costs of the outdoor recreation development program at Hecla Provincial Park totaled $4.413 million of government expenditure during 1968–75. The majority of this was incurred over the 1970–74 period, the park opening in 1975.

[e] "Agriculture" is defined as sectors 1 to 2 for the drainage, land clearing, and farm management programs and sectors 1 to 3 for the outdoor recreation program. The difference in classification has negligible effect on the analysis.

[f] Percentage of drainage benefits to farms under $10,000 gross receipts is calculated by Norton and MacMillan, of farmers participating in the land clearing program with gross receipts under $10,000 by Pareek, and of farm management trainees with gross receipts under $10,000 by MacMillan, Bernat, and Flagler. The impact of outdoor recreation on low-income farmers is negligible (Brown).

Interlake Area, the majority of impacts generated are tied to local park service centers and, given that capital constraints exist, the overall regional effects may not be as significant in terms of achieving income and employment policy goals as investment in certain types of agricultural resource programs. On efficiency grounds, therefore, expansion of the existing agricultural base of the region may yield a higher payoff than developing an extensive cottage development in a provincial outdoor recreation park. In these circumstances, recreation development may only generate significant localized effects.

The potential regional impacts of recreation development can be assessed relative to the achievement of the largest possible increase in the elements of a regional final demand vector. In the construction phase, the effects on final demand will be greater if more local people can be involved in construction and operation and if training is emphasized. Recreation sites can attract more additional visitors and expenditures to a region if care is exercised not to duplicate existing recreational opportunities. Regional impacts will increase if local businesses add services to meet the needs of visitors and facilities are designed to increase stay length of visitors.

The results indicate that recreation program impacts score below agricultural programs with respect to most indicators of regional development (output, employment, income, government revenue, and income distribution). Careful investigation of the long-term versus short-term impacts is required because the benefits of recreation increase over the long term relative to agricultural programs. The present analysis is limited with respect to assessing long-term impacts by the use of 1968 coefficients for the nonagricultural sectors; adjustments are not made for relative price changes, and the park development is continuing with the addition of a hotel-motel complex. Additional research to overcome such problems is required to facilitate policy decisions with respect to the emphasis on recreation in regional development planning.

Farm-Value Assessment as a Means for Reducing Premature and Excessive Agricultural Disinvestment in Urban Fringes

Howard E. Conklin and William G. Lesher

The possibility that farm-value assessments can prevent the spread of urban uses to farmland has been discussed at great length and answered in the negative (Barlowe and Alter; Council on Environmental Quality; Gloudemans; Gustafson and Wallace; Hady and Sibold; Schwartz, Hansen, and Foin). Real estate taxes cannot be reduced enough to assure that farmers will refuse to accept high urban offers for their land. Even the complete elimination of farm real estate taxes probably could not make farming that attractive.

This note considers only the possibility that farm-value assessments can help to prevent premature and excessive disinvestments in agriculture in urban fringes—prevent the discontinuance or debilitation of agriculture before urban users are willing to make high urban offers for all of the farmland in an area. It is argued that the usual process for allocating taxes in urban fringes discourages the continuance of agriculture wherever efficient farming requires large real estate improvements that must be maintained and occasionally replaced but lack value for nonfarm purposes. Evidence from two New York City urban fringe counties is used in support of this argument.

Nature of Urban Fringes

Urban fringes are considered to be the usually broad belts that extend outward beyond the closely settled suburbs of a city to the residential limits of the commuting population. There normally is an urban gradient within the fringe, with population densities, land prices, land taxes, and levels of public services higher near the suburban boundary (Bryant 1975b). In a growing metropolitan area, the frequency of conversions from open to urban uses also is higher near the inner edge of the fringe. There is no necessary relationship, however, between the width of the fringe and the area that will be newly occupied by close settlement within any specified time. In fact, fringes normally exist around U.S. cities whether they are growing or not.

Growth uncertainties have existed for long periods within most fringes. The fringes of most cities have been so large for many years that even under the patterns of population growth and distribution of the past three decades no one could realistically forecast their total incorporation into the adjacent densely populated urban complex in less than a matter of decades.[1] It has long been meaningful in the fringes to ask which areas are likely to experience the most growth and which individual parcels actually will be turned to urban uses in the near future, and it has been very difficult to provide reliable answers. Most population projections made a few years ago for fringe areas have proved to be wide of the mark. Speculators make a business of trying to anticipate what the market will do. If answers were easily arrived at, there would be no speculators.

Given these uncertainties, there have been marked tendencies to be overly optimistic in periods of growth. Real estate "booms" are well known. They are a special kind of mass psychological phenomena that feed upon a lack of full knowledge. They may be followed by "busts" that are corresponding phenomena in reverse.

It is possible to imagine that farmers in the fringe stand only to gain from the developments taking place about them. One might think that farm owners could continue to use their land as before until the day when they are offered a high urban price, or, if the city ceases to grow, they could continue indefinitely as before.

Such a picture could be realistic if the new uses that scatter increasingly among the farmers brought no adverse externalities and if farming involved no long-term investments that are immobile and of no value to urban purchasers. In some cases, the externalities could be avoided if the farmers *en masse* refused to sell any land until the urban market is prepared to purchase a large area. This, however, presupposes a larger measure of concerted action than normally is feasible. In many cases, also, farm and nonfarm lands are intermingled, so group ac-

The authors wish to thank A. Allen Schmid, David J. Allee, Richard E. Friday, William H. King, Nelson L. Bills, and the anonymous *Journal* reviewers for their suggestions on earlier versions of this manuscript.

[1] Since the area of a circle varies as the square of its radius, the fringe around the closely settled center of a metropolitan unit easily can exceed the area of the closely settled part by several times.

tion would need to extend beyond the farm community.

Most commonly, the externalities are not avoided. Stealing and vandalism increase; ordinances and informal pressures restrict farming practices; more services are demanded than farmers need, yet the costs they occasion often fall heavily on farmers; and the urban sale prices of some parcels provide the basis for assessment increases on all farmlands that further shift service costs to farmers.

In a few areas of the nation, farmland can be used successfully in its natural state. In most areas, however, it must be drained, leveled, or fenced; it must have buildings, irrigation facilities, or orchards added to it; and these investments not only must be maintained but occasionally replaced and almost never have appreciable value for urban purposes.

Farmers who own land in the urban fringe that will not produce efficiently without long-term improvements find the uncertainties of the fringe upsetting (Bryant 1975a). Throughout the fringe, any given parcel possibly can be sold soon for a high price relative to its farm value, but it is very difficult to predict which owners actually will have the opportunity to sell. The likelihood that neighboring sales will bring newcomers who introduce adverse externalities also must be weighed when a farmer contemplates a large new real estate improvement or major maintenance on an old one (Conklin and Dymsza).

Farmers often contribute importantly to the large rise in fringe land prices. Most are aware that to sell small plots or frontage modifies the usefulness of the remainder for farming, partly for reasons of reduced farm business scale but mostly due to the adverse externalities that flow from adjacent nonfarm settlement. Also, farmers considering the sale of their entire unit are aware that it is expensive and time consuming to relocate a farm business (Conklin). Farmers therefore ask a high price for their land until they and their family are through using it.

Some people, not understanding the constraints under which farmers operate, brand them speculators or opportunists. Others more dispassionately argue simply that, if farmers ask $5,000 for an acre of land when a commuting urban worker tries to buy it, farmland should be assessed for tax purposes at $5,000.

Many assessors in the past, being aware of the uncertainties in the fringe and the constraints on farming, assessed farms at urban values only after the farmers actually sold some portions of them at such prices. Some complain that this policy lets farmers who own valuable land go "free" if they sell all of it at one time. The point of view reflected in this complaint is bringing legislated revisions in assessment procedures. Some court decisions appear also to be guided by the same point of view.

The New York State Assessment Improvement Law of 1970 is an example of the new legislation (Lutz). This law placed the State Board of Equalization and Assessment in a stronger position to guide assessment policies, even though assessors still are local officials, and related subsequent action provided the means for computerizing the adjustment of assessed values. In both of these activities, strong emphasis is placed upon current sale prices. In effect, this law accedes to the argument that, if farmers ask a high price for land when nonfarmers wish to buy it, it should be assessed at a high price. Though farmers place a high price on their land because they are reluctant to sell due to nonfarmer-caused externalities and the costs of reestablishment, at least a few nonfarmers actually pay the price, even in the outlying areas of the fringe. These sales are then accepted as setting market prices for farmland assessment throughout the taxing jurisdiction.

The Orange County Experience

The 1974 reassessment of properties in Orange County, in the lower Hudson Valley about 60 miles from Manhattan, is an example of the consequences of the New York Assessment Improvement Law. The reappraisal in Orange County was done by a private firm, but they followed the guidelines suggested to assessors by the State Board of Equalization and Assessment. The task was undertaken at a time of high real estate activity, so numerous instances were at hand in which speculators, developers, or commuters themselves had paid the farmer's asking price.

Orange County's reappraisal put values of $1,000 to $2,000 per acre on most of the dairy farms in the county. These are farms of quite modest productivity, and comparable units were then selling for $300 to $400 per acre elsewhere in the state. Taxes would have risen sharply as a result of the reappraisal, approaching a total of $50 per acre on dairy farms had it not been possible to obtain farm-value assessments.

Farm-value assessments are provided for in New York by the agricultural district law passed in 1971 (Lesher and Conklin). This law permits the formation of agricultural districts through landowner initiative. Once a district is formed, six measures to facilitate farming and discourage nonfarm development are brought into play, one of these being farm-value assessments.[2] Farmers in districts may

[2] The agricultural district law, within the districts, also limits ordinances affecting agriculture, instructs state agencies to encourage farming, modifies eminent domain proceedings, restricts public funds to facilitate nonfarm development, and limits special service tax assessments on farmland (Conklin and Bryant). Farmers outside districts may obtain farm-value assessments by signing commitments for eight years (renewed annually), but conversion to a nonfarm use then involves a monetary penalty equal to twice the amount of taxes levied on the entire property for the year following breach of the commitment. In general, farmers consider

have the value of their land in excess of its value for farming exempt from taxation if they produce an annual average of $10,000 in farm products and file an annual application. Land that has received this exemption is subject to a maximum five-year rollback if converted to a nonfarm use. As soon as the probable results of the reappraisal became clear, agricultural districts began to be formed in all farming areas of Orange County, and farmers asked for farm-value assessments.

In-depth interviews of fifty-four full-time commercial farmers in Orange County were conducted in two studies made in 1975, shortly after the revised assessment rolls became official and the majority of the agricultural districts had been completed (Hunt, King). Farmers had been very much surprised and greatly distressed by the large tax increases that the new assessments would have imposed on them. For some, the proposed increases more than equaled their net farm incomes. They were much less optimistic about opportunities to sell their lands at urban prices than were local government officials and real estate agents. Young men, many of whom were heavily in debt, were the most disturbed.

While the agricultural district law was passed earlier, the farmers of Orange County had not planned action under it prior to the reassessment. The intent of the law is that an agricultural district increase a farmer's chances for staying in farming but reduce his chances for a nonfarm sale, and farmers seemed aware of this. Farmers earlier were not under serious urban pressure and saw no reason for action that would reduce their chances to make an urban sale even though these were not high.

With the reassessment, however, many farmers saw little possibility for financial survival even in the short run, and all would have been unable and/or unwilling to invest in long-run real estate capital maintenance or replacement.

Traditional economic theory accepts the possibility under these circumstances that the farmers currently operating in Orange County might fail financially due to high taxes and be eliminated from farming. This theory holds, however, that if farming remains the highest net income producing use, the value of the land will be lowered to compensate for the higher taxes and other farmers will take over the farm units (Stocker). Actually, a devaluation of the magnitude needed to compensate for the tax increases that would have resulted from the Orange County assessment reappraisal would involve many foreclosures. Those foreclosed on would henceforth be considered poor risks, and few are available with the needed skills and capital to replace them. Nonfarm employment is relatively plentiful in fringe areas, making farming somewhat less attractive by comparison. Bankers, having lost money on one round of foreclosures, would be very reluctant to loan on farm businesses again. The interruption in farming occasioned by the foreclosures would in turn interrupt agribusiness activities, and some of these would fail financially. The total agricultural industry would have been sufficiently disrupted for many years to destroy it in at least parts of the country.

If the rates of urban growth still prevailed that marked northeastern cities for thirty years after World War II, such agricultural disruption would merely occasion a premature death for the agricultural industry. After a few years of idleness, the land would be turned to urban uses. Today, conditions are different.

Since the reappraisal, the real estate market has weakened in Orange County. Many factors have contributed, including the national recession, the special economic difficulties experienced in New York, and, most importantly, the sharp decline in metropolitan growth in this region of the country. No major revisions have been made, however, in assessed values on any types of rural land in Orange County. Local officials and real estate interests still argue strongly for expecting renewed growth in the county, and some bitterness is expressed about how farmers were permitted to get their tax increases rolled back.

It is difficult, of course, to predict levels of future development in Orange County. It seems clear from the interviews that without farm-value assessments some farm businesses would have already been discontinued under conditions in which the land would not have been put to another use but only held by a speculator who bought it cheaply. Capital improvements on farms would be deteriorating, and more farm businesses would be discontinued soon.

It is the judgment of the authors that it will be many years before New York again experiences strong levels of metropolitan growth. The 1974 reassessment in Orange County was based on false anticipations, but it has become largely institutionalized and can be counteracted only by equally institutionalized arrangements—farm-value assessments.

The Suffolk County Experience

It is useful in attempting to see the Orange County experience in perspective to look at parallel developments on the opposite side of New York City. Suffolk County on Long Island has attracted much attention by its program for purchasing development rights on farmland. That program was several years in the making and finally materialized in a more limited form than originally planned. During this interval, interest in agricultural districts was low, but it is now growing.

A few of the differences between Suffolk and Orange counties are pertinent. (*a*) The population

the commitments less desirable than the farm-value assessments provided for in the districts.

of Suffolk County has grown much more rapidly. (*b*) Suffolk County is as far from downtown New York, but close suburban settlement associated with the city has extended into western Suffolk County while separated from Orange County by the highlands of the Hudson. (*c*) Suffolk farmers produce a higher value of farm products on less land. (*d*) There has been no comprehensive reappraisal of property in Suffolk County, and much farmland is assessed on its farm value. A recent court decision, known as the Hellerstein decision, has directed assessors in the Town of Islip, Suffolk County, to assess on the basis of "full market value" (Lesher). This is being interpreted as requiring the type of reappraisal conducted earlier in Orange County. Similar cases are pending in other towns.

Discussions of a possible development rights purchase program were begun in Suffolk County some five years ago, and provision was made for such a program in the 1974–77 capital budget (Newton, Scholvinck). Farmland owners were invited to submit bids for the sale of rights in 1975, and 381 of them indicated a clear interest in such sales on 17,000 acres (Bryant and Conklin). Twenty-one million dollars have now been appropriated. This money is expected to buy rights on about 4,000 acres, less than 10% of Suffolk County's 55,000 acres of farmland. It appears unlikely that additional money will be available for several years, if then.

Suffolk farmers expressed little interest in agricultural districts until the size of the development rights purchase program was determined because development rights purchase automatically keeps farm taxes at farm-value levels. Also, strong pressure has developed only recently for reassessment. Chances for nonfarm sales have been generally good in the county, and farmers were not willing to reduce them by forming districts so long as the advantages of districts would be small. (Farmers who anticipated possible sale of development rights spoke favorably of forming districts after the sale in order to gain the nontax benefits of districts, and some of the few who will be able to sell now plan to participate in district formation.)

The current certainty of reassessments in the county combined with the finalizing of the development rights purchase program are now stimulating interest in agricultural districts, and some districts are in process of formation. Many farmers in Suffolk County say they would be forced to discontinue farming if they were assessed for development rights.[3] These are especially the younger farmers who would have cash-flow problems. If they could retain their development rights with no limitations, they might find it profitable in the long run because the chances for a good nonfarm sale in ten to twenty years appear high. Even in Suffolk County, however, these chances are not 100%, and short-run chances are much lower (Lesher and Eiler). Moreover, agricultural credit agencies are reluctant to loan on the value of development rights.

Suffolk County thus is following a path similar to Orange County, though more slowly, due to the emergence of the development rights purchase program and the deferral of reassessment. Farmers in both counties are resorting to farm-value assessments when tax pressures become very high and are expecting them to permit their survival.

Conclusions

In two important agricultural counties of the New York metropolitan fringe, farm taxes, when added to the other adverse externalities created by scattering nonfarmers, threaten to discourage farmers from making the real estate improvements needed to remain efficient up to the time when urban users actually are ready to pay acceptable prices for the land and convert it to urban uses. In the first instance, agricultural districts have been formed, permitting farm-value assessments and reducing the other externalities. District formation is starting in the second instance. Farmers in districts appear optimistic enough to renew aggressive investment policies.[4]

Although there is a continuing urban demand for some farmland in both counties, most farmers within the fringe appear to realize that not all of them can sell at urban values possibly for decades. With no assurance of an immediate nonfarm sale and faced with escalating real estate taxes, farmers have opted for farm-value assessments through the formation of agricultural districts. Apparently, farmers feel that in taking this step they are trading a reduction in their chances for a nonfarm sale for increased security in farming (urban uses will go more frequently to the intermingled nonfarm lands) but consider the trade worthwhile. Farmers know they need to invest continuously in real estate improvements to remain competitive but also realize that to do so means a long-term commitment to farming. Thus, faced with the conditions of the fringe, farmers by choice have elected to operate in an environment where agricultural production is encouraged. There they can continue to produce efficiently until urban pressure becomes great enough to bring them an offer that will cover their fixed investments and the costs of moving or of changing occupation.

The developments that have produced high farm taxes in the New York City fringe probably are not

[3] Recent appraisals of total farmland market values have averaged about $5,000 per acre in several parts of the county, $1,500 of which is considered farm value. Taxes presently average about $75 per acre of farmland but could reach levels above $200 as a result of reassessment (Lesher and Eiler).

[4] No quantitative measurements of farmers' investment reactions have been made under these circumstances, but Nelson Bills (USDA, ERS, NRED, stationed at Cornell University) is undertaking such a study in western New York.

unique. While research repeatedly has concluded that farm taxes cannot be low enough to stop urban expansion, it is proposed here, with some evidence, that they can be high enough to destroy or debilitate agriculture far ahead of the advancing urban perimeter. If this proposition is correct, farm-value assessment can be an important public policy instrument even if it cannot create a fence around urban growth.

Developing a Competency-Based Curriculum in Agricultural Economics

Loys L. Mather, Joe T. Davis, Russell H. Brannon, A. Frank Bordeaux, Jr., and Robert L. Beck

In an article in this *Journal*, Manderscheid sets forth several guidelines for curricular changes (pp. 745–46). He suggests that curriculum change is a dynamic process requiring efforts to monitor developments both within the discipline and in supporting and complementary disciplines and notes the need for integration of individually planned instructional activities into a systematic whole. Manderscheid further hypothesizes that an inadequate humanities component, insufficient attention to the needs of students planning for a career in the public sector, and a tendency to base courses and curricula on teaching objectives rather than learning objectives all constitute weaknesses in current agricultural economics curricula. Manderscheid's work has exerted considerable influence on the direction taken in a recent review and restructuring at Kentucky. While much remains to be done in terms of implementation, the procedures followed may provide useful guidelines to other institutions contemplating similar curricular revision.

This paper reports on the process employed in developing a competency-based undergraduate curriculum in the Department of Agricultural Economics, University of Kentucky. While applying competency-based instructional techniques to academic programs in higher education is not new, this approach has received very limited use in our profession as well as in colleges of agriculture generally. A competency-based core curriculum has been developed in the College of Agriculture, University of Arizona (Zubrick).

Basically, a competency-based curriculum is an attempt to identify desired outcomes of an educational process (vis-à-vis experiences) and to certify these on the basis of demonstrated behavior (O'Connell and Moomaw).[1] The program being developed at the University of Kentucky is not strictly a competency-based program, since it will not be centered around individual, self-paced courses. It is competency-oriented, however, in that learning objectives were developed on a competency basis for formal classroom courses. Multimedia learning objectives are being developed to supplement rather than substitute for the classroom. The department chose this approach because it was felt that greater weight should be given to students' learning needs and objectives as opposed to faculty teaching interests and objectives.

The movement towards a competency-based approach was also influenced by recognition of the fact that higher education is entering an era of greater accountability. Funding sources, especially state legislatures, are likely increasingly to evaluate institutions of higher education in terms of their ability to produce a product that is employable, socially useful, and productive. In addition, students are demanding more a priori information on what they can expect "to learn" from a course or program of study and what applications can be made of their training programs. This latter demand requires clearer statements of course objectives and material to be covered, as well as improved systems of communication through advisors, student professional clubs, and printed materials in the office of the dean of undergraduate studies.

A competency-based curriculum requires an integrated instructional program, and our program was weak in this regard. Individual courses had been added over the years with little attention to appraising their relationship with other courses, to the total curriculum, or to educational needs. Additionally, the College of Agriculture has recently adopted a new curriculum permitting departments increased flexibility in curricula and program option development.

Finally, several external developments that affect the market for graduates and the currency of curricula have become apparent. These include (*a*) the phenomenal expansion of world marketing and trade that agriculture has experienced in recent years and the resultant demand, supply, and price implications; (*b*) structural changes in farming, agricultural industries, and rural America; (*c*) an increased concern over environmental issues and al-

Loys L. Mather, Robert L. Beck, and A. Frank Bordeaux, Jr., are associate professors, Joe T. Davis is an assistant professor, and Russell H. Brannon is professor of agricultural economics, University of Kentucky.

The authors gratefully acknowledge the helpful comments of R. W. Rudd and K. R. Anschel on an earlier draft of this paper. The work was supported by a grant from the Southern Regional Education Board.

[1] Most adaptations of competency-based programs in higher education have involved developing self-paced, multimedia courses as substitutes for the formal classroom presentations. As students satisfy the requirements of a given learning level, they move up to the next level of learning activities encompassed in another self-paced course.

location and utilization of finite natural resources; (*d*) the apparent lack of real understanding of agriculture by the general public and by decision makers—especially those in a position to influence agricultural and rural policy; (*e*) reduced percentages of students in colleges of agriculture who come from farm backgrounds; and (*f*) an increased activism in areas of consumer interests. These factors imply changes regarding the nature of demand for agricultural economics graduates and the types of training that they should receive. They also have implications for the service role of an agricultural economics department in the total university.

Procedures

Developing a competency-based curriculum represented a significant change in direction, and the faculty recognized at the outset the need for a comprehensive review of the entire undergraduate program. It was agreed that the review would proceed as if a totally new program were being developed, rather than designing a program around existing courses, program options, and resources. Any course retained in the new program would have to be justified on the basis of need rather than prior existence.

Overall responsibility for the review was vested in the department's Undergraduate Program Committee, composed of five faculty members and one student representative. While maintaining overall control and responsibility, the committee assigned tasks to three subcommittees representing marketing and agribusiness, farm management and production economics, and natural resources and rural development. Several factors prompted identification of these three subcommittees. Foremost was the fact that student interests tend to fall within these areas. Nearly all faculty members (research, teaching, and extension) were assigned to and involved in the work of one of these subcommittees. This "grass roots" involvement of the faculty appears to have been a critical factor in subsequent acceptance of the revised program by the department.

In order to profit from the experiences in undergraduate program development on other campuses, visits were made to four agricultural economics departments. An effort was made to develop an understanding of the structure, philosophy, and orientation of these programs and to derive useful insights and ideas that might be incorporated into the Kentucky program. The four departments to be visited were selected on the basis of several criteria, including size and recent change in size of undergraduate program, recent program reorientations of significance, and emphasis devoted to undergraduate training. An attempt was also made to achieve some regional diversity.[2]

In addition to visits to other campuses, broader insights into the structure of undergraduate education in the United States and Canada were obtained through a mail survey of agricultural economics departments in nearly eighty public institutions of higher education.[3] Responses to this questionnaire provided information regarding program options being implemented around the country and anticipated major growth areas in terms of student enrollment, kinds of employment opportunities available to recent graduates, numbers of students from nonfarm backgrounds, advising systems and approaches to evaluating advising and teaching assistants, and administrative support of undergraduate programs. This information proved quite useful in subsequent structuring of the new program.

A very critical and time-consuming step in the developmental phase consisted of identifying and preparing a set of learnings, competencies, and skills needed by graduates, which would serve as the basis for subsequent identification of courses needed in the curriculum. This phase involved obtaining information and ideas from several different groups.

Employers were surveyed regarding job titles, descriptions, duties, and overall training needs of agricultural economics graduates who they hire. Guidance was specifically sought in identifying those areas of training in which graduates are typically adequately prepared and those usually found to be lacking. Recent graduates were also surveyed in a similar context. Based upon their job experiences, graduates were asked to identify areas of academic training that should have been provided but that were inadequately treated.

Involvement of employers and former students provided a very useful information source and one that the department hopes to continue to utilize. As Butz has stated, "Too often . . . professors, department heads, or others assume that they know best what should be in the curriculum and how it should be presented, without bothering to research the market. . . . I believe that most agribusiness economists and executives would be willing to advise on training needs if they were asked to do so" (p. 467). In a similar vein, French has indicated the need for university and agribusiness representatives to get together on training and recruiting (p. 465).

Based upon information from the previously noted sources, descriptions of student learning needs were developed by each subcommittee. These areas of learning were then assessed to determine whether the training could be provided within the department or would require reliance on other departments. For those learnings that fell

[2] Visits were made to Cornell University, Michigan State University, North Dakota State University, and Oklahoma State University.

[3] Usable responses were received from forty-nine institutions including thirty-nine 1862 land grant universities, two 1890 land grant universities, three non-land grant institutions, and four Canadian universities.

within the department's area of teaching responsibility, potential courses were identified by grouping learnings that could logically be provided within a given course. Topical outlines and broad course objectives were then prepared. In areas requiring that learnings be provided by other departments, existing courses were assessed and where necessary new course proposals were discussed or developed in cooperation with relevant departments.

The next step, identification of potential program options within the agricultural economics major, was strongly influenced by the surveys and discussions with employers and by other information gathered by the department. Program options were defined with sufficient specificity to reflect meaningful categories of jobs, yet were broad enough to permit the student some alternative employment opportunities across options. Courses considered essential to provide the needed training were specified under each option.

Upon completion of the initial set of course proposals and program options, a draft reflecting the proposed structure of the undergraduate curriculum was developed. This was presented for critique both in written form and orally to the department faculty, other departments on campus that might be affected by the revision, employers, and former and current students. In addition, three agricultural economists from other institutions were invited to spend two days on the campus for the purpose of meeting with the committee and later with the department faculty to critique the proposed program.[4]

Concurrent with the critique of the proposed curriculum, the committee undertook to reconcile the optimal model of courses and program options with immediate and long-run resource availabilities. This entailed determining availability of faculty to staff the proposed set of courses, assessing the extent to which other departments would cooperate in course changes, and estimating space and equipment availabilities. In those cases where more courses were proposed in an area than could be provided by existing faculty resources, it was first determined which courses could be combined, while still meeting learning needs. Where combination was not feasible, an effort was made to establish priorities for courses and learnings and thus to determine which learnings must remain unmet due to current resource limitations.

Information gained during critique of the initial draft of proposals, plus results of efforts to adjust the optimal model to available resources, served as major inputs into the preparation of a second draft. This draft was then presented to the department faculty. Ensuing discussion, coupled with information solicited from individual faculty members regarding courses that they would be interested in teaching, permitted the faculty to approve the new program with full knowledge of likely demands on their time. Approval was granted with the understanding that not all facets of the curriculum would be implemented immediately but that approval was being given to a long-range planning model for the department's undergraduate curriculum.

Following approval by the departmental faculty, the revised program required approval by the college and university. This process was facilitated by the support provided to the review by administrators at all levels in the university. Without this, the approval process would likely have been a much more laborious procedure. Ultimate approval was also more easily obtained because of the numerous contacts established with other departments and colleges within the university throughout the review process. Most potential conflicts concerning specific courses, subject matter areas, and proprietary interests in addressing particular subject matter were resolved prior to formal submission for approval. Departments likely to be affected by changes in the agricultural economics program had an opportunity to express their views during the formative stages.

Implementation Phase

Several steps have been identified as essential to implementation of the revised curriculum. The initial step was to organize a faculty workshop (conducted by an external resource person) to provide training in writing and using competency-based learning objectives.[5] This workshop served as the basis for subsequently developing specific learning objectives and course content. Committees of two to three persons have been assigned to develop each course, with the eventual course instructor likely to be one of these committee members. This constitutes the most intensive and critical phase in the curriculum revision, since it is the implementing link between the desired and the realized curriculum. Utilizing the broad course objectives and topical outlines developed for each proposed course as a starting point, major subject areas or learning units within the topical outline are being identified. Within each unit, statements of competency-based learning objectives are developed along with an estimated amount of time to be spent on the unit, prerequisite material necessary for that unit, and identification and preliminary development of instructional and learning activities

[4] The three outside reviewers were Dale C. Dahl, professor of agricultural economics, University of Minnesota; Carroll V. Hess, dean of agriculture, Kansas State University; and R. J. Hildreth, managing director, Farm Foundation. Each reviewer received a full set of documents concerning the review in advance of his arrival on campus, and each subsequently prepared and sent to the Undergraduate Committee a detailed set of written comments following the campus visit.

[5] Frank Colton, director of the University of Kentucky's Continuing Education Center, conducted an all-day workshop devoted primarily to the development of course outlines utilizing the behavioral (competency-based) objective approach. Film strips, worksheets, and other materials were furnished. Over 90% of the department faculty participated in the entire workshop.

including assigned reading, field trips, audiovisual software, papers, reports, exercises, etc.

Course committees have also been assigned the task of identifying topics or units within courses that will require supplementary learning aids. A part of the department's long-range plan is to develop, in conjunction with the college, a multimedia learning resource center. Such a center can serve a variety of purposes. One such function could be to provide out-of-class remedial work for less adequately prepared students, or additional review for those desiring it, without slowing down the formal classroom pace. Reliance would be placed upon slide-tape presentations, audiovisual cassettes, computer-assisted learning, etc., located in the learning resource center.

Another major step in implementation is the design of an appropriate structure for providing closer monitoring of the undergraduate program. A position of Director of Undergraduate Studies is being established to assist the department chairman in coordinating the undergraduate program. The incumbent will also serve as chairman of the Undergraduate Program Committee and will have major responsibility for developing a means of continuous review and evaluation of the curriculum. This will likely require periodic review and revision of the learnings and competencies needed by graduates, as well as revisions in course content and program requirements as learning needs change. Additional areas needing attention include development of a system to maintain contact with employers and former students, coordinating the department's student advising efforts, and supervising recruitment of potential students.

New Features in the Curriculum

Several new features of the revised curriculum are noteworthy. The department now has a long-run plan for its undergraduate program. While various facets will be implemented in phases, a specific direction has been taken and a commitment has been made. The importance of a strong undergraduate program has been established and accepted by the department faculty.

Prior to the restructuring of the college curriculum, every agricultural student, regardless of departmental major, satisfied the requirements in one of three curricula: technology, science, or business. Under the revised college and departmental program, a student majoring in agricultural economics specifies an option within the department. In the area of agricultural marketing and management, students can choose from among agribusiness management, agricultural financial and credit management, and farm management. In the area of natural resources and rural economic development, options are provided in natural resource and environmental economics and in rural economic development. While there will naturally be a number of courses that will be common to all options, there is sufficient diversity to provide a differentiated product. This differentiation will be accentuated by supporting courses outside of the department.

The revised curriculum represents a reorientation in thrust in some learning areas. Greater emphasis will be devoted to economic principles, methodologies and their application (linear programming, computer science, etc.), and to oral and written communications. In some other areas, such as agricultural commodities, emphasis will be redirected to provide greater flexibility, depending on student interests. Appropriate sequencing of the entire set of undergraduate offerings has been developed along with identification and enforcement of prerequisites for each course.

As a result of developing the set of learnings and grouping related learnings into courses, several courses evolved that will require less time than the traditional three-credit course to cover the material. This has led to identification, in several areas, of basic material to be covered in three-credit courses, with the option for taking follow-up application courses in a variety of one-credit modules. These one-credit modules will be organized and taught in the same way as a three-credit course but for only one-third of the semester. In a given semester, a student may choose from among a number of modules to be taken at various times throughout the semester. One-credit modules will be offered in marketing agricultural commodities, farm and agribusiness management topics, data processing, linear programming, and agricultural credit institutions.

The department has developed improved communications with other departments in the college, and this has enhanced understanding and appreciation of the potential service role in providing applied economic content to their programs. To help meet outside needs, a minor in agricultural economics is being established and will be one of only two minors currently offered in the university. Employer discussions and surveys indicate that agribusiness recruits from among two major categories of agricultural graduates. One group comprises those potential employees whose primary training is in agricultural economics and agribusiness, with training in technical agriculture being of secondary importance. There is a sizable demand, however, for graduates with primary training in technical agriculture who have some competence in agricultural economics or agribusiness. The agricultural economics minor addresses this latter category. In addition to the minor, more courses in the department will likely provide a service component than was the case under the previous curriculum.

The revised curriculum will give greater emphasis to both oral and written communications, a requirement that was dropped from the college curriculum a few years ago. Surveys of employers

show that this is the greatest weakness among graduating students. In reinstating the requirement, a flexible approach is to be followed, with students being required to take courses in the area at levels appropriate to upgrading their existing competencies. One or two courses in communications obviously will not bring all students to a satisfactory level of competence, and it is recognized that instruction within the array of departmental offerings must also stress the improvement of written and oral communication skills. Individual instructors must be encouraged to devote greater emphasis to this dimension.

Preliminary Assessment

While assessment of the revised curriculum is premature, some observations on the procedures followed are appropriate. (*a*) The initial decision to proceed as if the department were designing a totally new program constituted an essential and critical step in insuring faculty involvement in the process and also in creating a faculty awareness that significant change was under way. (*b*) Developing the list of learnings and competencies needed by graduates, while time consuming, was useful in identifying essential training areas and in minimizing repetition of material and course overlap.

(*c*) Visits to other agricultural economics departments were extremely helpful. Since visits were made early in the review process, it was possible to take advantage of numerous ideas, experiences, and philosophies in planning our curriculum revision. (*d*) The external review was a very valuable contribution. The three invited reviewers pointed out some previously unseen weaknesses. In other instances, they lent support to committee findings and recommendations and thus facilitated their acceptance by the faculty. Although some of the reviewers' suggestions were not implemented, many of these caused the faculty to reassess previous positions. Clearly, a much better product has evolved as a result of the outside review. (*e*) Discussions with other departments on campus were fruitful and would form an integral part were we starting the review anew. All parties appear to have derived better mutual understanding. Similar discussions should continue in the future, at least on a semiformal basis.

(*f*) Student involvement in the curriculum review contributed substantially to the final product. The student committee members provided a significant input in a tangible way by pointing out problems in department offerings and proposed offerings as well as in courses in supporting departments. Less tangibly, but equally important, their formal and informal discussions with other students formed an invaluable communication channel throughout the review process and in subsequent implementation efforts. (*g*) At this juncture, faculty commitment appears stronger than one might have anticipated, given the history in academic institutions of resistance to curriculum change. One manifestation of support is the expressed willingness to teach undergraduate courses. In recent years, about half of the faculty has been involved in teaching at the undergraduate level. Once the revised curriculum is implemented, roughly 85% have volunteered to teach undergraduate courses. (*h*) While members of the department have established contact with employers and former students in the past on an individual basis, previous efforts by the department were not coordinated. The recent experience has resulted in a heightened awareness of the important contributions that such contacts can make in a variety of ways. Strengthening of these contacts will be essential to efforts to maintain conversancy with changing needs in the market place and thus in departmental programs. (*i*) To successfully undertake a comprehensive curriculum review, the full support of appropriate university administrators is essential. Without this support, any such effort is almost surely destined to fail.

In the final analysis, the major faculty concern should be how well the educational program is equipping graduates for on-the-job performance and for assuring a personally satisfying and productive role in society. As higher education moves into a period of greater accountability, the type of person trained and his or her social and economic utility will be an important factor in the evaluation of our discipline. Thus, performance of graduates is a critical issue. Continued inquiry is needed into the success of programs in preparing students for the type of work they are expected to carry out and in equipping them with the necessary skills to advance within the system.

This department has concluded that a competency-based approach to curriculum development has much to offer. Such an approach is oriented towards those things that students should be able "to do" upon graduation rather than what they should "understand." Although much remains to be done, hopefully the steps taken in developing the Kentucky curriculum will help move our students' educational process in that direction.

Undergraduate Programs in Agricultural Economics: Some Observations

Robert L. Beck, A. Frank Bordeaux, Jr., Joe T. Davis, Russell H. Brannon, and Loys L. Mather

In recent years, increased attention has been focused on undergraduate education in agricultural economics. The profession's interest in undergraduate education has been demonstrated through sponsoring workshops, the Distinguished Undergraduate Teacher Awards, and, more recently, program emphasis at the annual meetings. Periodic evaluation of courses and programs at the department level in many institutions suggests a continuing concern for quality undergraduate education.

As part of a comprehensive review of undergraduate agricultural economics programs at the University of Kentucky, a mail survey was conducted to obtain information relative to the current status and anticipated changes in programs in the United States and Canada.[1] Questionnaires were mailed to departments at land grant institutions in the United States and Canada in early 1975. Data obtained from forty-six departments are presented in this note. While the data requested touched on many facets of the undergraduate program, this note focuses primarily on the current size of agricultural economics programs, departmental characteristics and faculty involvement, and potential growth areas. As such the note offers some parallels to the Storey and Christensen survey of graduate programs previously reported in this *Journal* and elaborates on aspects of undergraduate programs discussed by Davis et al.

Undergraduate Enrollment

During the period under study (1970–75), enrollment in agricultural economics programs increased. For all regions in the United States and Canada, average departmental enrollment increased from 97 to 118 or 22% (table 1). The highest rate of increase (38%) occurred in the southern region. Although the largest departmental enrollments are still found in the North Central region, very little growth (7%) occurred during the study period.

As a profession we might view a 22% increase with a great deal of satisfaction. But, how have we fared relative to other disciplines? Their increases have largely paralleled increased enrollment in colleges of agriculture in the United States, which increased 39% from 1971–72 to 1974–75, while the average enrollment in agricultural economics increased only 20% during this period. While the relative rates of enrollments may be reason for some concern, it should be noted that this applies only to declared departmental majors. Agricultural economics departments may be performing a greater service role, and thus student contact hours may be increasing at a greater rate than enrollment.

With a declining farm population and increasing enrollment in colleges of agriculture, an increasing proportion of majors with nonfarm backgrounds is expected. Fifty-four percent of the departments indicated that more than half of their students came from farms. In the Northeast, all departments indicated that less than 50% of students had farm backgrounds, compared with the South and North Central, where 60% and 72% of the departments, respectively, reported that more than 50% of undergraduate majors come from farms.

The high percentage of students currently coming from nonfarm backgrounds introduces a new dimension into planning and implementation of undergraduate programs. Must we compensate by increasing requirements in applied biological science areas, particularly agronomy and animal science? Or, should we consider the employment opportunities for agricultural economics majors to be in sales, finance, management, etc., and thus emphasize accounting, business management, communication, etc.? Perhaps a flexible program that permits students to complete necessary training as agricultural economists but that also provides coursework in technical agriculture may substantially strengthen students' employment opportunities.

Student Advising

There is a general presumption that colleges of agriculture do a "better" job of advising students than do most other colleges. The survey data suggest that the student-faculty ratio is in most instances

Robert L. Beck, A. Frank Bordeaux, Jr., and Loys L. Mather are associate professors, Joe T. Davis is an assistant professor, and Russell H. Brannon is a professor of agricultural economics, University of Kentucky.

[1] Financial support for this review was furnished by the Southern Region Education Board. Detailed information on the survey and results is available from the authors.

Table 1. Average Enrollment in Agricultural Economics Departments by Region

Years	Northeast	South	North Central	West	Canada	All Regions
1970–71	105	73	175	74	24	97
1971–72	110	75	167	78	22	98
1972–73	116	85	157	73	34	99
1973–74	118	89	164	75	44	104
1974–75	130	101	188	86	48	118
Percentage increase	24	38	7	16	100	22

considerably lower in colleges of agriculture than in colleges such as arts and sciences. The apparent difference of orientation in colleges of agriculture towards students as individuals may be a function of this lower student-faculty ratio. If enrollment in colleges of agriculture continues to grow in the face of relatively lean budgets, some adjustments may be necessary in order to maintain the "outstanding" advising reputation.

From the survey it is apparent that approaches to carrying out the advising function vary from assigning a few faculty members to do all of the advising to spreading it among all faculty members. One-third of the respondents indicated that all of the advising was done by one to five advisors with advising loads ranging from two to fifty students and an average of fifteen students per faculty member. Only 20% of the departments indicated that some system of evaluating undergraduate advising was used. Thirty percent indicated that all faculty members were involved in advising students. When asked to reply to the question, "what is the average advising load for faculty members involved in undergraduate advising?", over one-half (63%) indicated nineteen or fewer advisees per advisor.

Program Options and Growth Areas

While economics may be a science of scarcity, no paucity of program options offered by agricultural economics departments was found. To the contrary, identifiable options indicate a range from the traditional farm management and marketing to very specialized programs such as veterinary business management. Although a wide variety of options was reported, a tendency to stay with the more traditional ones is evidenced by thirty-six departments offering a curriculum in agribusiness, twenty-five in general agricultural economics, eighteen in farm and ranch management, and seventeen in resource economics. This apparently reflects a tendency to hold on to traditional programs while expanding into new areas of emphasis. Unfortunately, data were not available to evaluate student demands for the specialized options.

In addition to current program options, respondents were asked to identify program options or anticipated areas of growth during the next five to ten years. The choices provided and responses received are in table 2. Not too surprising is the fact that almost two-thirds of the respondents (62%) identified agribusiness management as the program likely to experience the greatest growth in the near future (five to ten years). There was no way to determine the extent to which this response was influenced by the phenomenal growth in the program during the last decade. Suffice it to say that perhaps we have not exhausted the potential for expansion or growth in the area. We must continue to be "alert to the opportunities for developing new markets for our services both traditional and new . . ." (Nicholls, p. 970), lest we become a declining industry. This admonition continues to be timely and appropriate.

Preparing students for a wide variety of job opportunities requires breadth in a program option as

Table 2. Areas of Anticipated Growth in Undergraduate Enrollment in Agricultural Economics in the Next Decade

Areas of Undergraduate Instruction	Percentage of Responding Institutions Specifying Each Category			
	Greatest Growth Area	Second	Third	Fourth
Agribusiness management	62	19	13	4
Farm management/production economics	16	44	18	18
Natural resource economics	11	14	53	14
Rural development	7	17	13	50
Other	4	6	3	14
Total	100	100	100	100

well as the number of options offered. The function of any option is to provide guidance to the student in planning. Thus, there is need for innovative thinking on the part of faculty. The cost of offering additional options may be very minimal to the department. Benefits to the student may be great. Thus, benefit-cost may become a relevant criterion on which to base the decision of number and types of curricula to offer.

Summary

In summary, the study reveals that, although enrollments in agricultural economics programs are continuing to grow, the increase is occurring at a relatively slower rate than at the college level. This increased enrollment, plus the changed background of students coming into agricultural economics programs, will most likely present new challenges for both curricula development and departmental advising programs. While some departments are moving toward some rather specialized program options, the traditional options are still viewed as potential program growth areas.

An Economic Analysis of a Regionalized Rural Solid Waste Management System: Comment

Wesley N. Musser and Fred C. White

In a recent article, Hardy and Grissom present an analytical procedure for planning rural solid waste disposal systems. The planning model simultaneously considers both location of landfills and the design of collection routes in the efficient organization of a regional solid waste disposal system. Because this problem is beyond the capacity of existing optimal solution algorithms, a stepwise heuristic procedure was developed. The authors can be commended for attempting to develop heuristic methods to analyze complex economic problems of empirical relevance. However, the authors fail to consider if the procedures yield empirical results that are reasonable in comparison with existing economic theory and past empirical analysis. The purpose of this comment is to propose some evaluation standards for Hardy and Grissom's methodology and to compare their empirical results with these standards.

The efficient organization of a solid waste disposal system is a special case of the general economic problem of the efficient location of processing plants that simultaneously considers processing costs and costs of assembly of raw materials from spatially dispersed production areas. The economic relationships involved in this problem are well established in the agricultural economics literature (Bressler and King, Stollsteimer). With economies of scale in processing, a decrease in number of plants decreases processing costs. A compensating increase in assembly costs results from decreasing plant numbers, since the total distance traveled between production and processing sites increases. The optimum number of plants involves a trade-off between these two cost relationships. While these concepts were developed for agricultural processing situations, they can be reinterpreted to encompass the problems of regional provision of rural public services. Holland and Baritelle conceptualize school consolidation problems in a similar framework and find that the same relationships hold. In an earlier study of solid waste disposal, Schreiner, Muncrief, and Davis affirm the applicability of this theoretical framework to solid waste disposal when they state that "combining several communities and service areas for purposes of utilizing common disposal sites and thus reducing unit costs of operation must be compared against increased costs of longer transfer distances in the collection and transfer process" (p. 573).

Considering the theoretical and empirical background in the agricultural economics literature, decreasing processing costs and increasing assembly costs with decreasing number of landfills are surely reasonable expectations for a useful heuristic analytical procedure. While these are only hypotheses, it is a reasonable expectation that research results that are at variance with the rich prior support of these hypotheses should receive explanation. In this comment, these hypotheses are used as standards for evaluation of Hardy and Grissom's heuristic procedure.

Hardy and Grissom's results on disposal costs are largely consistent with the hypothesis of increasing returns to scale in landfill operation. The one exception is in the regional system in which decreasing returns to scale are present as the number of landfills decreases from two to one; disposal costs are $233,535 with two landfills and $236,661 with one. While these cost differences are small, the authors do not even note this exception in the text (p. 183). Since only increasing returns to scale have been evidenced by past research on rural solid waste disposal (Schreiner, Muncrief, and Davis; Carley), decreasing returns to scale with the largest plants are an important empirical result. Furthermore, it is reasonable to expect the authors to explain this unique finding. While decreasing returns to scale for large plants are a part of standard economic theory, the theoretical reason for such a cost relationship—limiting managerial ability—is not a priori applicable to this problem. Would a larger plant in one geographical location be more difficult to manage than two smaller plants in different geographical locations?

Their results on collection costs have more serious variance with expectations from theory and earlier empirical work. In all the single-county systems, collection costs decrease as the number of landfills decreases. In the two-county subregional system, collection costs increase and then decrease as the number of landfills decreases. The three- and four-county systems do follow prior expectations. However, the collection costs for the regional system decrease as landfills decrease from six to two and then increase as landfills decrease from two to one. These results, which for the most part are inconsistent with theory and past research, are noted in the text but not fully explained or synthesized. The au-

thors do attempt to use population density to explain the differences in response of costs to decreasing landfills in the subregional multicounty systems (pp. 182–83). However, they do not explicitly consider the general concept that distance traveled increases as the number of landfills decreases. While the added cost of this increase in distance would be less in a densely populated area, some increase in collection costs would be expected for all systems.

The serious unexplained problems with the results on collection cost indicate that economists could have very little confidence in Hardy and Grissom's heuristic procedures. Inspection of the results in table 2 further reduces the confidence in the methodology. In several cases, combinations of subregional landfills that would serve the entire region have lower total operating costs than the regional landfill systems that Hardy and Grissom describe as least cost. An example of such a combination would be three landfills in the subregional system including Winston, Marian, Franklin, and Colbert counties and two landfills in the Lauderdale County system. This combination would represent a five-landfill regional system and would have operating costs of $310,196 plus $171,800 for a total regional cost of $481,996. This cost is considerably smaller than $552,497, which is the authors' least-cost regional system with five landfills. Other examples of lower cost combinations of subregional landfills than the same number of landfills in the regional solution exist but are not discussed here for the sake of brevity.

In summary, Hardy and Grissom's heuristic procedure does not have much promise. The collection cost relationships are not consistent with expectations based on previous research, and regional results have higher costs than combinations of subregional results in many cases. Even though an optimal procedure is not available, Hardy and Grissom's procedure cannot be expected to be a reliable alternative to independently considering the location of landfills and the design of routes for solid waste collection.

An Economic Analysis of a Regionalized Rural Solid Waste Management System: Reply

William E. Hardy, Jr., and Curtis L. Grissom

In their comment, White and Musser make some rather strong accusations concerning the reliability of the heuristic procedures used in our article. We agree that inconsistencies exist in the data that could lead to erroneous conclusions. These inconsistencies are not caused by either the location or routing algorithm but by errors and omissions in the budgets that were developed for the analysis.

The questions raised in the comment may be grouped into two general categories: those relating to whether or not the results are consistent with economic theory and those questioning the cost relationships between subregional combinations of landfills that would serve the entire region and the total regional systems. Musser and White are correct in assuming that if regionalization is good then a regional system with a given number of landfills should have a lower cost than a subregional combination.

The data presented in table 1 give revised cost information for specified service areas and numbers of landfill operations. Corrections in the budget

data answer most of the theoretical questions in the comment. A divergence from what would be expected still exists in the collection cost data for the four county combinations (Winston, Marion, Franklin, and Colbert) and in the total regional systems. In each case, the cost of collection is reduced as the second landfill is added but increases thereafter. With each of these operations serving a very large geographic area, the addition of a second collection system permits a substantial decrease in vehicle travel. The savings generated by these reductions exceed the costs of additional management and back-up equipment to support the second system. For any more than two landfills, however, the travel savings are not great enough to overcome the added administrative and support costs.

The data given in table 2 represent the total annual operating costs for various systems that serve the entire five-county region. These cost values indicate (as in Hardy and Grissom, p. 185) that definite savings can be realized through cooperative efforts in providing a solid waste management system for the area under study. The least-cost system is to have two regional sanitary landfills. Numerous other systems, some of which are presented in table 2, give a lower annual operating cost than the system where each county operates independently. This system with an annual operating cost of $566,999 is over 33% more expensive than the least-cost regional system.

We feel that the unreliability contention of Musser and White concerning our simultaneous use of heuristic location and routing algorithms is completely unfounded. The weakness in our procedure is in the development of consistent and accurate budgets for the many county and multicounty combination solid waste management systems that were considered. As better information becomes available from equipment suppliers on the sizes and types of equipment needed for specific sizes of landfill operations, then the budgeting process will become a great deal more precise.

The Von Thuenen Paradigm, the Industrial-Urban Hypothesis, and the Spatial Structure of Agriculture: Comment

Alan P. Jones, William J. McGuire, and Ann D. Witte

In a recent article in this *Journal,* Katzman offers empirical tests of two models of the intensity of agricultural production in the Goiás region of Brazil.[1] We contend that many of the empirical tests applied to the first of these models, which Katzman describes as a mathematical version of a Von Thuenen type intensity model, are not specified or interpreted appropriately. In particular, given the data at hand, the choice of the dependent variable in many of the regression equations confuses the effects of changes in production technology for a given crop (an intensity model) with the effects of changes in the crops produced (a crop model). Accordingly, many of the results in fact do not refer to an intensity model of agricultural production and therefore cannot be employed to infer an appropriate form for agricultural production functions in Goiás.

Katzman assumes a Cobb-Douglas production function in the theoretical development of his intensity model. Certain a priori expectations about distance-intensity relationships are implied by this functional form, and these are presented in Katzman's table 2. It is clear that these expected distance-intensity relationships are valid only in the production of a single crop. Thus, appropriate empirical tests of these a priori expectations can only be undertaken if crop-specific information is utilized. At several points in the empirical investigations this requirement is not met.

Our reservations are primarily with Katzman's tables 6 and 7. Table 6 reports estimates of factor proportions. In the ten regression specifications presented, it is not clear that any pertain to the single-crop situation. If we assume that the keeping of animal stock is exclusive to cattle raising and that the use of fertilizer is exclusive to rice production, it is possible to interpret equations (3) and (8), and equations (4) and (9), as referring to the single crops meat and rice, respectively. It is not possible, however, to readily identify the dependent variable in any of the other six equations with either activity. Table 6 thus provides at best only insights into capital-land and capital-labor variations with distance in rice and meat production separately. In table 7, equation (5) exhibits like problems with the dependent variable; only equations (1) through (4) may be interpreted as providing adequate representations of output-land and output-labor variations with distance.

Katzman rejects the Cobb-Douglas form of the production function because of certain inconsistencies between his a priori expectations and his empirical results. The stricter interpretation of the regression equations presented above leads us to believe that this rejection is premature. Katzman's inconsistencies 1, 5, and 6 are predicated upon equations (10) and (5) of table 5 and equation (5) of table 7. As noted, we believe all of these equations to be inappropriately specified as they appear to mix information for both meat and rice production. Inconsistency 3, while based upon a correctly specified estimation, clearly refers only to meat production. Inconsistency 4 likewise applies only to rice production. Neither result can be generalized to all agriculture. In addition, the comparison of the price-distance and output per hectare-distance coefficients for 1960, on which inconsistency 4 is based, is open to question. If the true specification is that used for the 1940 estimates, the form of which follows from Katzman's theoretical model, then the equation estimated for 1960 is misspecified because of the exclusion of two explanatory variables. The exclusion of these variables will result in a biased estimate of the coefficient on the distance variable in the 1960 regression (Kmenta, pp. 392–99). The use of this coefficient in drawing inferences is thus suspect, not for data reasons but because of its specification bias.

Finally, we can confirm Katzman's inconsistency 2 for only one of the four rental and price gradient comparisons permitted by the information presented in Katzman's table 4. Due to data limitations, Katzman is only able to estimate both price and rental gradients for a single year, 1970. Thus, appropriate comparisons between these gradients are only possible for this year, and these comparisons are tests of an intensity model only if made on a crop-specific basis. In comparing the price gradient for rice with the rental gradients of arable land and forest land, which Katzman refers to as potential farmland, and the price gradient for

Alan P. Jones and William J. McGuire are graduate students and Ann D. Witte is an assistant professor in the Department of Economics, University of North Carolina, Chapel Hill.

[1] Additional empirical tests are offered in a comment by Garlow. The reservations expressed here extend to certain portions of Garlow's presentation and to Katzman's reply to Garlow.

meat with the rental gradients for natural and planted pasture, we find that only in the last comparison can we accept the hypothesis that the coefficients are not statistically different at the 99% confidence level.[2]

The only conclusions that we feel are warranted by Katzman's empirical results are those based solely upon correctly specified equations, i.e., those that refer to one crop only. These conclusions, which appear to hold for both meat and rice production except where noted, are as follows. (*a*) Land value gradients decline faster than crop price gradients except perhaps for the comparison of meat with planted pasture, where the decline may be equal. (*b*) Capital-land and capital-labor ratios vary inversely with distance. (*c*) Output-land and output-labor ratios vary inversely with distance. None of these results calls for rejection of the hypothesis that each agricultural activity may be characterized by a Cobb-Douglas production function. Nor of course do they offer conclusive support for this hypothesis. The whole question, however, would be better addressed by estimating production functions directly, a point made by Garlow.

[*Received December 1976; revision accepted May 1977.*]

[2] This is based upon the test $\beta_P - \beta_R = 0$, assuming independence between the parameter estimates. This assumption is not as restrictive as it first appears, since if the covariance between the coefficient estimates is positive, the most likely case, then the only effect is upon the power of the test, which would be increased by including the covariance term in the denominator of the test statistic. Thus, the results we report are probably conservative, being possibly biased toward accepting H_o.

The Von Thuenen Paradigm, the Industrial-Urban Hypothesis, and the Spatial Structure of Agriculture: Reply

Martin T. Katzman

Jones, McGuire, and Witte (J-M-W) present an interesting discussion of the pitfalls of empirically testing the relevance of the Von Thuenen intensity model in the agricultural context. In doing so, they specifically point to some shortcomings of my 1974 and Garlow's papers. In this reply the theoretical criticisms of J-M-W are assayed, and empirical tests are revised along the lines they suggest.

One can easily dispose of the red herring that the neoclassical production relationships presented in my paper do not strictly correspond to Von Thuenen's theoretical presentation. The original paper was less an exercise in intellectual history, reinterpreting what Von Thuenen really said, than a reintroduction of the Von Thuenen paradigm into the analysis of rural spatial structure. A paradigm is simply a broad conceptual scheme that identifies a set of categories, suggests operational measures of these categories, and posits functional relationships that are useful in explanation and prediction and suggestive of further research. Some of the confusion stems from the fact that my paper really deals with two separable but related subjects. The first part shows that a neoclassical version of a Von Thuenen paradigm, which simply postulates that the pattern of urban or rural spatial structure is dominated by the factor of distance from a market center, generates many results similar to the industrial-urban hypothesis, which hitherto was considered a paradigm *sui generis*. The second part of the paper attempts to test whether the Von Thuenen or industrial-urban models could accurately explain the spatial structure of a frontier region in a developing country.

While Von Thuenen obviously predates formal neoclassical analysis and *a fortiori* its mathematical elaborations, there is ample evidence in his examples that as both practicing farmer and scholar he was sensitive to continuous changes in factor proportions (e.g., applications of manure) as a function of distance from the market. He also focused upon discrete changes in production technique, as J-M-W rightly indicate. Which mechanism of intensification applies in a particular situation is an empirical matter. Indeed, our evidence for the period 1940–60 suggests very little land-labor substitution in response to rent gradients. In locations closer to the market, larger amounts of potential farmland were exploited for both intensive (rice) and extensive (cattle) activities and less land was unused. The mechanism of intensification during this period was simply the incorporation of unused land under traditional techniques. Garlow's evidence for 1970, however, persuaded me that by 1970 Goiás agriculture has become more neoclassical (Katzman 1975b). Whether intensification occurs by continuous factor substitution or by discrete changes in technique is less interesting in this context than the fact that distance from the market is the major influence on intensity of land use.

The second objection is that Garlow and myself "combine elements of both the crop and intensity models," and that we do not appear to "clearly recognize the intermingling of the crop and intensity models." This is not quite the case. Goiás was recognized as "the outermost Von Thuenen ring in South-Central Brazil, specializing in the supply of nonperishables, live cattle and rice" (1974, p. 690). This point has been elaborated elsewhere (Katzman 1975a). J-M-W, moreover, seem to misunderstand the crop model, which predicts the existence of rings of monoculture or of distinct crop mixes surrounding a market center. Within any structurally homogeneous ring, several commercial crops may coexist according to the intensity model because of the possibility for sequential cropping, the necessity for rotation when little fertilizer is used, variations in the suitability of land for particular crops, and the need for portfolio diversification. Our implicit assumptions in analyzing Goiás are that until the 1970s rice was essentially the only commercial crop, while cattle was consigned to residual, exhausted land and that within Goiás the percentages of farmland devoted to rice and cattle vary continuously with distance from the market, there being no abrupt shifts to other crop systems.

Since no data are available to permit an allocation of labor or capital between rice and cattle, the original table 6 does not present unambiguous factor proportions. The potential for confusing changing factor proportions and changing mix of rice and cattle then exist as J-M-W intimate. This is not so disastrous, since the amount of both arable land and pasture vary inversely with distance, and the equations in this table can be interpreted as reduced

forms. These results are intentionally presented in a form compatible with results from tests of the industrial-urban hypothesis, which does not distinguish between crop and intensity effects either.

It was also assumed that almost all labor and nonanimal capital were allocated to the rice crop. This was justified by knowledge of conditions in Goiás and by the finding that is reproduced here (table 1) that the "labor-land ratio . . . is directly related to the share in pasture" (1974, p. 694). These underlying assumptions are made explicit, and the regressions are revised here by allocating all inputs between arable and pasture.

The revised results for capital inputs are similar to the original (table 2). The distance coefficients for the three capital-cropland ratios are generally lower than the original capital-farmland coefficients. The same result holds for animal capital/pasture vis-à-vis animal capital/farmland. This is because the denominators (cropland and pasture) themselves are responsive to distance. In other words, estimated neoclassical factor substitution is weakened when land area is properly measured.

Inconsistency 1 in the original paper—the invariance of the man-farmland ratio with distance from the market—is not eliminated but rather magnified in the revised regression of man-cropland ratios. The resolution of this inconsistency requires an exact allocation of manpower between farming and grazing that cannot be performed with the available data.

In a third set of points, J-M-W discuss the inconsistencies found between the neoclassical model and the empirical results. They quite rightly identify an egregious error in inconsistency 2: the rental

[a] Distance in 10 km. units.
[b] Standard error in parentheses (48 d.f.).

gradient does not have the same slope as the price gradient as stated originally; the land value gradient declines considerably faster than the crop price gradients in 1950–70. From a neoclassical production function with a land coefficient of 0.7, one expects the rental gradient (gk/a from equation (16)) to be about 1.5 times greater than the price gradient ($-gk$). In fact, the land value gradient is three to five times greater than the price gradient, which is explicable only by a substantial interest rate gradient (1974, p. 692, fn. 8). An inconsistency thus remains to be explained.

Inconsistencies 3 and 4—the gradients of animal capital/farmland and crop output/farmland were equivalent to the respective price gradients in 1960—are not as troublesome as J-M-W make them to be. In the corrected regressions, animal capital/pasture is significantly less steep than the beef price gradient, an inconsistency that cannot be easily explained.

Inconsistency 5—the value of land inputs per man varies inversely with distance—is not problematic either. In the original table 4, one finds that the gradient for improved farmland and improved pasture are similar and that the gradient for unimproved farmland (forest) and natural pasture are similar. The changing mix of land use between rice and cattle should not affect the observed ratio of land value per man.

Contrary to the third conclusion of J-M-W, the inverse relationship between output per man and distance from the market is inconsistent with a Cobb-Douglas function in which wages are invariant or decreasing with distance. Second, given their objections to our measures of output/farmland, there is no way to determine whether the gradient of rice output/cropland or cattle output/pasture is steeper than the corresponding price gradients.

While there is no disputing the second conclusion of J-M-W that capital-land and capital-labor ratios vary inversely with distance, this does not temper my earlier conclusion of limited land-labor factor substitutability.

It is clear from my original paper, the comments of Garlow and J-M-W, and this reply that the available data from Goiás are as underdeveloped as its agriculture and that refined discriminations between neoclassical and fixed-proportions production models cannot be drawn. This is really a side issue, since the point of the original article was not to estimate production functions. The two original arguments stand: that many of the deductions of the industrial-urban hypothesis can be arrived at through a neoclassical Von Thuenen model and that the spatial structure of the Goiás rice and cattle economy is largely determined by distance from the market and modified by access to local centers of industrial urbanism.

Optimum Resource Allocation in U.S. Agriculture: Comment

C. Richard Shumway, Bruce R. Beattie, and Hovav Talpaz

Over ten years ago, Tyner and Tweeten presented two imaginative and pervasive articles in this *Journal*. The first notes past statistical difficulties in obtaining reliable parameter estimates for aggregate U.S. farm production functions with several input variables (Tyner and Tweeten 1965). In proposing an alternative approach, Tyner and Tweeten note that factor elasticities must equal their respective factor shares, given the assumptions of perfectly competitive product and factor markets and market equilibrium.[1] They also assume that entrepreneurs attempt to organize production such that actual factor shares adjust toward an equilibrium in a geometric distributed lag fashion. Since the parameters of a Cobb-Douglas production function are factor elasticities, they propose computing elasticities from historical data on factor shares, avoiding the problem of multicollinearity. Estimates of factor elasticities for nine input categories were developed by decade for 1912–61 using data from published and unpublished ERS sources.

The second article (1966) built upon the first by incorporating these elasticity estimates into a Cobb-Douglas production function for each decade. This was accomplished by regressing farm output (in constant dollars) on a composite input variable (in constant dollars) defined as the product of each factor raised to its exogenously estimated factor elasticity. A linear model with a zero intercept was used to estimate the constant term for each decade. Having in this manner synthesized a production function, minimum-cost input levels, equilibrium output and input levels, factor-substitution relationships, and factor-demand and product-supply elasticities were derived, and comparisons were made with the actual situation in each decade. Based on these comparisons, Tyner and Tweeten conclude (*a*) adjustment to a least-cost input combination to produce the actual average 1952–61 output would have reduced the input dollar volume by $1.9 billion, or 5.6%; (*b*) adjustment of farm resources to an equilibrium level with all variable resources earning an opportunity-cost return would have entailed a reduction of $4.2 billion ($1947–49), or 12.5% of the actual input volume in the 1952–61 period; (*c*) labor was in excess supply by two-fifths in the 1952–61 period;[2] and (*d*) capital inputs supplied by the nonfarm sector were not generally used in excess by farmers (1966, pp. 629–30). In summary, their results "serve as a guideline for public policy by indicating the magnitude of resource adjustment needed to achieve economic equilibrium, and the economic cost of maintaining nonoptimal resource levels and combinations in agriculture" (1966, p. 630).

These were, and remain, important conclusions resulting from an ambitious and innovative study—conclusions that added empirical credence to the popular notion of substantially excess labor resources in agriculture. The conceptual, methodological, and policy significance of this work was emphasized by the inclusion of the second article in the *A.E.A. Readings in Agricultural Economics*. Impressed with the ingenuity of the Tyner and Tweeten approach and its implications for agricultural policy analysis, we, like others, have used their articles in graduate teaching. In so doing, we have discovered an error in the Tyner and Tweeten analysis that substantially affects the policy conclusions presented in the second article. It is the purpose of this comment to present revised results for an article that remains an important source of economic hypotheses and policy prescriptions even a decade later.

Alternate Model Specifications

The error in Tyner and Tweeten's analysis—an error the consequence of which led to a substantial overstatement of resource misallocation in U.S. agriculture—is addressed by considering the first-order conditions for profit maximization under two alternative specifications of the production function

C. Richard Shumway, Bruce R. Beattie, and Hovav Talpaz are associate professors of agricultural economics, Texas A&M University.

Texas Agricultural Experiment Station Technical Article No. 12896. The authors are appreciative of the many helpful comments and criticisms of colleagues John Penson and Bob Taylor. They are indebted to Fred Tyner for his assistance in providing and interpreting the data upon which this paper and his earlier work are based.

[1] Each factor elasticity, $E_i = MPP_i/APP_i$, equals its share of total value product expressed as the ratio of expenditure on the input ($r_i x_i$) to total value product (py). Given perfect competition and equilibrium, $MPP_i = r_i/p$, implying that $MPP_i x_i/y = r_i x_i/py$ or $E_i = r_i x_i/py$, where MPP_i, APP_i, and r_i are the marginal productivity, average productivity, and price of the ith factor, respectively; y denotes product and p the product price.

[2] There is a discrepancy in Tyner and Tweeten (1966) as to the extent of excess labor supply in the 1952–61 decade. In the text a two-fifths excess supply is mentioned, but in table 5 a 68% excess is implied.

(i.e., in physical versus constant dollar units) and two objective functions (i.e., in nominal versus constant dollar prices). (We are indebted to the *Journal* editors for suggesting this expositional approach.)

Starting with the conventional case in which output (y_t) and inputs (x_{it}) in time period t are measured in physical units, the production function is given by

$$(1) \qquad y_t = f_t(x_{1t}, \ldots, x_{nt}).$$

With p_t and r_{it} being product and factor i price, respectively, and assuming zero price flexibilities, profit π_t in any time period t is expressed in actual prices prevailing in that period:

$$(2) \qquad \pi_t = p_t f_t(x_{1t}, \ldots, x_{nt}) - \sum_i r_{it}x_{it},$$

and first-order conditions for maximizing nominal profits are

$$(3) \qquad \partial\pi_t/\partial x_{it} = 0 \Rightarrow \partial y_t/\partial x_{it} = r_{it}/p_t.$$

An equivalent approach is needed when output and inputs are measured as revenue and expenditures in base period ($t = b$) prices as was Tyner and Tweeten's case for all inputs except labor (which was measured in man-hours). This production function is given by

$$(4) \qquad p_b y_t = f_t(r_{1b}x_{1t}, \ldots, r_{nb}x_{nt}).$$

Profit in any year t is

$$(5) \qquad \pi_t = (p_t/p_b)f_t(r_{1b}x_{1t}, \ldots, r_{nb}x_{nt}) - \sum_i (r_{it}/r_{ib})r_{ib}x_{it},$$

where the appropriate product and factor prices are actual prices deflated by base period prices, i.e., p_t/p_b and r_{it}/r_{ib}, respectively. These are the nominal price equivalents of a product or factor measured in constant dollars. First-order conditions for maximizing profits are

$$(6) \qquad \partial\pi_t/\partial r_{ib}x_{it} = 0 \Rightarrow \partial p_b y_t/\partial r_{ib}x_{it} = r_{it}p_b/r_{ib}p_t.$$

With the base year prices (p_b and r_{ib}) specified as unity, equation (6) is equivalent to equation (3). The only difference between equations (3) and (6) is that the former is measured in physical output and input units and nominal prices per physical unit and the latter is in constant dollar output and input units and nominal prices per constant dollar unit. For any time period t, producers, if rational and all the usual assumptions of static analysis are satisfied, allocate resources according to the conditions specified in equation (3) or (6). Either of these approaches is appropriate and yields equivalent results as resource allocation decisions are (and should be) based on existing (or anticipated) prices in that period.

Rather than following the approach in equations (5) and (6), Tyner and Tweeten implicitly assume a different specification of the objective function. They express product and input prices as well as input and output levels in constant (base period) prices; that is, given the production function expressed in constant dollars (equation (4)), the following is maximized:

$$(7) \qquad \pi_t = (p_b/p_b)f_t(r_{1b}x_{1t}, \ldots, r_{nb}x_{nt}) - \sum_i (r_{ib}/r_{ib})r_{ib}x_{it}.$$

First-order conditions would then be

$$(8) \qquad \partial\pi_t/\partial r_{ib}x_{it} = 0 \Rightarrow \partial p_b y_t/\partial r_{ib}x_{it} = r_{ib}p_b/r_{ib}p_b = 1.$$

Maximizing profit so expressed results in the same first-order conditions for every period and fails to take account of the prices actually faced by producers in any time period except the base period. Yet it is this function that Tyner and Tweeten apparently sought to maximize.

Except for labor, their input and output data series are measured in 1947–49 constant dollars. Consequently, the appropriate first-order conditions are those of equation (6). Yet, it appears that they use base period prices to derive least-cost input combinations, etc., in every decade despite the fact that those prices are relevant only in the 1947–49 base period. Tyner and Tweeten acknowledge assuming prices of \$1 for output and all inputs except labor (1966, p. 617). Further, their results can be duplicated when prices of \$1 are used in all decades but not when nominal prices are used.

The use of constant prices rather than nominal prices has a major empirical consequence as is demonstrated in this note by comparing results using prices actually prevailing in each decade with the results of the \$1 prices used by Tyner and Tweeten. Nominal price equivalents (hereafter referred to simply as "nominal prices") (i.e., p_t/p_b and r_{it}/r_{ib}) can be computed directly from their two data series—a USDA nine-input data series of $p_b y_t$ and $r_{ib}x_{it}$, measured in 1947–49 constant dollars, and a comparable series developed by Tyner and Tweeten in current dollars, i.e., $p_t y_t$ and $r_{it}x_{it}$. Prices (p_t/p_b and r_{it}/r_{ib}) are given by dividing the respective current dollar series by the constant dollar series. These prices are reported in table 1 as decade averages and are substantially different from the 1:1 ratios assumed by Tyner and Tweeten.

Implications

We compare several results—minimum-cost input combinations, supply function, and equilibrium output and input levels—by using Tyner and Tweeten's aggregate U.S. production functions and correcting the output and input prices used.[3] Our

[3] The parameters of the aggregate U.S. agricultural production function estimated by Tyner and Tweeten for each decade, 1912–61, are accepted for purposes of this exposition without challenge. Our efforts to reestimate those parameters using an alternative distributed lag hypothesis result in only minor differences (Shumway, Talpaz, and Beattie).

[a] T-T is the minimum-cost level reported by Tyner and Tweeten (1966, table 2) with labor priced at 85% of the nonfarm rate and all other inputs at $1; T-T* is the minimum-cost level using appropriate nominal input prices; A is the actual average for the period as reported by Tyner and Tweeten (1966, table 2).

[b] Except for labor, which is in million man-hours.

[c] Insufficient data to compute.

[d] Tyner and Tweeten report this figure as 1,211.0. Other differences between their reported averages and the decade averages of the Tyner data (appendix A, tables 2 and 3) are minor.

results are contrasted with those of Tyner and Tweeten, where their derivations assumed labor priced at 85% of the nonfarm rate.

Minimum-Cost Input Combinations

Minimum-cost input levels and actual expenditure levels (A) in constant dollars are presented by decade in table 2. Results using nominal prices (T-T*), as compared with the original Tyner and Tweeten results (T-T), were closer to actual expenditures in thirty-six of the forty-three cases.

Minimum-cost labor and land inputs were much closer to actual than implied by Tyner and Tweeten. Labor was in equilibrium in the 1932–41 decade and was in excess supply by only 6.2% in 1942–51 and 0.8% in 1952–61. Actual real estate level was also closer to the minimum-cost level: 5.9% in 1912–21, 2.0% in 1922–31, 7.5% in 1932–41, 7.7% in 1942–51, and −4.2% in 1952–61. In no period was labor in substantially excess supply nor real estate greatly below the minimum-cost level. These findings are in direct contrast to Tyner and Tweeten's conclusion that labor was greatly in excess supply and real estate in short supply in all decades.

With all inputs priced at $1 per unit, except labor, which they priced at 85% of the nonfarm rate, Tyner and Tweeten's estimates imply that input costs could have been lowered by 18.7% in the 1932–41 decade, 9.1% in the 1942–51 decade, and 10.5% in the final decade. However, with inputs correctly priced, the opportunity for reducing production costs is substantially less. Input costs could have been lowered by only 1.5% in the 1932–41 and 1942–51 decades and 0.9% in the 1952–61 decade. The large misallocation of resources suggested appears to have been illusory.

Because real estate enters their original derivations at levels higher than they believed reasonable (1966, p. 618), Tyner and Tweeten recalculated the minimum-cost combination of other inputs holding real estate fixed at actual average decade levels. Holding real estate fixed changed the minimum-cost combination of other inputs in their original calculations substantially and increased total cost of inputs by 3.9% in the 1932–41 decade, 1.3% in the next, and 5.4% in the final decade. Using nominal prices, the relative impact on input combinations and total cost was considerably less. The differences between assuming all factors variable and real estate fixed are minor when the appropriate nominal prices are used.

Equilibrium Output and Input Combinations

The aggregate U.S. agricultural supply and demand situation for the 1952–61 decade is depicted in figure 1. Demand curve D_{T-T} is that reported by Tyner and Tweeten (1966, p. 623). Demand curve D_{T-T^*} is the T-T demand curve using the nominal 1952–61 product price—0.967 (i.e., $\bar{P}^*$). In deriving their demand curve (D_{T-T}), Tyner and Tweeten assume an elasticity of −0.25 and pass a straight line through the output point ($\bar{Y}$) at the assumed output price ($\bar{P}$, i.e., 0.904), in figure 1. This output, $30,933 million ($1947–49), represents their estimate of farm output in the absence of government programs (5% lower than actual farm output—$\bar{Y}$). Our demand curve (D_{T-T^*}) was developed similarly using the nominal output price ($\bar{P}^*$).

The product supply functions presented in figure 1 assume perfectly elastic input supply functions except for real estate, which was presumed fixed. The supply function derived by Tyner and Tweeten assuming labor priced at 85% of the nonfarm wage rate is identified as S_{T-T}. With nominal output and input prices, the supply function is represented by S_{T-T^*}.

Each of these supply functions is supposedly derived based on expansion path conditions. Yet the T-T supply function lies above their estimated point of actual decade production adjusted for the effect of government programs ($\bar{Y}\bar{P}$). Thus, the implication is that producers were actually more efficient than they would have been if they had combined inputs optimally. The real reason that S_{T-T} lies above the point of actual production is that incorrect prices were assumed. Among other differences, the labor price was too high and output and real estate prices were too low. The supply function based on nominal prices (S_{T-T^*}) lies below our estimated point of actual adjusted production ($\bar{Y}$, $\bar{P}^*$) as indeed it must if any misallocation of resources is to be claimed.

As expected, equilibrium output level based on nominal prices ($\bar{Y}_{T-T^*}$) was greater than the adjusted actual output ($\bar{Y}$), but only slightly. Output was 0.6% above adjusted actual as opposed to Tyner and Tweeten's estimate of 2.1% lower. Elasticity of product supply was unaffected by using nominal prices; with real estate fixed, it was 3.41 for both S_{T-T} and S_{T-T^*}.

At the estimated equilibrium output level, Tyner and Tweeten conclude that labor was greatly in excess supply in the 1952–61 decade. Our findings using nominal prices indicate that it was much closer to optimal—only 5.0% in excess. They determine that there was underinvestment in capital items purchased from the nonfarm sector (i.e., all inputs except labor and real estate); our findings indicate overinvestment of about 6%. Their results indicate that machinery was used at less than the optimal level, yet we observed usage more than one-third greater than optimal.

Tyner and Tweeten conclude that adjustment of farm resources to an equilibrium level would have reduced actual input volume by 12.5%. We estimate that adjustment to equilibrium would have reduced expenditures only 4.9%. They further estimate that slightly more than half of this reduced volume of inputs would occur through reducing output level

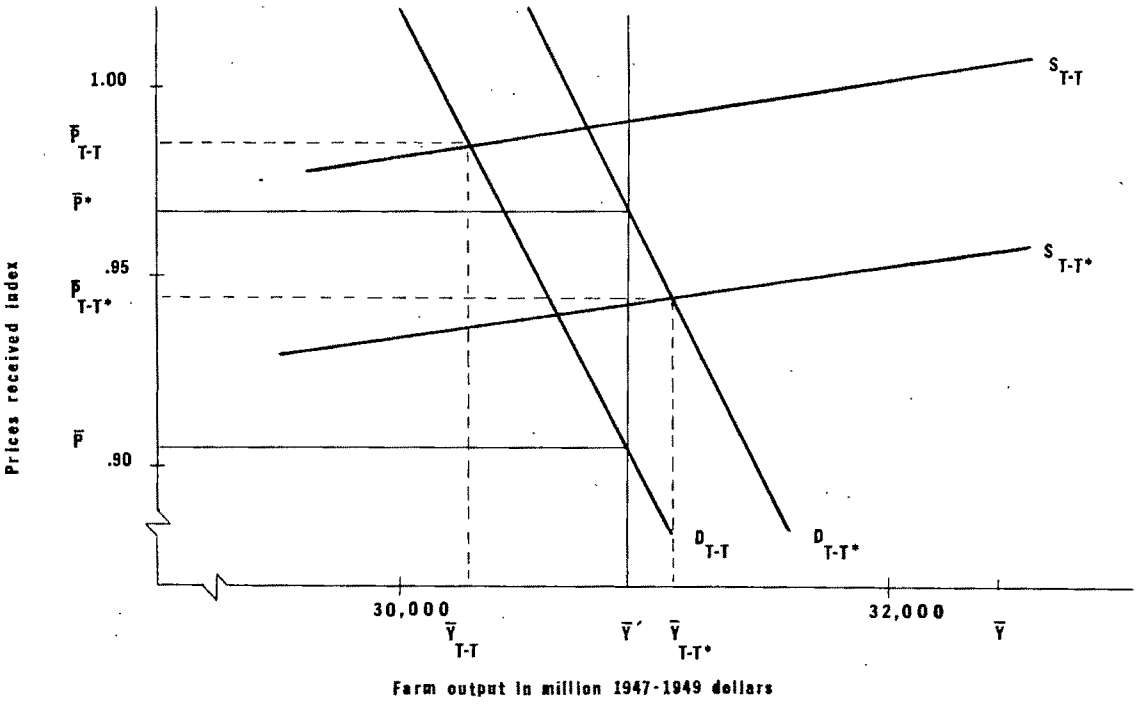

Figure 1. Aggregate farm demand and supply for the 1952–61 period

and the remaining half through using the least-cost input combination. We estimate that less than one-sixth of the reduction could occur through reorganizing the input mix, and the remainder would be due to lowering output from its actual unadjusted level ($\bar{Y}$ in figure 1).

Conclusions

The pioneering research by Tyner and Tweeten, reported in two articles in this *Journal* in the mid-1960s, was and remains imaginative and comprehensive. However, an important error exists in their analysis, viz., inappropriate product and factor prices were used in estimating the extent of nonoptimality in input usage in U.S. agriculture. Consequently, Tyner and Tweeten's conclusions (1966) regarding differences between optimal and actual input usage appear not to be reliable as policy prescriptions. Many of the implications for "desired" change in factor usage were reversed in this study. Of major importance is the apparent large overestimation of excess labor in agriculture.

The following conclusions based on nominal prices are presented in contrast to the four Tyner and Tweeten conclusions presented at the beginning of this paper: (*a*) adjustment to a least-cost input combination to produce the actual average 1952–61 output would have reduced the input dollar volume by $282 million or 0.9% (i.e., less than one-fifth as much reduction as the Tyner and Tweeten estimate); (*b*) adjustment of farm resources to an equilibrium level in the 1952–61 decade, with all variable resources earning an opportunity-cost return, would have entailed a reduction of $1.5 billion or 4.9% of the input volume (i.e., less than two-fifths as much savings as the Tyner and Tweeten estimate); (*c*) labor was in excess supply by only 5% in the 1952–61 period (i.e., only about one-tenth the Tyner and Tweeten estimated oversupply); and (*d*) capital inputs supplied by the nonfarm sector were used in slight excess (6.3%) by farmers in this period, and machinery in particular was used in substantial excess (36%).

While both farm output and input combinations appear to be somewhat out of equilibrium, that disequilibrium in the 1952–61 decade was apparently no more than about two-fifths the magnitude estimated by Tyner and Tweeten (1966). Thus, farmers appear to be producing considerably more efficiently than previously intimated. Further, as an anonymous reviewer pointed out, if adjustment costs were fully endogenized into the adjustment model, it seems reasonable to hypothesize that differences between optimal and actual resource allocation would be negligible.

Optimum Resource Allocation in U.S. Agriculture: Reply

Fred Tyner and Luther Tweeten

Shumway, Beattie, and Talpaz contend that "Tyner and Tweeten's conclusions (1966) regarding differences between optimal and actual input usage appear not to be reliable as policy prescriptions." The authors of the comment have also distributed a publication on the same topic that has the purpose to "critically evaluate the validity of the key assumption that factor shares adjust toward equilibrium in a geometric distributed lag fashion and to determine whether there are significant differences in equilibrium factor shares between decades" (Shumway, Talpaz, and Beattie, p. 3). The publication states three conclusions:

> 1. Tyner and Tweeten's choice of a geometric distributed lag specification for the adjustment model seems adequate for the data and time periods upon which their study was based. 2. Differences in estimated factor elasticities between decades are for the most part nonsignificant. 3. Tyner and Tweeten's conclusions regarding substantial misallocation of resources in U.S. agriculture are unfounded because they were based on an inappropriate set of product and factor prices. Importantly, labor was not nearly so much in excess supply . . . as originally suggested . . . (Shumway, Talpaz, and Beattie, summary).

The main difference between the conclusion in their comment (and the third conclusion in their 1977 publication) and ours results from a simple but highly significant error in their procedure. We examine first the combinations of inputs that would have provided the average output levels during the 1932–61 period at the least cost.[1]

Minimum-Cost Input Levels

The basic point in the argument of Shumway, Beattie, and Talpaz is that an error exists in the input and output prices used. We did state, since input and output levels were expressed in value terms based on 1947–49, that "the prices of these inputs are assumed to be $1" (p. 617, fn. 4). In their comment, they note correctly that the price of the ith input should have been r_{it}/r_{ib}, where t is current dollars and b represents base periods prices. (They acknowledge the *Journal* editors for suggesting this expositional approach.) Shumway, Beattie, and Talpaz state that "Nominal price equivalents . . . can be computed directly from their two data series . . . by dividing the respective current dollar series by the constant dollar series."

This they did, using appendix data from Tyner, presenting the results in their table 1. By these conclusions they recovered, with one vital exception, the respective U.S. Department of Agriculture series on "prices paid for items used in production, 1947–49 = 100." The exception is the labor input nominal price, which they incorrectly calculate as the ratio of a current dollar series to a man-hour series (not a base period value series). The nominal labor prices by decade that they obtain are 0.145 for 1932–41, 0.501 for 1942–51, and 0.758 for 1952–61, whereas the appropriate values are 0.748, 1.042, and 1.230 for the three decades, respectively.[2]

We examine Shumway, Beattie, and Talpaz's assertions by recalculating the least-cost combinations using their "nominal prices." These results, labeled SBT* in our table 1, differ from theirs by negligible amounts attributable to truncation and rounding errors in logarithms.[3] The next step in our analysis is to use all of their input prices except labor (we used the 0.748, 1.042, and 1.230 values) to calculate the minimum-cost input levels. These results, labeled T-T (1977) in table 1, are not substantially different from our results published in this *Journal* in 1966. Actual labor usage exceeded the least-cost levels by 153% in 1932–41, by 66% in 1942–51, and by over 42% in 1952–61. Actual real estate inputs were judged to be below optimum in our original results, and the revised results T-T (1977) agree, indicating that real estate inputs should have been higher by 54%, 24%, and 20% in the three decades, respectively.

The average values (in million 1947–49 dollars) of inputs used during the three decades (pricing labor at 85% of the nonfarm wage rate) were $25,163, $31,599, and $31,887, respectively. In contrast, the calculated least-cost levels shown as T-T (1977)

Fred Tyner is a professor of agricultural economics, Mississippi State University, and Luther Tweeten is Regents professor of agricultural economics, Oklahoma State University.

Journal articles 3229 of the Oklahoma Agricultural Experiment Station and 3596 of the Mississippi Agricultural and Forest Experiment Station.

[1] The 1912–31 period is omitted for brevity and because the original results did not include a "least-cost" quantity of labor. The importance of the labor variable in this exchange will become clear shortly.

[2] The appropriate "prices" are 85% of the average values for the index "price of nonfarm labor, 1947–49 = 100."

[3] Our comparative results, including converting arithmetic data to logarithms, were obtained using the UNIVAC 1108 system, Thomas E. Tramel Computing Center, Mississippi State University.

Table 1. Estimated Minimum-Cost Levels of Inputs Required for Average Actual Output by Decades, 1932–61

Input[a]	Item[b]	1932–41	1942–51	1952–61
Fertilizer and lime	T-T (1966)	626.0	975.0	1,282.0

Average output		20,737.5	27,291.7	32,452.5

[a] Results by Tyner and Tweeten are based on labor priced at 85% of the nonfarm wage rate.
[b] Results are T-T (1966) = original results; A = actual average inputs; SBT = Shumway, Beattie, and Talpaz; SBT* = results obtained by Tyner and Tweeten using SBT prices; T-T (1977) = results using SBT prices except for labor.
[c] This value, miscellaneous current operating expense in 1942–51, was incorrectly reported as 1,211 in the original article.

amounted to only $22,147, $28,932, and $30,042, respectively, indicating the opportunity for reducing production costs by 12.0%, 8.4%, and 5.8%. Thus, the statement by Shumway, Beattie, and Talpaz that the "large misallocation of resources suggested appears to have been illusory" is incorrect.[4] Our results are buttressed by other studies using very different methodologies but showing an

[4] The original estimates T-T (1966) suggest possible cost savings of 14.8%, 8.7%, and 8.7% for the three decades, respectively.

even larger economic disequilibrium. A review of literature concerning this issue provides conclusions from more disaggregated analyses that are consistent with ours (Kaldor and Saupe, Tweeten and Walker).

Equilibrium Output and Resource Levels

Shumway, Beattie, and Talpaz present "nominal output prices" of 0.422, 0.945, and 0.967, respectively, for the three decades 1932–41, 1942–51, and 1952–61 in their table 1. We were unable to find data to reproduce these figures. However, the theoretical basis for their prices was stated as p_t/p_b (i.e., the current year price divided by the base year price). The analogous index—prices received by farmers, 1947–49 = 100—has average values of 0.364, 0.873, and 0.904 for the three decades (USDA).

A disequilibrium in the input mix means that any given output could have been produced at a lower cost, increasing the profitability of that given level of output. Further, the fact that demand for farm products is inelastic means that total revenue could be increased by lowering output. These conclusions strongly suggest that profit increases may well involve a reduction in output and a concomitant adjustment in resource use. Shumway, Beattie, and Talpaz on the other hand attempt to justify their equilibrium output result for 1952–61 by stating "As expected, equilibrium output . . . was greater than the adjusted actual output . . ." and by talking about an undefined "efficiency."

Their assertions regarding the incorrectness of our equilibrium output estimates stem from their use of an incorrect price for labor (as discussed in the previous section). Had they used the correct labor price, they would also have found a disequilibrium in resource use. Our results, showing an optimum output level smaller than the actual 1952–61 output, are compatible with our 1966 results, with the T-T (1977) results of this reply, and with economic logic.

Other Remarks

Shumway, Beattie, and Talpaz state that our original estimates imply that input costs could have been lowered by 18.7%, 9.1%, and 10.5%. The origin of these figures is unclear; our correctly calculated figures are 14.8%, 8.7%, and 8.7%.

They also state in footnote 2 of their comment that a discrepancy exists as to the extent of the excess labor supply in the 1952–61 decade. In 1966, we stated (p. 629) that labor was in excess by two-fifths in 1952–61. Alternatively, in table 5, actual labor was reported to be 168% of equilibrium labor. A minor mathematical calculation indicates that the excess is, in fact, two-fifths of the total labor; that is, $(11{,}782.2 - 7{,}009.7) \div 11{,}782.2 = 0.4051$.

The authors of the comment conclude that the equilibrium output in 1952–61 should have been greater than the actual output, a highly questionable result when one considers that this period was one of recognized surpluses in agricultural output.

The intent of the original article in 1966 was to measure disequilibrium in resource allocation in U.S. agriculture. The conclusions developed at that time were consistent both with economic theory and with observation of actual circumstances within agriculture. As the result of reexamining our analysis, we find those conclusions to be unchanged and the policy implications valid.

Optimum Resource Allocation in U.S. Agriculture: Rejoinder

C. Richard Shumway, Bruce R. Beattie, and Hovav Talpaz

Tyner and Tweeten's (1966) estimates of equilibrium factor shares were indirect estimates of the exponent parameters for Cobb-Douglas production functions. Given these production functions, they addressed the issue of resource missallocation in each of five decades. Subsequently, we solved for optimum input combinations using the decade averages of the same prices (including the labor wage rate) as those implicit in Tyner and Tweeten's factor share data and concluded there was no evidence that the use of any input was greatly out of equilibrium. This result was quite different than that offered by Tyner and Tweeten in their original article and in their reply to our comment.

While they acknowledge in general (for eight of nine input categories) that inappropriate prices were used in their original work, Tyner and Tweeten do not acknowledge any error with regard to the labor price used. The upshot of their reply is that only minor differences in results occur when just the nonlabor prices are corrected, and the implications of their original article for resource misallocation in agriculture still hold. They further suggest that we erred in the labor price used in the analysis reported in our comment. We think not.

Tyner and Tweeten used the *hired farm labor* wage rate to determine current expenditures on all farm labor, which in turn were used in the factor share adjustment model to estimate labor's production elasticity. They then suggest in their reply that "the appropriate 'prices' [for deriving economic implications such as resource misallocation, supply elasticity, etc.] are 85% of the average values for the index 'price of *nonfarm labor*, 1947–49 = 100' " [italics added] (fn. 2). In effect, their procedure means that one set of prices should be used to determine expenditures on the input and another to reflect its cost when calculating optimum input levels, etc. We contend that to use a nonfarm labor price in the derivations is inconsistent with their method for indirectly estimating labor's production elasticity, and this inconsistency is the cause of the large disequilibrium they found.[1]

Perhaps there is justification for arguing that the appropriate shadow price for all farm labor is greater than the nominal price of hired farm labor because of nonpecuniary benefits accruing to both hired and family labor, quality improvements in labor over time, and management skill of operator labor. But if a price equal to 85% of the nonfarm wage rate is the appropriate one for deriving optimum input levels, it is also appropriate for determining the labor factor share in order to obtain a reliable indirect estimate of labor's production elasticity.

It indeed may be that considerable disequilibrium existed in the agricultural sector during the period 1910–61, but the underlying properties of the Tyner and Tweeten model do not reveal it.[2]

[*Received July 1977.*]

[1] Whenever the analyst assumes a set of conditions (e.g., prices) markedly different from those perceived by the economic actors, he is likely to conclude that the actors are less rational than they really are. In this particular case, the greater the difference in prices assumed between the two parts of the analysis, the greater the erroneous disequilibrium.

[2] Three additional minor points are (*a*) nominal output prices in our table 1 were computed in the same way as nominal input prices, i.e., by dividing Tyner and Tweeten's current dollar data (adjusted gross farm income) by their quantity data (farm output in constant dollars); (*b*) our derived equilibrium output in 1952–61 was slightly greater than output adjusted for government programs but less than actual output, and given a competitive industry and a negatively sloped demand curve, a downward shift in the supply function implies an increased, not decreased, output irrespective of the price elasticity of demand; and (*c*) if actual labor used is 168% of equilibrium labor, then labor is in excess supply by 68%, not 40%.

Books Reviewed

Cochrane, Willard W., and Mary E. Ryan. *American Farm Policy 1948–1973*. Minneapolis: University of Minnesota Press, 1976, xlv + 431 pp., $18.50.

As the authors note (p. 120), agricultural economists have the kind of skills that make them potentially useful to political practitioners, persons romantically but imprecisely called "policy decision makers." These skills when coupled with an interest in political activity have sometimes led agricultural economists into positions of direct participation in the political process, as in the case of Cochrane. Out of these experiences one is likely to be able to write an interesting review of the events of the era but not necessarily an insightful analysis of the political and economic systems. Cochrane and Ryan have written an easy-to-read account of the era and have compiled considerable legislative and commodity program detail. To a degree their work has the flavor of a personal saga. The other side of this coin is that the book is largely a tract for a particular political point of view in which neither the economic nor political analysis represents an advance in the professional literature. The review that follows is divided into three parts: a review of the order in which the issues are presented, some attention to the politics and public choice model that is used, and a listing of some of the issues amenable to economic analysis that are not resolved in the book.

Organization

The book is composed of three major sections. Part I contains four chapters that deal with the history of policy concepts, economic theory of supply and demand response, and a review of the legislative process. Part II is composed of four chapters containing various elements of the "historical record," and the two chapters of part III are devoted to an appraisal of the programs and a look to the future. A six-page glossary that introduces the major terms is presented at the front of the book.

Part I: Toward an Understanding of Farm Policy. In chapter 1, the "agroeconomic" setting of the twenty-five-year period is reviewed. In introducing the "facts," a number of theories related to factor use, sector growth, and income distribution are presented as if they were accepted propositions. They are used in the latter half of part II and in part III in justifying the conclusions of the authors. Chapter 2 contains an historical review of the broad political controversies of the era, while specific policies and programs are reviewed in chapter 3. These two chapters are reminiscent of Benedict's classic study of an earlier era, but in tone they are closer to Paarlberg's partisan description of the activities of seven secretaries of agriculture. Chapter 4 consists of a review of the legislative and administrative process. Because no formal model of political behavior is presented, it is difficult to determine if the space given to the Commodity Credit Corporation (CCC) reflects the author's admiration for its bureaucratic excellence or its considerable power to operate outside of the usual appropriation channels.

Part II: The Historical Record. Chapter 5 contains a usable compendium of the legislative acts, organized by the year of their passage. Although the organization of the material is unique, the bulk of it is available in various government publications, e.g., Agricultural Handbook No. 345 (USDA). Major commodity operations are presented in chapter 6 and represent something of an updating of Benedict and Stine. The program data have two minor flaws: (*a*) there is almost no attention to the special small farmer program provisions that may have influenced acreage diversion responses and the income distribution characteristics of the programs, and (*b*) hard-to-find materials are not referenced, making it difficult or impossible for later scholars to locate documents available to the authors. The program provisions summarized in chapter 6 are not formally related to the compendium in the previous chapter, so it is not easy to tie commodity program provisions to specific acts. Given the senior author's interest in quota programs, it is surprising that there is no space given to flue-cured tobacco, the most important quota program with transfer possibilities. The topics of land retirement, exports, and food programs presented in chapter 7 are useful, but students of individual topics will need to go to more detailed sources for fuller treatment, for example, Shepherd's treatment of the land retirement programs of the late 1950s. Chapter 8, program interrelationships and costs, contains the most complete accounting of treasury costs to be found anywhere currently.

Part III: Consequences and Appraisal. Chapter 9 is divided into four major topics: farm prices and incomes, resource allocation and efficiency, foreign trade, and consumer welfare. In each of the sections, hypotheses (theories) are presented as facts, and much of the relevant literature is not cited or utilized. Some of their empirical conclusions are suspect. For example, they conclude that prices were at or close to free market levels by 1965 (pp. 380, 390). Diversion programs affected output and prices at least through 1969 and probably through 1971. Thus, their estimates of consumer costs and producer benefits should be taken cautiously. Chapter 10 provides a short review of program benefits and a list of guidelines for future policy for-

mulation. The failure to specify rigorously a welfare model is apparent when in two adjoining paragraphs they conclude that the surpluses "literally gave life itself" and that the programs were costly because of "undue reliance on storage and surplus disposal programs" (p. 386). They call for a "concept of real social cost" (p. 391) that seems to reject consumer and producer surplus but turns instead on "vital interests of producers and consumers," implicitly assuming that inherent conflicts will somehow be resolved. The guidelines to the future are not useful because they are unspecific: storage stocks are needed but no holder is identified; flexibility is desirable but no mechanism is formulated; social "needs" are mentioned but no model is developed, etc.

Public Choice Questions

Books written about agricultural policy usually draw on political or public choice models as well as on economic models. In the present book, a number of public choice propositions are explicitly or implicitly put forward that are open to challenge or need fuller development. Several are presented as examples.

(*a*) Where should the initiative for formulating legislation lie: the Congress, the Secretary, or the Bureaucracy? In 1961 the Kennedy Administration proposed legislation to shift the initiative for farm legislation to the administration, leaving Congress the power to veto but not alter specific commodity programs. The proposal died in committee, but it is treated favorably by the authors in the sense that they explain that the agricultural sector is complex and problems are difficult to solve. Further, congressmen are presumed to not have the national interest in mind. If one generalizes from such reasoning, it is clear that all complex issues should be handled by the executive. In fact, the whole idea of representative government is called into question by this line of thought.

(*b*) How do contending forces work out their compromises most effectively? This question is addressed indirectly when the authors suggest that legislation cannot be developed on the floor of either house, leaving the main work to be done in committees. There is some evidence to suggest that committee decisions are important and that procedures (rules) that do not allow amendments on the floor speed up the legislative process. How then shall conflicts be resolved? The authors hint at a solution without addressing it fully: food and farm (consumer and producer) interests might be represented on one committee. Such a theory has important implications for the current organization of the U.S. Department of Agriculture. Food-aid programs and perhaps even "consumer protection" activities should be administered alongside commercial farm programs so that in each house of the Congress the compromises can be ground out in committee. Thus, the waning power of a small number of commercial farmers would be (is?) enhanced if their representatives have some power in committee over other legislation that is important to nonfarm representatives. What will happen to this power if food stamps are "cashed out" and the resources shifted to HEW? Who loses if commercial farm interests maximize their legislative power?

(*c*) What are the trade-offs in the use of alternative sources of funds to carry out program objectives? Congress may be reluctant to enact legislation that requires additional treasury outlays, particularly with the new congressional budgeting system. One obvious source of revenue for farmers is the consumer: if product quantities are restricted, market prices rise and farm incomes rise. In a sense, farmers unobtrusively collect the tax, which in the period studied may have been at about the rate of the average sales tax (Gardner and Hoover). Cochrane and Ryan discuss supply management, the euphemism for supply restraint, but never directly examine its role in the political acceptability of the programs. Another alternative is the expenditure of import duties. The praise of the CCC in chapter 4 probably should be reserved for section 32, which allows the secretary to use tariff proceeds to finance price support operations. Once the "surpluses" were accumulated, the secretary was empowered to give them to schools, institutions, and low-income households, removing any tell-tale evidence of price support. The reader interested in formal treatment of the political and economic principles involved in the choice among alternative devices used to transfer income will have to look elsewhere. This is a question that is intriguing and important if students of agricultural policy are to advance their understanding of the policy process.

(*d*) What is the relationship between price supports and votes in the next election? This public choice issue receives some attention in the book, but the treatment is not evenhanded. The authors describe political practitioners who frame and administer laws that win continuing assent as "practical." On the other hand, a preelection change in price support policy by Hardin and Butz is treated derisively. Since price support manipulation ("timing") is a tradition in both parties, its role in public decision making should be addressed formally and seriously. There is a question about how much income distribution through the Congress the citizens of the country can afford, given that each of us can afford to expend some resources (dead weight losses) to maintain the flow of funds from congressional action.

(*e*) Is completed political action the subject of analysis of conflicts and compromise or is it to be regarded as a frictionless revealer of the national will or the social welfare function? While many of their historical examples stress partisan fighting, governmental decisions are generally treated as

desirable. Such words and phrases as "we" in reference to federal legislation, "society," and "public interest point of view" lead toward reverence for rather than analysis of the process of public action. In preparing to sum up, the authors identify their position clearly when they ask if the "appraisal above is simply the judgment of two people, . . . worth no more than two votes" (p. 391). Not surprisingly, they conclude that their appraisal (all of it?) is judged to be correct when "The Congress of the United States confirmed year after year the need for price and income programs . . ." (p. 391).

Models, Analyses, and Assertions

As noted earlier there are a number of models presented as accepted facts at crucial points in the authors' arguments. It would take an inordinate amount of space to indicate the exact use of each proposition about which there is some doubt or need for additional evidence. Consequently, only the most important of the issues are listed with a brief indication of the role of each one in the authors' conclusions followed by a note in the nature of a question about the statement.

The role of the programs in increased agricultural productivity: the authors assert that output per unit of input grew because the programs reduced the amount of price uncertainty. To the extent that greater factor efficiency resulted, the real cost of the programs is less than reported amounts. Question: where are the empirical tests of the proposition? With price supports and program rules set politically, a new source of uncertainty was generated. On balance did farmers experience any change in the *ex ante* uncertainty they believed they were facing?

The role of the programs in generating the conditions that call for their continuation: the authors conclude that excess inputs at the end of World War II led to the set of programs to maintain product prices and not the other way around. They note that the programs may have prolonged the problem "depending on one's point of view" (p. 372), but they imply that the problem has decreased from the time of its recognition. Question: what was the role of the programs in discouraging migration, stimulating land development, and speeding research and extension dissemination of yield-increasing technology? The responses could have been substantial. One reading of the historical record is that farm programs generated one-third of net farm income over a two-decade period and that only with an unforeseen shift in export demand did the degree of "excess capacity" decline.

The role of the programs in firm-size growth: the authors argue that the programs helped the "fittest" to grow. They argue this would be another generally uncounted benefit arising from the programs because, implicitly, nonhuman factor efficiency is an important goal. Question: since no theory is developed that identifies the "fittest" before they grew, is not the statement tautological? *Ex post* it is necessarily true that those that grew were somehow the most successful or fittest. No data are brought to bear on the question, and no theory of firm growth is specified in a testable form. An interesting internal contradiction exists if one takes the initial problem to be one of the distribution of income. If the "fittest" were large, well-managed units and the programs helped them to grow, then the programs probably led to a concentration of income within the farm sector.

The role of the programs in raising farm incomes: the authors conclude that the farm programs were crucial in keeping farm incomes from falling in the past twenty-five years. Even with the programs, the "period 1948–73 was not a happy one." By implication the programs were the most important factor in farm income in the period. Question: were not other forces at work over this period that were more important in raising income of farm persons than were the farm programs? Off-farm sources of income of the farm population accounted for two-thirds of the advance in real per capita income between World War II and 1970 (U.S. Department of Commerce, pp. 225, 483). These sources grew at a little more than twice the rate of the growth in income from farming. Between 1942–46 and 1965–70 per capita income from farming of the farm population did not keep up with per capita nonfarm income, while the nonfarm sources of the farm population doubled relative to the income of nonfarmers.

The income distributional goals of the programs: by neglecting the issue the authors appear to believe that the income distribution of the program costs and benefits are unimportant in assessing the desirability of the programs. Average farm incomes would have been lower than they were in the absence of the program. Generally, incomes of farmers have been below nonfarmer incomes. Question: since income transferred through the market is in proportion to consumption, was not the food tax collected by farmers regressive on the payee side since poor people spend a larger percentage of their income on food than do the nonpoor? Were not the benefits concentrated among the upper half of the farm income distribution? In a redistributionist age, surely the average income of the losers and the gainers will not be taken as a sufficient guide to policy.

The goals of research and development expenditures by government: the authors conclude that a "subpolicy on agricultural resource use may need to be developed" if there is a period of "short food supply" (p. 397). Question: is not food always in "short supply," i.e., scarce? Is the land grant system such an important source of increased efficiency and so easily controlled by federal legislation that withholding funds can affect farm income in the short run? The general idea of restriction of research was close to a peak in 1956. Surely it was

not good public finance or economic analysis then, nor is it now.

Conclusion

No book can be expected to serve all possible purposes equally well. Many agricultural economists will find Cochrane and Ryan's book a useful place to begin their study of the post-World War II policy experience. This review has been directed to the identification of questions not resolved in the book, many of them still open for study and debate.

In this volume, the authors strive to enhance the readers' understanding of the economic organization and operation of the food and fiber sector of the U.S. economy. The authors attempt to fill a void in the subject matter areas of marketing and price analysis by treating both subjects comprehensively and analytically. The book is intended for use in introductory courses in marketing and price analysis; however, students should previously have had a course in microeconomic principles and college algebra.

Following the introductory chapter, a discussion of agricultural markets and marketing systems is presented in chapter 2. This discussion characterizes the marketing channels for the major products and inputs of U.S. agriculture. In the food retailing and wholesaling section, the authors incorrectly define a supermarket as a store with more than $500,000 annual sales when the current definition is twice that amount.

Some basic analytical tools of accounting, mathematics, and statistics are presented in chapter 3. Balance sheets, income statements, descriptive statistics, and index numbers are the principal items discussed. This chapter will be most valuable for students who have not had introductory courses in statistics and accounting.

Chapters 4, 5, and 6 contain a most competent presentation of the principles of price determination. Food consumption trends and elements of demand theory are presented in chapter 4. The chapter contains a comprehensive treatment of demand elasticities for farm products including an excellent application of these concepts to the analysis of demand for lamb. Chapter 5 discusses the concepts that underlie agricultural production and supply relations. This is a strong chapter that demonstrates the relationship between the production function, cost curves, and the supply curve. The discussion in the last part of this chapter focuses on the elasticity of supply and long-term trends in output and productivity of U.S. agriculture. The process of price determination in a competitive market and adjustment to price changes and price movements in agricultural markets are the subject of chapter 6. The chapter contains a good discussion of price trends, cyclical and seasonal patterns, and price discovery mechanisms for agricultural products.

The next four chapters focus on price differences and price variability. A thorough coverage of marketing margins for farm products comprises chapter 7. The spatial organization of markets in chapter 8 is one of the best chapters in the book. It is an excellent example of the way in which the authors have successfully applied economic principles to the analysis of agricultural problems. The discussion of price differences through time in chapter 9 focuses on storage and the futures market. This chapter needs considerable expansion and improvement; for example, the discussion of hedging and speculating in the futures market is inadequate. More illustrations of alternative positions are needed as well. The one illustration of a hedge that is presented needs improvement. More information on basis and basis movements is required, since this concept is so important to the use of the futures market. Finally, a section discussing the controversy surrounding the futures markets would be appropriate.

Quality differences and grades for farm products are discussed in chapter 10, as well as the advantages and disadvantages associated with a grading system. The last section of this chapter, which identifies the problems of using grades, would be

enhanced by a discussion of the recent controversy in grain grading and quality. Market information, discussed in chapter 11, focuses on market news, market outlook, and advertising. The section on generic advertising and check-off legislation is an interesting part of this chapter.

Chapter 12 defines the types of market structures that exist in our economy and presents an example of each type as it is found in the food and fiber system. This chapter is somewhat disappointing because it fails to discuss the industrial organization theory so widely used in agricultural economics. The market structure-conduct-performance paradigm would be a valuable addition to this chapter.

The presentation of marketing and pricing institutions in chapter 13 focuses on cooperatives and market orders. This chapter contains an excellent discussion of the characteristics of these institutions, their economic importance, and impact on agricultural markets. Chapter 14, market and price policy, focuses on the goals of agricultural marketing policy in terms of the competitive norm and why marketing activity differs from this competitive norm. The last chapter, chapter 15, discusses marketing and economic development. This chapter presents a brief overview of product and input market problems in developing countries. This brief chapter does not fit the general orientation of the rest of the book and will probably not provide students with any real understanding of an important but very complex topic. The chapter should be retained in future editions only if it is considerably enhanced.

A weakness of the text for some users is the lack of any specialized commodity or food retailing and wholesaling chapters. The book would have to be supplemented with outside materials for those users who desire more detail on a particular commodity, a group of commodities, or food wholesaling and retailing.

Market and Price Analysis is, overall, a well-written and organized text. It is appropriate for an introductory course in market and price analysis. This text provides students with an understanding of the economic organization and operation of the U.S. food and fiber system. An important strength of the text is the extensive application of economic principles to analysis of agricultural marketing problems. This use and application of theory far excels that found in any other introductory agricultural marketing textbook.

The Ohio State University

Meyendorff, A. L. *Optimization of Farm Decisions through Marginal Analysis*. Moscow: Ekonomika, 1976, 39 kopeks

The basic contents of this new Soviet book would be familiar to any American undergraduate who has completed a course in intermediate price theory. Still, publication of this book should be of interest to western agricultural economists. Soviet publication for a wide audience of a broad framework of marginal analysis is quite novel. Additionally, it is interesting to see how a Soviet agricultural economist (with western training) relates this framework to Soviet agricultural policies and traditional modes of economic analysis. The author's discussion may be especially interesting for those westerners who have had contact with the latter, perhaps through recent East-West exchanges.

The book is an orderly introduction of terminology and progressively complex models. The exposition includes the familiar use of numerical examples, geometry, and algebra. The author first defines total, average, and marginal products and costs through the example of finding the optimal variable seeding rate for a farm producing wheat under fixed short-run conditions of diminishing returns. The author then proceeds to introduce isoquants, isocost lines, and marginal rates of factor substitution through the example of minimizing the cost of livestock rations. A final major section examines the farm's optimal structure of production—introducing product transformation curves, marginal rates of product transformation, and isorevenue lines.

These concepts are sufficiently foreign to warrant a prefatorial nod to the 1971 Party Congress's endorsement of optimal decision making and to early glimmerings of marginal analysis in the writings of Marx, Lyudogovsky of the prerevolutionary Petrovsky Agricultural Academy, and the 1920 writings of Studensky. The book's preface also mentions the native pioneering programming work of Kantorovich and Novozhilov. Meyendorff holds that neoclassical marginal analysis can be useful where the resources for programming are not available. He also maintains that marginal analysis illuminates the economic sense of certain decisions that may not be apparent under programming analysis.

In the book's first section, the traditional diagram of rising and falling product curves establishes three zones of rational and irrational input intensities. In the first "irrational" zone (in the range where the average product of the "variable" input is increasing), total output can be increased by simply using less of the "fixed" variable. This analysis is insightful, writes Meyendorff, for ongoing Soviet discussions of intensification, in particular for policies regarding the optimal size of the Soviet livestock herd given limited feed and the extension or retention of cultivation of some lands given limited capital goods.

The author illustrates the difference between average and marginal values with the avowed goal of concentrating attention upon information about increments specific enough to be useful. He feels that the propagation of marginalistic theory will promote the development of information useful for less aggregative planning.

A typical Soviet statistical study of "economic effectiveness" correlates production decisions (e.g., about intensification, specialization) with performance indicators of some sort (e.g., profit per hectare, per man, or per ruble invested) for a sample of farms or regions. These studies tend to recommend for all farms or regions those decisions employed on the "advanced" farms. Meyendorff criticizes this approach as one that slights differences in farming conditions, and he maintains the need for criteria for optimal decision making by farms in specific circumstances. Planning authorities should pass on to farm managers more general functional information for these decisions and fewer production norms.

Meyendorff points out that marginal analysis with its focus on functional relationships puts some order into otherwise confusing discussions. Standard planning discussions offer a plethora of (often hortatory) directives for farms (for example) to simultaneously minimize cost, maximize yields, and maximize profits. His simple examples show that these goals are generally logically incompatible.

In the Soviet Union at the present time, some farms may receive several times the price paid farms in other price zones. In such a situation, decentralized profit maximization cannot lead to a socially optimal distribution of production. The author briefly acknowledges this special circumstance of Soviet markets, as well as the fact of rationed inputs and compulsory sales plans. He does direct his analysis to make a comment on government pricing of farm inputs. However, the author does not go on, for instance, to bring to bear the tools he has developed to make an analytic contribution to the now old discussion of Soviet price zoning, differential rent, and efficient specialization.

As also happens in college courses, time limits apparently intervene before this book gets to the last chapters of the price theory course. Despite this, neoclassical production theory is apparently thought useful for Soviet circumstances. Of the 18,000 copies released in spring 1976, none were to be found in Moscow book stores in the late summer.

Announcements

1977 Meeting Allied Social Sciences Association

The American Agricultural Economics Association will meet jointly with the Allied Social Sciences Association in New York, New York, 27–30 December 1977. Sessions are being scheduled as follows: (*a*) Contemporary Issues in Resource Economics; Emery N. Castle, Resources for the Future, chairman; (*b*) Agricultural and Food Policy Making—Concerns, Forces, Participants (a round table discussion); R. G. F. Spitze, University of Illinois, chairman; (*c*) Appropriate Technology for U.S. Agriculture: Are Small Farms the Coming Thing?; Otto C. Doering III, Purdue University, chairman; (*d*) The Economics of Rural Household Behavior; W. Keith Bryant, Cornell University, chairman. Program details are available from the AAEA president at the following address: R. J. Hildreth, Farm Foundation, 1211 West 22nd Street, Oak Brook, Illinois 60521.

Nominating Committee

R. J. Hildreth, president of the American Agricultural Economics Association, has appointed the following persons to the nominating committee: Kenneth Farrell, ERS, USDA, chairman; Richard King, North Carolina State University; Glenn C. Himes, Ohio State University; Eugene E. Gerke, Super Market Institute, Inc.; A. M. Weisblat, Agricultural Development Council, Inc.; Fred D. Sobering, Kansas State University; B. D. Gardner, University of California, Berkeley; and C. E. Willis, University of Massachusetts. This committee will nominate two persons for the office of president-elect and two sets of two paired candidates for directors of the Association. Individual members of the Association should submit their suggested nominees to Kenneth Farrell, Economic Research Service, U.S. Department of Agriculture, 500 12th St., S.W., Washington, D.C. 20250, by 10 December 1977.

Oral History Memoir Available

An oral history memoir with Harry R. Wellman, professor of agricultural economics, emeritus, has been completed by the Regional Oral History Office of The Bancroft Library, University of California, Berkeley. Wellman was Giannini Foundation director, 1942–52. The bound and indexed manuscript with an introduction by Chester McCorkle, Jr., and Herman T. Spieth is available for research at The Bancroft Library and at UCLA. Copies are available to other depositories at $30.00. For further information, write the Regional Oral History Office, Room 486 The General Library, University of California, Berkeley 94720.

AAEA Awards Program

Through its awards program the American Agricultural Economics Association recognizes professional excellence in several subfields of agricultural economics. The AAEA recognizes professional achievement at the student, the young professional, and the more experienced levels in research, teaching, and extension activities. Seventeen awards will be presented in 1978.

The program has a rich tradition as can readily be noted by a review of the roster of award winners over the years. The AAEA believes that this tradition will be continued in the 1978 program.

The 1978 program has been organized and will be conducted by committees representing a substantial professional input of nearly 100 committee members. We hope you will submit nominations for the categories outlined in this announcement. The general awards chairman is A. Gordon Ball, College of Agriculture, University of Guelph, Guelph, Canada N1G 2W1, telephone (519) 824-4120, ext. 2284 or 2285.

Distinguished Extension Programs

The distinguished extension program awards recognize achievement of excellence in extension economics teaching programs. Two awards are offered in 1978. One award will be given to an individual with less than ten years experience in extension education, and the other award will go to an individual with ten or more years of experience in extension education.

Nomination. Nominations may be made by any member(s) of the AAEA, and selection will be made from among those nominated. The nominee must have been active in extension teaching for at least one year at the time of the nomination, and the content of teaching efforts must be principally in the field of agricultural economics. Each nomination must be made by separate letter accompanied by eight copies of documentary evidence indicating nominee's name and extension title; extension program area in which teaching is conducted; identification of the clientele served; objectives of the educational program; teaching techniques, educational methods, and materials utilized; and effec-

tiveness of the extension teaching effort in terms of clientele response and/or establishment of the utility of the extension teaching program.

Evaluation. Each nominee will be evaluated on the quality of work as indicated by the documentary evidence submitted with the nomination relative to the following characteristics: effectiveness in teaching application of economic principles and tools of analysis appropriate to the problem and audience involved; ability to conceptualize new extension educational programs and application of new teaching concepts to existing programs; effectiveness in bringing about significant behavioral change and/or understanding of clientele; and contribution to improved extension teaching in agricultural economics as evidenced by participation in appropriate professional activities and organizations.

Due dates. Nominations and supporting evidence must be submitted by 1 February 1978 to the subcommittee chairman: Robert J. Bevins, Department of Agricultural Economics, University of Missouri, Columbia, Missouri 65201. Recommendations of the subcommittee will be forwarded to the general awards chairman by 15 May 1978.

Distinguished Policy Contribution

The distinguished policy contribution award recognizes an outstanding contribution to policy decisions or to the advancement of public understanding of major policy issues related to food, fiber, agriculture, and human welfare. Policy issues are interpreted in their broadest sense. They may relate to either a national or international situation. Their focus may be on production, marketing, or consumption. They include such things as price and income policy, environment and land-use issues, local government, rural poverty, and community development problems. The purpose of the award is to encourage interest in economic analysis of public policy issues that can provide timely and relevant information for more effective public policy and program decisions. The award is intended to focus attention on important efforts in research, education, or public service that facilitate the policy process and improve public performance and understanding. It may be given annually.

Nominations. Nominations may be submitted by individuals, groups, or institutions. In addition, the Distinguished Policy Contribution Award Committee is encouraged to generate nominations to assure that all outstanding policy contributions are considered. Winners will be selected on the basis of the supportive material showing major contributions within the previous five years. Renominations are invited provided the supportive material is updated. Each nomination must be made by separate letter accompanied by documentary evidence supporting the nominee's contributions to the development and/or understanding of public policy. Eight copies of each entry should be submitted. Return of the material submitted is not customary but can be requested.

Evaluation. Entries must demonstrate significant contributions to the development and/or understanding of policy through research, extension, education, or public service activities. They will be evaluated on the quality of contribution to policy decisions or to the advancement of public understanding of major policy issues related to food, fiber, agriculture, and human welfare. Additionally, contributions will be evaluated based on the impacts they have had on the decision-making process. The effort must be a significant contribution to policy understanding as indicated by publication, program participation, or public response and awareness. The work should show evidence of demonstrated excellence in defining and articulating policy issues to the public and helping the public to understand and be aware of such issues.

Due Dates. All nominations and documentation should be sent by 1 February 1978 to the chairman of the distinguished policy contributions award subcommittee: J. Edwin Faris, Department of Agricultural Economics and Rural Sociology, Clemson University, Clemson, South Carolina 29631. Recommendations of the subcommittee will be forwarded to the general awards committee chairman by 15 May 1978.

Distinguished Undergraduate Teaching

The distinguished undergraduate teaching awards recognize and encourage meritorious performance in undergraduate teaching in agricultural economics. Two awards will be given: one for an individual with less than ten years of experience as an undergraduate teacher, and one for an individual with ten or more years of experience as an undergraduate teacher.

Nomination. Nominations may be submitted by any member(s) of AAEA. Winners will be selected based entirely on the supportive material submitted. Renominations are invited providing the supporting evidence is updated and resubmitted. Nominees must be actively engaged in teaching at a professional level during the 1977–78 school year. Nominees must have demonstrated outstanding ability as an undergraduate teacher of agricultural economics. The format of the nomination material submitted should use as primary categories the five major criteria areas listed in the evaluation criteria section that follows. Include biographical data of the nominee—name, present position, education, and number of years of university-college teaching and experience in the profession. Supporting evi-

dence must be limited to three pages for each of the five primary categories of the nomination. No more than three letters of reference from peers and students for each of the five primary categories should be included. Adjunct material may be included as an appendage to the nomination package if desired, for example, summaries of student class evaluations for courses taught. Eight copies of each nomination package are required.

Evaluation. Five major criteria areas will be used in evaluating nominations with relative weights as follows. (*a*) Quality of teaching (45%)—ability to motivate and stimulate student to learn (20%); innovation for presentation, evaluation measurements (15%); and mastery of subject, use, and application to business conditions (10%). (*b*) Academic advising, counseling, and extracurricular activities of students (20%)—advising and counseling (14%); and catalyzing extracurricular activities of students, i.e., department clubs or organizations, student council or senate, student publications, convocations, seminars, community involvement (6%). (*c*) Campus participation in instructional, course, and curricular improvement efforts (15%)—department, college, and university-wide. (*d*) Professional improvement in teaching for benefit of self and peers (15%)—published textbooks, manuals, bulletins (5%); research papers related to improved teaching (5%); and participation in professional meetings and committees related to improved teaching and student activities (5%). (*e*) Department/college/university teaching awards (5%)—student association/alumni awards.

Due dates. Nominations and supporting evidence must be sent by 1 February 1978 to the chairman of the distinguished undergraduate teaching awards subcommittee: John D. Helmberger, Department of Agricultural and Applied Economics, University of Minnesota, St. Paul, Minnesota 55108. Recommendations of the subcommittee will be forwarded to the general awards chairman by 15 May 1978.

Outstanding Master's Degree Program

The outstanding master's degree program awards have as their objective development of professional excellence by individuals pursuing master's degree programs in agricultural economics. Three awards are offered. A cash supplement of $250 accompanies each award.

Nomination. Any department engaged in training agricultural economists at the master's degree level may submit nominations. Entries must be submitted by the head of the department where the degree is earned. A department may submit one nomination for each fifteen master's degree candidates or fraction thereof presented to a graduate school faculty during the year. To determine the number of eligible candidates, departments should limit consideration to candidates who will receive a degree in agricultural economics and to candidates who have taken agricultural economics as a field of emphasis. Nominations should include thesis or other comparable documentation. Selection will be made from documentation approved in final form by the student's advisory committee during the calendar year 1977, provided the candidate has met all other formal requirements for the master's degree. A published thesis may be entered in both the published research and master's program classes but will be eligible for only one award. Although a published thesis is acceptable, a copy of the thesis as submitted to the graduate faculty should be sent whenever possible. Three copies of all nomination materials (i.e., thesis) are required to be sent to the committee chairman. All copies will be returned after reading by the judges.

Evaluation. Copies of evaluation criteria may be obtained from the chairman of the subcommittee.

Due dates. All nominations and documentation should be sent by 1 February 1978 to the chairman of the outstanding master's degree award subcommittee: Larry J. Martin, School of Agricultural Economics and Extension Education, University of Guelph, Guelph, Ontario, Canada N1G 2W1. Recommendations of the subcommittee will be forwarded to the general awards committee chairman by 15 May 1978.

Outstanding Doctoral Degree Program Award

The outstanding doctoral program awards are given in recognition of development of professional excellence for persons pursuing a doctoral program in agricultural economics. Three awards will be given in 1978. A cash supplement of $250 accompanies each award.

Nomination. Entries must be submitted by the head of the department where the thesis or comparable document was presented in partial fulfillment of requirements for a degree. A department may submit one nomination for each twelve doctoral candidates or fraction thereof presented in agricultural economics to a graduate school faculty during the year. To determine the number of eligible nominations, departments should limit consideration to candidates who received a degree in agricultural economics and to candidates who have taken agricultural economics as a field of emphasis. Selection will be made from theses (or comparable documents) approved in final form by the student's advisory committee during the calendar year 1977, provided the candidate has met all other formal requirements for the doctoral degree. A published thesis may be entered in both the published research and thesis categories but will be eligible for

only one award. Although a published thesis is acceptable, a copy of the thesis as submitted to the graduate faculty should be sent whenever possible. Three copies of a thesis must be sent to the subcommittee chairman. All copies will be returned after they have been read by the judges.

Evaluation. Criteria for evaluation of nominations may be obtained from the chairman of the subcommittee.

Due dates. Nominations and supporting evidence should be sent by 1 February 1978 to the chairman of the outstanding doctoral thesis award subcommittee: Terrence F. Glover, Department of Economics, UMC 35, Utah State University, Logan, Utah 84322. Recommendations of the subcommittee will be forwarded to the general awards chairman by 15 May 1978.

Quality of Research Discovery

This and the following three awards are given to encourage excellence in publications in all areas of agricultural economics.

Rules. There are no requirements regarding the number of authors or professional experience. Nominations may be submitted by individuals, departments, or agencies. Nine copies of each publication should be submitted, unless expense for the individual is excessive. Return of the publications is not customary but can be requested. Nominations should be submitted for only one award in either the quality of research discovery or quality of communication category for 1977.

Nomination. A maximum of two awards are given. Entries must specify that the nomination is to be judged for the quality of research discovery. Entries must have been published in 1977.

Evaluation. The research must be a significant contribution to the field of knowledge in agricultural economics. The work should demonstrate excellence in research methodology and may deal with conceptualization of researchable problems as well as empirical verification.

Due dates. Entries should be sent by 1 February 1978 to the subcommittee chairman: Irving Dubov, Department of Agricultural Economics and Rural Sociology, University of Tennessee, Knoxville, Tennessee 37901. Recommendations of the subcommittee will be forwarded to the general awards chairman by 15 May 1978.

Quality of Communication

The rules pertaining to the award for quality of research discovery also apply to this award for quality of communication.

Nomination. A maximum of two awards will be given. Entries must specify that the entry is to be judged for its quality of communication. Entries must have been published in 1977.

Evaluation. Entries must demonstrate superior communication of concepts or knowledge in any subject matter area or professional specialization (i.e., research, teaching, or extension) in agricultural economics to a specified audience. If dealing with transmission of research findings, the publication need not contain the author's original research but should improve communication within the profession as well as between it and other professions.

Due dates. Entries should be forwarded by 1 February 1978 to the subcommittee chairman: Irving Dubov, Department of Agricultural Economics and Rural Sociology, University of Tennessee, Knoxville, Tennessee 37901. Recommendations of the committee will be forwarded to the general awards chairman by 15 May 1978.

Publication of Enduring Quality

One award is offered for a publication with a publication date during the fifteen-year period 1953–67. Entries are judged on the basis of the enduring quality of their contribution to the profession.

Eligible entries are articles in this *Journal* (during part of the period considered, the *Journal* was known as the *Journal of Farm Economics*) regardless of whether the authors are AAEA members and also other publications by authors, one of whom was a member of the AAEA at the time of publication. Entries must be submitted by departments or other administrative units, colleagues, or the authors themselves. Publications receiving an award in any other category in previous years are eligible for this award.

Entries should be sent by 1 February 1978 to the subcommittee chairman: A. H. Harrington, Department of Agricultural Economics, Washington State University, Pullman, Washington 99163. Nine copies of the publication should accompany the entry. Recommendations will be forwarded to the general awards chairman by 15 May 1978.

Outstanding Journal *Article*

The editor and editorial council of the *Journal,* with the editor as chairman, will choose the outstanding article in the 1977 volume of the *Journal.*

AAEA Fellow

Nominations for AAEA Fellow should be sent to the secretary-treasurer, John C. Redman, University of Kentucky, Lexington, by 1 December 1977. Any living AAEA member may be nominated. Those submitting nominations should be prepared to submit upon request biographical information in support of the nominee.

General Recognition

Awards will be presented at the annual AAEA awards program during the annual meeting at Virginia Polytechnic Institute and State University, Blacksburg, Virginia, 6–9 August 1978. Winners will be identified in the annual meeting awards program brochure and in the December proceedings issue of the *Journal*.

Personnel

University of Arkansas

Appointments: George L. Greaser, Ph.D. Virginia Polytechnic Institute and State University, is an assistant professor; **Robert N. Shulstad,** assistant professor, is editor of the *Southern Journal of Agricultural Economics,* 1978–80.
Retirement: William J. Windham, former assistant professor, after 26 years of service.
Honor: J. Martin Redfern, associate professor, received the Outstanding Faculty Member Award for 1976–77.

University of California, Davis

Leave: Gordon A. King, professor, is on sabbatical leave at Cornell University through Feb. 1978.

University of Chicago

Appointment: Theodore W. Schultz, professor emeritus, is chairman of the Social Science Section, National Academy of Science.
Honor: D. Gale Johnson, professor, is a fellow of the American Academy of Arts and Sciences.

Clemson University

Appointments: Eddie H. Kaiser, Ph.D. Iowa State University, is an assistant professor in agricultural finance; **Stephen E. Miller,** Ph.D. Virginia Polytechnic Institute and State University, is an assistant professor in agribusiness management; **James L. Novak,** M.S. University of New Hampshire, is a visiting instructor in Florence, South Carolina; **Gary J. Wells,** Ph.D. North Carolina State University, is an assistant professor in interregional competition and trade.
Retirements: Lewis D. Malphrus is an associate professor emeritus after 31 years of service; **James M. Stepp** is an alumni professor emeritus after 36 years of service.

Colorado State University

Appointments: Jerry B. Eckert, assistant professor, is the chief of party with the CSU/Lesotho Agricultural Sector Analysis team, Maseru, Lesotho; **Kenneth L. Leathers,** Ph.D. Colorado State University, is on a two-year assignment with the CSU/LASA team, Maseru, Lesotho.
Leave: Charles W. Howe, professor of economics, is the Hill visiting professor of natural resource economics, University of Minnesota, academic year 1977–78.
Returns: Rex D. Rehnberg, professor, is back on full-time duty after serving half-time for two years as university mediation officer; **Robert A. Young,** professor, is back from a research assignment with the Department of Farm Management, Lincoln College, Canterbury, New Zealand.
Resignation: Sam H. Johnson, III, formerly with the CSU Water Management Research Party, Pakistan, is with the Ford Foundation team, Bangkok, Thailand.
Honor: S. Lee Gray received the Oliver P. Pennock Award for excellence in teaching.

University of Connecticut

Appointment: Joseph Diamond, Ph.D. Michigan State University, is an assistant professor of community development.
Leave: T. C. Lee, professor, is on sabbatical leave at the University of Georgia for one academic year.
Return: Carlos Stern, associate professor, is back from the U.S. Geological Survey, Reston, Virginia.
Retirement: Arthur W. Dewey is a professor emeritus after 30 years of service.

Cornell University

Appointment: Gerald White, Ph.D. The Pennsylvania State University, is an assistant professor in production economics.
Leaves: Richard N. Boisvert, associate professor, is on leave with the Federal Insurance Administration, Department of Housing and Urban Development, Washington, D.C., until August 1978; **Duane Chapman,** associate professor, is a visiting associate professor for the Energy and Resource Program, University of California, Berkeley, through June 1978.
Honor: Wendell G. Earle, professor of marketing, received the Professor of Merit Award for 1977 for excellence in classroom teaching, advising, and contribution to undergraduate programs.

University of Florida

Appointments: James R. Simpson, formerly with Texas A&M University, is an associate professor in livestock marketing; **Thomas S. Walker,** formerly with Stanford University, is an assistant research scientist under the UF/USAID program for technical assistance to El Salvador.

Return: J. Kamal Dow, associate professor, is back after serving as chief of party in Ecuador for five years.

University of Idaho

Appointments: Stephen Smith, Ph.D. University of Wisconsin, and **David Walker,** Ph.D. Iowa State University, are assistant professors of resource economics.
Leave: Gerald Marousek, professor, was a visiting professor, New Mexico State University, fall 1976, and is a visiting professor, University of New England, Armidale, Australia, through August 1977.

University of Illinois

Appointments: Bruce L. Dixon, Ph.D. University of California, Davis, and **Philip Garcia,** Ph.D. Cornell University, are assistant professors; **Roger E. Schneider,** Ph.D. University of Missouri, is a research associate.
Leaves: Emer E. Broadbent, professor, is on sabbatical leave for six months through Nov. 1977; **George G. Judge** is on leave of absence at the University of Georgia through May 1978; **J. W. Robinson** is on sabbatical leave for one year, ending in July 1978.
Honor: Lowell D. Hill was named the first Laurence J. Norton Professor of Agricultural Marketing.

Iowa State University

Appointment: John T. Scott, professor of economics, is Coordinator of International Programs, College of Agriculture.
Honor: Earl O. Heady, professor of economics and distinguished professor in agriculture, received a citation from the ISU Alumni Association in recognition of long and outstanding service.

Kansas State University

Appointments: George Brandsberg, formerly with Creative Services, Des Moines, Iowa, is assistant extension editor; **Barry Childs,** M.S. Kansas State University, is an area extension economist in Concordia; **Harold Lobmeyer,** M.S. Kansas State University, is an area extension economist in Garden City; **Barry L. Flinchbaugh,** former extension economist, public affairs, is the assistant to the president of KSU in charge of public affairs, information, and development.
Resignation: Fred Delano, former area extension economist in Baldwin City, is vice-president, Lawrence National Bank, Kansas.

University of Kentucky

Leave: Garnett L. Bradford, professor, is a visiting professor, University of Minnesota, academic year 1977–78.

Michigan State University

Appointments: Vince Barrett and **Greg Lassiter** are specialists with the Upper Volta Project; **Philip G. Favero** is a temporary assistant professor with the public affairs program; **Thomas Stickley** is a temporary associate professor with the Upper Volta Project; **David Wilcock** is a temporary assistant professor and chief of party with the Upper Volta Project.
Honor: Herb Kriesel, professor, is a member of the eighteen-person Joint Advisory Committee to the Directors General of the FAO, ILO, and UNESCO on agricultural science, education, and training.

University of Minnesota

Appointments: Paul Gallagher, formerly with the CED, ERS, USDA; **Richard J. Magnani,** M.S. University of Minnesota, is a research specialist in marketing structure and performance.
Leave: Mathew D. Shane, associate professor, is on sabbatical leave to do research on Malaysian development and trade, University Pertanian, Malaysia, through June 1978.
Resignation: Martin E. Abel, professor, is vice-president of Schnittker Associates, Washington, D.C.

Mississippi State University

Appointment: Charles E. Powe, Jr., formerly with the Farmer Cooperative Service, USDA, is an assistant professor and assistant agricultural economist.

Oregon State University

Appointments: James K. Whittaker, former assistant professor, Purdue University, is an assistant professor in agricultural production economics; **Russell C. Youmans,** professor, is director of the Western Rural Development Center.
Leaves: James B. Fitch, associate professor, is an agricultural project specialist with the Ford Foundation in Cairo, Egypt; **R. Bruce Rettig,** associate professor, is on sabbatical leave at the University of Washington and the National Marine Fisheries Service office, Seattle, until August 1978.
Resignation: George L. Wyatt, former assistant professor, is with the Oregon College of Education, Monmouth.

Pennsylvania State University

Appointments: Dan E. Moore is an assistant professor of rural sociology; **Robert D. Weaver** is an assistant professor.
Return: Milton C. Hallbert, professor, is back after five months as a visiting professor, Oklahoma State University.

Purdue University

Appointments: James K. Binkley, Ph.D. Virginia Polytechnic Institute and State University, **Robert D. Boynton,** Ph.D. Michigan State University, **Jon A. Brandt,** Ph.D. University of California, Davis, **Craig L. Dobbins,** Ph.D. Oklahoma State University, and **John Spriggs,** Ph.D. University of Minnesota, are assistant professors; **Paul N. Blick,** M.S. Purdue University, is a temporary instructor; **Martin T. Pond** is assistant director for community resource development, Indiana Cooperative Extension Service; **G. Edward Schuh,** professor, is director, Purdue University Center of Public Policy and Public Administration; **Thomas K. White,** professor, is acting director, International Programs in Agriculture and International Education and Research.
Resignation: Mario Coria-Salas is head, Graduate Department of the School of Economics, National Polytechnic Institute, Mexico City.
Honor: G. Edward Schuh, professor, was elected a fellow of the American Academy of Arts and Sciences.

University of Rhode Island

Leave: Virgil Norton, professor, is studying at the University of Maryland.

Rutgers—The State University

Resignation: William L. Park, former professor of agricultural economics and marketing, is the agricultural economics department chairman, Brigham Young University.

University of Tennessee

Appointment: B. H. Pentecost, formerly with the Development Office, is a professor in agricultural law.

Texas A&M University

Return: Ray Billingsley, professor, is back from a two-year United Nations assignment in Thailand.

U.S. Department of Agriculture

Appointments: William T. Boehm, formerly with the Virginia Polytechnic Institute and State University, is with the Consumer Economics and Demand Analysis Program Area, NEAD; **Linda Kay Lee,** Ph.D. Iowa State University, is with the Resource Inventories and Use Program Area, NRED; **Dean Richards,** M.S. Texas A&M University, is with NEAD; **Tanya Roberts,** former consultant in private industry, is with the Structure and Adjustments Program Area, NEAD; **Debra Waldon** is with the Resources Systems and Productivity Analysis staff, NRED.
Appointments in CED: Robert W. Bohall is deputy director; **William H. Meyers,** Ph.D. University of Minnesota, and **Robert D. Remmele,** Ph.D. Iowa State University, are with the Forecast Support Group; **John G. Stovall** is director.
Appointments in EDD: Susan D. Brown, William F. Fox, Wanda Godsey, and **Patrick Sullivan** are with the State and Local Government Program Area; **James Cantwell** and **Peggy Ross** are with the Health and Education Program Area; **Irma Elo** is a social science analyst with the Health and Education Program Area.
Reassignments: Robert I. Coltrane, leader, Manpower Program Area, EDD, is on a one-year assignment to work with the National Commission of Manpower Policy, Washington, D.C.; **William Crosswhite,** assistant director, NRED, is on a one-year study program at Vanderbilt University; **Eric Oswald,** formerly with the Soil Conservation Service, is with the Environmental Studies staff, NRED, Tucson, Arizona.
Resignations: Joseph Combs, formerly with the Fruits, Vegetables, Sweeteners, and Tobacco Program Area, CED, is studying at Massachusetts Institute of Technology; **Gary A. Davis,** formerly with the Meat Animals Program Area, CED, Lansing, Michigan, is with a private consulting firm; **Gary G. Frank,** formerly with the Dairy Program Area, CED, returns to farming in Wisconsin; **Duane Paul,** formerly with the Environmental Studies staff, NRED, is with Chase Econometrics, Philadelphia; **Linda Zygaldo,** formerly with NRED, is with the Environmental Protection Agency, Washington, D.C.
Retirements: Harold Ellis, formerly with the Resource Organization and Control Program Area, NRED, after 30 years of federal service; **Norman D. Kimball,** formerly with the Small Watershed staff, NRED, after 29 years of federal service.
Honors: Arvin R. Bunker, with NEAD, received one of three awards in a competition sponsored by *The Logistics and Transportation Review,* University of British Columbia; **Dan Colacicco,** with the Environmental Studies staff, NRED, was a member of a research team receiving a USDA Superior Service Award for research on land utilization of sewage sludge.

Utah State University

Appointment: Basudeb Biswas, Ph.D. University of Chicago; **Bruce Godfrey,** former associate professor of forest and range resource economics, University of Idaho, is an associate professor.

Virginia Polytechnic Institute and State University

Appointment: Kenneth H. Baum, Ph.D. Iowa State University, is an assistant professor.

Washington State University

Leaves: Smith Greig, professor, is on leave for one year with the USAID, Washington, D.C.; **Don West,** associate professor, is on leave for one year with the Food and Nutrition Service, Washington, D.C.

Other Appointments

Kamel S. Al-Ani, Ph.D. Pennsylvania State University, is an economist with the Ministry of Agriculture, Baghdad, Iraq.
Jeffrey Doutt, Ph.D. University of California, Berkeley, is the chairman, Department of Management, Sonoma State College.
Richard Dowell, Ph.D. University of Chicago, is in Sydney, Australia.
Raymundo E. Fonollera, Ph.D. Oregon State University, is vice-president for Resources Development and Planning, Central Mindanao University, Philippines.
Edward M. Jones, Jr., M.S. Virginia Polytechnic Institute and State University, is with the Federal-State Crop Reporting Service, Louisville, Kentucky.
James A. Mize, Jr., M.S. Virginia Polytechnic Institute and State University, is with Resources for the Future, Washington, D.C.
Richard E. Nellis, Jr., former lecturer, Lyroming College, is a staff economist with the Pennsylvania Public Utility Commission.
Leslie Nieves, M.S. Virginia Polytechnic Institute and State University, is with Battelle Pacific Northwest Laboratory, Richland, Washington.
Todd Petzel, Ph.D. University of Chicago, is with Macalester College.
Randall Pope, M.S. University of Arkansas, is with the Prudential Insurance Company, Little Rock, Arizona.
Vasant Suhkatme, Ph.D. University of Chicago, is an economist, World Bank.
Daniel Sumner, Ph.D. University of Chicago, is with the RAND Corporation.
J. Karl Wise, Ph.D. Pennsylvania State University, is a staff economist with the American Veterinary Medical Association, Schaumburg, Illinois.

Obituary

Harry M. Love

Harry M. Love died on 21 June 1977 in Blacksburg, Virginia. He had retired as head of the Agricultural Economics Department, Virginia Polytechnic Institute and State University, ten years previously as professor emeritus.

He was born in Virginia in 1902 and received his undergraduate education at Virginia Polytechnic Institute and State University and his Ph.D. at Cornell University. He taught vocational agriculture in Virginia public schools and was employed by the Farm Credit System before returning to his alma mater in 1938 as a member of the agricultural economics faculty.

Love was a keen observer of life about him, impatient with faulty workmanship and incompetence, and absolutely intolerant of duplicity and dishonesty. His wit was keen and was used freely to illustrate a point or to attack a position he considered wrong or inferior. He was a strong advocate of traditional free-enterprise economics.

He is survived by his widow Elsie W. Love, two married daughters, and four grandchildren.

TENURED FACULTY POSITION
in the
Department of Agricultural and Resource Economics
College of Natural Resources

Title: Tenured level position in International Rural Economic Development.

Qualifications: Extensive background in the economics of development applied to problems of food and agricultural policy in developing regions, supported by a substantial record of research publications, is required. Interest in food policy as it relates to nutrition is sought. Some competence in one or more of the relevant social science disciplines such as rural sociology or social anthropology would be desirable.

Responsibilities: Instructional obligations normally comprise teaching two or three courses a year and supervising doctoral thesis research. The appointee will be expected to develop and participate in research programs encompassing various economic and social aspects of food and agricultural policy in developing regions and to establish and maintain contacts with public and private agencies required for their implementation. Full participation in the functions charged to faculty in the governance of the Department, College, and the University is expected.

Applications: Applicants are requested to submit a *curriculum vitae* containing a complete bibliography and provide copies of three publications.

Filing Deadline: 31 January 1978.

Contact: Professor J. N. Boles, Chairman, Department of Agricultural and Resource Economics, 207 Giannini Hall, University of California, Berkeley, California 94720.

The University of California is an equal opportunity and affirmative action employer. Applications from women and/or minorities are encouraged.

BERKELEY

Examining the problems of increasing food production on millions of small farms in developing countries

Robert D. Stevens, professor of agricultural economics at Michigan State University, edited these papers detailing the economic analysis in studies representative of small farms in an area. The focus is on important general problems in the development of small farms.

Specific policies and programs are discussed, aimed at increasing production, transforming the traditional peasant farming into science-based agriculture, and accelerating development on small farms.

Tradition and Dynamics in Small Farm Agriculture

IOWA STATE UNIVERSITY PRESS, *Box TR-2, South State Avenue, Ames, Iowa 50010*

Announcing publication of the second volume of an important work

A SURVEY OF AGRICULTURAL ECONOMICS LITERATURE

Volume 2, Quantitative Methods in Agricultural Economics, 1940s to 1970s
Lee R. Martin, general editor; George G. Judge, Richard H. Day, S. R. Johnson, Gordon C. Rausser, and Lee R. Martin, volume editors

This is the second volume of a comprehensive three-volume work *A Survey of Agricultural Economics Literature*, published for the American Agricultural Economics Association. Members of the association may order copies at a special price (see order form for details).

Table of contents for Volume 2:

Part I. Estimation and Statistical Inference in Economics. Estimation and Statistical Inference in Economics. George G. Judge. Discussion of George G. Judge's "Estimation and Statistical Inference in Economics." Richard J. Foote.

Part II. Economic Optimization in Agricultural and Resource Economics. On Economic Optimization: A Nontechnical Survey. Richard H. Day. Optimization Models in Agricultural and Resource Economics. Richard H. Day and Edward Sparling. Agricultural Production Function Studies. Roger C. Woodworth.

Part III. Systems Analysis and Simulation in Agricultural and Resource Economics. Systems Analysis and Simulation: A Survey of Applications in Agricultural and Resource Economics. S. R. Johnson and Gordon C. Rausser.

Part IV. Agricultural Economic Information Systems. Developments in Agricultural Economic Data. M. L. Upchurch. Technical Developments in Agricultural Estimates Methodology. Harry C. Trelogan, C. E. Caudill, Harold F. Huddleston, William E. Kibler, and Emerson Brooks. Assessment of the Current Agricultural Data Base: An Information System Approach. James T. Bonnen. Rural Economic and Social Statistics. W. Keith Bryant.

Appendix. A Brief Review of the Literature by subject category. References.

Note: *Volume 1, Traditional Fields of Agricultural Economics, 1940s to 1970s*, edited by Lee R. Martin, was published in January, 1977.

The regular price of Volumes 1 and 2 is $25.00, each volume. Members of the American Agricultural Economics Association may order copies at a special price of $18.00 each volume ($20.00 outside the U.S.), postpaid. Send your order now (special price offer for Volume 1 good only until January 19, 1978).

Image and Reality in Economic Development

Lloyd G. Reynolds

In a major contribution to the study of development economics, Reynolds sums up the fundamental elements in this important new branch of economics and tests some of its key concepts against the available historical and empirical evidence. A Publication of the Economic Growth Center, Yale University $25.00

Now available in paper

Up to the Mountains and Down to the Villages

The Transfer of Youth from Urban to Rural China

Thomas P. Bernstein

Between 1968 and 1975 the People's Republic of China sent twelve million urban middle and secondary school graduates to the countryside, evidently for life, in an effort to control urban growth and spur rural development. In the first detailed analysis of the program by a Western scholar, Bernstein presents carefully documented information on what has undoubtedly been one of the largest social experiments of this century in any country. Illus. $17.50

Agriculture in Development Theory

edited by Lloyd G. Reynolds

"Those interested in agricultural development and its relationship to economic development will find this volume to be a useful reference."
—*American Journal of Agricultural Economics*

"A comprehensive and encyclopedic coverage of material by an international group of scholars. . . . Should be read by every teacher, student, and practitioner of agricultural economic development."—*Choice*

A Publication of the Economic Growth Center, Yale University Cloth $25.00 Paper $6.95

The Moral Economy of the Peasant

Rebellion and Subsistence in Southeast Asia

James C. Scott

"In this major work, . . . Scott views peasants as political and moral actors defending their values as well as their individual security, making his book vital to an understanding of peasant politics."—*Library Journal*

"[This book] is regarded in the field of Southeast Asian studies as one of the most important works of its time."—*Asia Bulletin*

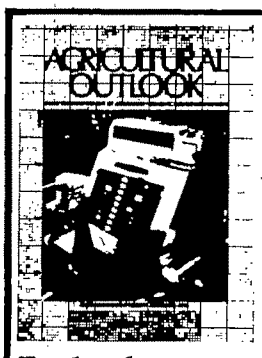
WAERSA/CAB ABSTRACTS ON-LINE

CAB ABSTRACTS, the world's leading database in agriculture and related fields are now available on-line through Lockheed's DIALOG Retrieval Service.

Features of the service include:



—records taken from 8,500 world serials in 37 languages
—450,000 records on tape for 1972 to 1976, increasing by 10,000 monthly
—searches may encompass the whole database or be limited to one or more journals like WAERSA, or to groups of "animal" or "plant" subfiles.

WORLD AGRICULTURAL ECONOMICS AND RURAL SOCIOLOGY ABSTRACTS (WAERSA) is still available both in its normal form and in microform at the same price. In 1976 it included 7,683 fully indexed abstracts on agricultural economics and policy; development and agrarian reform; land use and conservation; rural development; supply, prices, marketing and trade; farm management and production economics; education, extension and research; co-operation; rural sociology.

1977 Subscription Rates: US$110 (1 year) US$210 (2 years)
£24.88 (1 year) £46.00 (2 years) (members of CAB)

Statement of Ownership, Management, and Circulation (Act of 23 October 1962; Section 4869, Title 39, United States Code)

1. Title of Publication: *American Journal of Agricultural Economics*
2. Date of filing: 8 September 1977
3. Frequency of issue: Quarterly and December Proceedings issue (February, May, August, November, and December). (*a*) No. of issues published annually: 5. (*b*) Annual subscription rate: $12.50; $25.00 and $35.00.
4. Location of known office of publication: Department of Agricultural Economics, University of Kentucky, Lexington, Kentucky 40506
5. Location of headquarters or general business office: Department of Agricultural Economics, University of Kentucky, Lexington, Kentucky 40506.
6. Name and addresses of publisher, editor: American Agricultural Economics Association, Department of Agricultural Economics, University of Kentucky, Lexington, Kentucky 40506; Editor: William G. Tomek, Department of Agricultural Economics, Cornell University, Ithaca, New York 14853.
7. Owner: American Agricultural Economics Association, Department of Agricultural Economics, University of Kentucky, Lexington, Kentucky 40506.
8. Bondholders, mortgagees, and other security holders: none
9. Nonprofit organization: status unchanged during preceding twelve months.
10. The following circulation figures are provided for (*a*) the average number of copies of each issue during the preceding twelve months and (*b*) the single issues nearest to filing date:

	Average Copies	Actual Copies
Total number of copies printed	(*a*) 6,500	(*b*) 6,500
Circulation		
Sales through dealers, carriers, etc.	(*a*) None	(*b*) None
Mail subscriptions	(*a*) 6,106	(*b*) 6,106
Total paid circulation	(*a*) 6,106	(*b*) 6,106
Free distribution	(*a*) 3	(*b*) 3
Total distribution	(*a*) 6,109	(*b*) 6,109
Office use, leftover, inventory, balance, etc.	(*a*) 391	(*b*) 391
Returns from news agents	(*a*) None	(*b*) None
Total	(*a*) 6,500	(*b*) 6,500

Information on Submitting Manuscripts

1. **Cover letter.** In a cover letter to the editor, the author must state (*a*) that the material has not been published, and is not being published or being considered for publication elsewhere; (*b*) that the material in the manuscript, so far as the author knows, does not infringe upon other published material protected by copyright; and (*c*) that he or she is aware that each issue of the *Journal* is copyrighted, that submission of a manuscript to the *Journal* gives the AAEA the right to publish and to copyright the material, and that republication elsewhere at a later date is contingent upon written approval from the *Journal* editor. If the applicability of point (*a*) is unclear, the author should provide an explanation of the publication status of the manuscript.
2. **Author's identification.** In order to protect their anonymity in the review process, authors should avoid identifying themselves in the manuscript. Attach a separate page including the names of the author(s) and appropriate biographical information, as well as the title of the manuscript. Include only the title on the first page of the text.
3. **Typing.** Double-space all material, including footnotes, tables, quotations, and references, on 8½-by-11-inch standard weight white paper with margins on all sides of at least 1¼ inches.
4. **Style.** Follow *A Manual of Style* by the University of Chicago Press as well as previous issues of this *Journal*.
5. **Mathematical notation.** Use only essential mathematical notation; such notation is costly to typeset and may limit the readership. Avoid using the same character for both superscripts and subscripts, using capital letters as superscripts or subscripts, and using overbars, tildes, carets, and other modifications of standard type. Asterisks, primes, and small English letter superscripts are suitable substitutes.
6. **Footnotes.** Number footnotes consecutively throughout the paper, not page by page. Type the footnotes, double-spaced, on a page following the article. The institutional paper number and acknowledgments, if any, should be placed at the beginning of the list of footnotes. Footnotes should be only explanatory and should not be used for citations or for directing the reader to a particular work. This information can be incorporated into the text itself.
7. **References and citations.** Place all references, alphabetized by author, in a list at the end of the paper entitled "References." Only cited works should be included in the reference list. All citations should appear in the text and contain the author's name and page numbers, when necessary. Citations can be inserted parenthetically, e.g., (Doe) or (Doe, p. 5). Specify the date of publication if the same author appears more than once in the reference list, e.g., (Doe 1971, p. 5). If the author's name appears as part of the sentence, a parenthetical reference is unnecessary unless you need to cite page numbers or a date. A style sheet on references and citations is available upon request.
8. **Tables.** Place each table on a separate page; double-space all material; omit vertical rules.
9. **Figures.** Prepare figures on heavy white paper or acetate sheeting using black India ink or paste-up types suitable for black and white reproduction by a photographic process. Typescript is not suitable.
10. **Three copies.** Send the typed original and two carbon copies or photocopies. All copies should be inspected for completeness and quality of reproduction.
11. **Abstract.** Instructions for the preparation of an abstract will be sent when the manuscript is accepted for publication.
12. **Page charge.** Published contributions are subject to a page charge of $40 per printed page or fraction thereof, payable by a supporting institution or granting agency. Exemptions are granted for book reviews, the presidential address, the fellow's lecture, and those invited addresses and papers receiving written exemption from the AAEA president. Payment of the page charge is not a prerequisite for publication. If the charge is honored, 100 reprints are provided. Instructions for making payment and for requesting an exemption are provided with galley proofs.

American Agricultural Economics Association

President /R. James Hildreth, Farm Foundation
President-Elect /Bernard F. Stanton, Cornell University
Secretary-Treasurer /John C. Redman, University of Kentucky
Past-President /Kenneth R. Farrell, Economic Research Service

Directors

Wallace Barr, Ohio State University
Joseph D. Coffey, Virginia Polytechnic Institute and State University
Richard T. Crowder, Pillsbury Co.
Sylvia Lane, University of California, Davis
Philip M. Raup, University of Minnesota
G. Edward Schuh, Purdue University

Objective

The AAEA seeks to further the systematic development of knowledge of agricultural economics in order to improve agriculture and agriculture's contribution to the general economy. The activities of the AAEA include:

—publishing the *American Journal of Agricultural Economics;*
—planning and conducting two annual meetings of the membership;
—sponsoring annual awards for outstanding extension programs, distinguished teaching, and outstanding research;
—recognizing outstanding agricultural economists through a fellows program;
—supporting a literature retrieval system in cooperation with the U.S. Department of Agriculture;
—publishing periodically a biographical directory of the AAEA's members;
—supporting an employment registry for agricultural economists in cooperation with the U.S. Department of Labor.

Membership and Subscriptions

Membership in the AAEA is open to individuals having a professional interest in agricultural economics. Dues, payable at the beginning of each calendar year, are as follows: regular members, $25, senior members, $12.50, and junior members, $12.50. Senior membership is open to persons, upon written request, who are sixty-five years of age or older and have retired from active professional work. Junior membership is for students and is limited to three years; students should use application forms available from and signed by the head of the department in which they are studying. Members receive this *Journal.*

Any firm, corporation, association, or partnership may become an institutional member upon payment of $100 per year; institutional members receive three copies of each issue of the *Journal.* Library subscriptions are $35 per year. Individual issues of this *Journal* are $10.00.

Payment of membership dues, correspondence regarding subscriptions, orders for individual copies of the *Journal,* changes in address, or inquiries about the general affairs of the AAEA should be sent to John C. Redman, Secretary-Treasurer, American Agricultural Economics Association, Department of Agricultural Economics, University of Kentucky, Lexington, Kentucky, 40506.

The *American Journal of Agricultural Economics* is published five times a year (February, May, August, November, December) by the American Agricultural Economics Association. Prior to 1968, this *Journal* was the *Journal of Farm Economics.*

Printed for the AAEA by Heffernan Press, Inc., Worcester, Massachusetts, USA.

Second class postage paid at Lexington, Kentucky, and additional mailing offices, Pub. No. 019500.

Copyright © 1977 by the American Agricultural Economics Association.

An article, note, or other material appearing in the *American Journal of Agricultural Economics* may not be republished in full or in part without the express written permission of the editor.

Editorial Policy

The purpose of the *Journal* is to provide a forum for creative and scholarly work in agricultural economics. Thus, acceptable manuscripts should have a relationship to the economics of agriculture, natural resources, or rural and community development. Contributions, methodological or applied, in the business, extension, research, and teaching phases of agricultural economics are equally encouraged.

Editorial Communications

All manuscripts and editorial correspondence, except as noted below, should be addressed to the editor, V. James Rhodes, Department of Agricultural Economics, Mumford Hall, University of Missouri, Columbia MO 65201.

Communications concerning book reviews and books submitted for announcement in the *Journal* should be sent to the book review editor, Herbert H. Stoevener, Department of Agricultural Economics, Oregon State University, Corvallis OR 97331.

Lowell S. Hardin

1977 Fellow

Professor, Department of Agricultural Economics, Purdue University, 1943–65; head of department, 1957–65.
Program advisor, program officer, Ford Foundation, 1965–present.
Consultant, Office of State Experiment Stations; member, Agricultural Board, National Academy of Sciences, 1966–72; member, Panel of President's Science Advisory Committee on World Food Supply, 1966–67.
Secretary-treasurer, American Farm Economics Association, 1953–57; vice-president, 1959; president, 1963–64.

Lowell S. Hardin has achieved an international reputation as a builder of professional talent and institutions. He has been a perceptive student of world agriculture, and he has contributed significantly to the joining of agricultural sciences with socioeconomic and policy concerns. Much of his influence is not copyrighted but reflected in the expressions, writings, and programs of others. He has given unselfishly of himself behind the scenes to nurture and encourage the professional growth of numerous students and colleagues. This style is characteristic of the best teachers and of the most self-effacing "developers of human capital."

Born in 1917 in Indiana, Hardin received his B.S. in agriculture from Purdue University in 1939 and his Ph.D. from Cornell University in 1943. He joined the Purdue staff in 1943 as an instructor and assistant director, National Work Simplification Project.

At Purdue University, Hardin had a distinguished career in teaching, research, and administration. He did pioneering research in work simplification and helped popularize techniques that in part contributed to today's operations research methodology. His book, *Farm Work Simplification,* is a landmark in the field.

Lowell Hardin was recognized as an excellent teacher by both his students and peers. He had a knack for bringing the practical into the classroom and, in the process, making important concepts come alive. Later, as an academic administrator, he led a development that saw traditional departments of agricultural economics transformed into departments that grappled with broad applications of economics to social and economic problems.

In 1965, Hardin joined the Ford Foundation. He was initially responsible for Foundation

agricultural programs in Latin America, but his responsibilities were later broadened through joint appointments to the Foundation's Office of the Vice-President (International Division) and the Office of the Middle East and Africa, with management project development, and monitoring responsibilities for several hundred projects around the world, and a significant share of the Foundation's budget for overseas operations. He has played a key role in the development of the international agricultural research centers and helped spearhead the creation of the Consultative Group for International Agricultural Research.

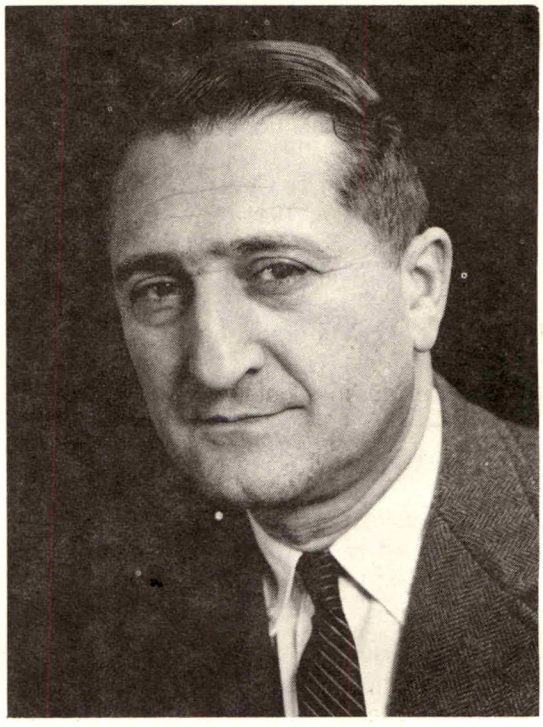
Hardin has been an intellectual leader, synthesizer and conceptualizer, "entrepreneur" innovator, and diplomat/statesman *par excellence*. He is specially noted for inviting the expression of contrary views and for absorbing and blending them into new ideas that push hard on the frontiers of conventional wisdom. In all of this, his wife, Mary, has been a constant partner. They have given unselfishly of themselves to help others realize their professional and personal potential.

Austin C. Hoffman

1977 Fellow

Vice-president, Kraft Foods, 1944–70; retired since 1970.
Director of Food Price Control, Office of Price Administration, 1941–43.
Economist, Division of Marketing Research, Bureau of Agricultural Economics, 1935–40.
Economist, Agricultural Adjustment Administration, 1934.
Assistant professor, University of Wisconsin, 1931–33.

Austin C. "Oscar" Hoffman is an agricultural economist who has blended with distinction careers in teaching, research, public service, and private agribusiness. While working with the late Frederick V. Waugh in the Bureau of Agricultural Economics, he was an innovating pioneer in the industrial organization approach to research in agricultural marketing. In the late 1930s, he contributed to marketing publications of that agency and of the Temporary National Economic Committee. His work on the economic principles of the Food Stamp Plan was original and anticipated later inquiry.



During World War II, Hoffman played the important role of directing control of food prices in the Office of Price Administration.

Beginning in 1944, he carved out a new career. As vice-president in charge of purchasing for Kraft Foods, he devoted his talents to management. He did not lose his scholarly research interests. He served frequently in liaison between business and academic economists. He took part in panel discussions, research symposia, and similar sessions. One of his published contributions was his penetrating analysis of the economics of conglomerate growth (1969). Since retirement he has continued to be professionally active. He has appeared before committees of the U.S. Congress to offer counsel on issues in industrial organization and antitrust policy. For years he has been a member of the Agricultural Committee of the National Planning Association.

It is a truism that most individuals are best able to perceive economic events when objectively detached from them. Rarely can an agricultural economist philosophize about the sector in which he is aggressively engaged. Not often can he see the broader public interest when daily concerned with the private interest. Hoffman has been simultaneously philosopher and practitioner in the marketing system for the products of agriculture. Our profession is the richer for his unusual capability.

Sidney S. Hoos

1977 Fellow

Professor, Department of Agricultural Economics, University of California, Berkeley.
Dean, academic personnel, University of California, Berkeley, 1964–67.
Consultant, Agricultural Settlement Department, Israel, 1960–61.
Chief economist and deputy chief, Requirements Branch Office of Quartermaster General, U.S. War Department, 1942–45.
Senior economist, assistant to president, Commodity Credit Corporation, Department of Agriculture, 1941–42.

Sidney S. Hoos grew up in Old Town, Maine. Mathematics and economics lured him from a career of teaching and playing the violin. He attended the University of Maine and the University of Michigan, where he received his B.S. in mathematics. The course of his life was changed by his decision to enroll in an economics course given by Visiting Professor Holbrook Working. He received his M.S. from the University of Michigan and then joined the Food Research Institute at Stanford, where he studied under Working. He earned his Ph.D. in economics in 1939 and accepted an appointment with the Giannini Foundation and the Department of Agricultural Economics, University of California, Berkeley.

Six months prior to World War II, Hoos went to Washington as an assistant to the president of the Commodity Credit Corporation. When the war started, he joined a small group in the War Department assigned the task of improving the methods used to determine material requirements for the Army. There he played a leading role in the development of the Army Supply Program, which was eventually adopted throughout the Army. He received a special commendation from the Commanding General for his work.

After the war, Hoos returned to Berkeley and resumed his career in undergraduate and graduate teaching, research, and public service. At an early age he was given full professorship in the Departments of Agricultural Economics, Economics, and Business Administration. Hoos had the reputation of being a dedicated and demanding teacher of students from all over the world.

Sidney Hoos worked closely with California agricultural industries in the application and implementation of research on their problems—research that he conducted with Harry R. Wellman and George M. Kuznets. His contributions to the agriculture of the state were recognized by numerous citations and

awards of merit. He also consulted with and advised state and federal government agencies and officials. His distinguished service to foreign governments earned him international stature and reputation. His long and varied bibliography includes articles in trade and professional journals, contributions to many books, and many reports.

Hoos's commitment to good citizenship has resulted in his serving and giving leadership to many significant committees and boards in the community and university. However, his heavy schedule in teaching, working with students, and in research continued unabated.

Throughout his career, Hoos has been an active member of our profession. He helped guide the Western Agricultural Economics Research Council through its formative years, and he served as president of the Western Agricultural Economics Association. He also served as vice-president of the American Agricultural Economics Association and made significant contributions on many AAEA committees.

Earl R. Swanson

1977 Fellow

Professor, Department of Agricultural Economics, University of Illinois, 1950–present; associate head, 1967–70; acting head, 1974–75.

Editor, *American Journal of Agricultural Economics,* 1965–68.

Member, Hazardous Materials Advisory Committee, U.S. Environmental Protection Agency, 1971–74.

Member, Corn/Soybean Study Team of the Study of Problems of Pest Control; A Technology Assessment, National Academy of Sciences, 1973–75.

Chairman, Selection Committee on Publications of Enduring Quality, American Agricultural Economics Association, 1974–75.

Cochairman, AAEA-ERS-SRS Committee on Agricultural Capacity, 1976–77.

Member, Research Advisory Committee, Agency for International Development, Department of State, 1976–77.

Ernest H. Wakefield Award, 1975, Agricultural Alumni Award of Merit, 1976, Paul A. Funk Award, 1977, University of Illinois.

Earl R. Swanson has been a leader in developing and applying the concepts of production economics and operations research to farm management, aggregate farm output analyses, the economics of soil and water conservation, and the impacts on farm output of public policy alternatives with respect to environmental quality.

Born in 1921 in Illinois, Swanson received his B.S., with highest honors, from the University of Illinois. He completed his M.S. at the University of Minnesota and his Ph.D. at Iowa State University. He also did postgraduate work at the University of Oslo, Norway. He joined the Department of Agricultural Economics, University of Illinois, in 1950.

Swanson has excelled in the depth of his analysis and in his ability to coordinate and lead research involving researchers from other disciplines. Publications by him attest to the care and creativity of his analysis and to his skill in communicating the results to others. He has made significant contributions to his department, college, and university and to numerous national and international committees concerned with public policy impacts on farm production. These contributions flow from the excellence of his research, his depth of knowledge, and the more subtle characteristic sometimes called wisdom and other times called good sense.

He has led in the development of operations research techniques for the analysis of farm management and aggregate farm production problems. He developed production models that incorporate dynamic features that take account of risk and the time horizon and integrate cropping and livestock systems that incorporate enterprise complementarities and

diminishing marginal returns. He analyzed difficulties involved in making the transfer of experimental results to actual farm operations and suggested methods for overcoming them.

Swanson has also provided empirical evidence that helps in understanding the differences and congruencies of private (farmer) and public interests in soil erosion control. Objective appraisal of public policy alternatives to take these differences into account has been a key feature of aggregate farm production analyses undertaken by him. His recent research activity has centered on decision processes related to environmental quality, technology assessment of weather modification, and measurement of agricultural production capacity.

He has been a visiting professor, Hokkaido University, Japan; Fulbright Research Scholar, Royal College of Agriculture, Denmark; visiting lecturer, USSR, under the US-USSR Cultural Exchange Program; consultant, Ford Foundation, India; research scholar, International Institute for Applied Systems Analysis, Austria; and visiting scholar, U.S. Environmental Protection Agency.

Throughout his career, Swanson has fostered and shared with his students and fellow workers an unusual skill to ask the right questions and to untangle the complex questions.

R. J. Hildreth

1977–78 President

Managing director, Farm Foundation.
Secretary-treasurer, International Association of Agricultural Economists, 1973–present.
Member, American Agricultural Economics Association; Agricultural Economics Society, England; Western Agricultural Economics Association; American Economics Association; Southern Agricultural Economics Association; Canadian Agricultural Economics Association; Phi Kappa Phi; Sigma Xi.

R. J. Hildreth is managing director of the Farm Foundation, Oak Brook, Illinois, a position he has held since 1970. Prior to that time he served as associate managing director of the Foundation.

Hildreth was raised on a farm in central Iowa. He did his undergraduate work in industrial economics at Iowa State University, where he specialized in labor economics for his M.S. The following two years he taught at Augsburg College, a small liberal arts college in Minneapolis, Minnesota. After receiving his Ph.D. from Iowa State University in 1954, he spent four years teaching and researching farm management and production economics in the Department of Agricultural Economics, Texas A&M University. He became research coordinator for West Texas in 1958 and assistant director of the Texas Agricultural Experiment Station shortly thereafter. In this position he was responsible for research project development.

He has written broadly in the field of agricultural economics. His writings include journal articles and experiment station publications; he has contributed chapters to a number of books, edited a book of readings in agricultural policy, and coedited a book on research methods in resource economics.

Hildreth has long been active in the AAEA. He has served on the Board of Directors and as chairman of the Visiting Lecturer Committee, the Professional Activities Committee, and the Economic Statistics Committee.

The American Agricultural Economics Association: Its Prospects

R. J. Hildreth

The American Agricultural Economics Association (AAEA) is at a significant juncture. Breimyer, in his 1968 presidential address, said, "the . . . Association (will) want to give thoughtful attention to how it can best conduct its internal affairs in the years to come" (p. 1111). Almost a decade later, few people inside or outside the Association appreciate the significance that should be attached to the direction we take.

Many Association members have a hard time seeing the linkage between activities of the Association and the contribution our profession can and should make to the well-being of people in society. Many members expect the officers to keep the Association providing the services they desire at a reasonable cost and do not wish to spend too much time on its affairs. A successful Association requires active support and participation from its members.

If I were to propose to terminate the Association, concern would be expressed by a large number of members. Such a proposal would likely lead to considerable excitement and perhaps some useful discussions. I do not choose to put forth such a proposal but rather to discuss less drastic alternatives. I hope in this process to stimulate useful discussion to improve the workings of the Association.

My discussion starts with an examination of the relationship of the Association and its members, then the relationship of the Association and society. Some opportunities for the Association are presented, and two strategies for the Association are developed.

Presidential address.

R. J. Hildreth is the managing director, Farm Foundation.

The author is indebted to the agricultural economics faculties at Cornell University, University of Illinois, Oklahoma State University, Pennsylvania State University, Purdue University, Washington State University, University of Wisconsin, as well as the Economic Research Service, U.S. Department of Agriculture staff, where he presented seminars on the topic. He also profited from reviews of early versions of the paper from the officers and directors of the AAEA, members of the Professional Activities Committee, and other colleagues. Appreciation is expressed to Madelyn Naumes for hard work and care in preparation of the drafts of this paper. However, they are in no way responsible for the contents.

The AAEA and Its Members

The changing nature and structure of the profession was described by Bonnen in his "Report of the President." He said, "Twenty years ago, to be an agricultural economist was automatically to be a member of the AAEA. That was the way in which one identified oneself; it was universally expected" (p. 1033). Today, the situation is different.

A characteristic of professional groups is that they "profess" something. The "profession" of agricultural economics groups has moved from a few concerns to many and diverse concerns. The diversity of the membership of the profession and the Association has increased. There has been increasing specialization among agricultural economists. Agricultural economists are fragmented into many, far narrower, specialties than in the past. Regional interests have led to the growth of regional associations in the South, the West, and the Northeast. Members have interests in research, teaching and extension, and administration. Some members work for universities, for the government, for private firms, or even for thenselves. Most academicians work for land-grant universities, while others work for state universities or community colleges.

Johnson's paper, given at the recent International Conference of Agricultural Economists, usefully illustrates the diversity. He discusses the contribution of agricultural economists in roles as participants in decision making, as doers of subject matter analysis, and as doers of disciplinary analysis. He suggests all three roles are important, and none should be denigrated. Participants in decision making focus on a specific particular problem, and the economic analyst in this process "contributes theory, empirical knowledge, and command over quantitative techniques for handling empirical information and for processing it into prescriptions" (pp. 29–30). Subject matter analysis is designed to bring to-

gether information on a specific subject that would be relevant for solving a set of problems requiring that kind of information. Johnson defines economic disciplinary analysis as "attempts to improve theories, quantitative techniques and data of economics" (p. 34).

Agricultural economists participate in one or more of these roles. Thus, I prefer to use the word "profession," as opposed to "discipline," when speaking about the full range of activities of people who were trained as agricultural economists and call themselves agricultural economists.

These trends and issues are not unique to the United States. Kenneth Hunt of Oxford University, reviewing agricultural economics in Great Britain since the 1920s, observes the principal aim in the 1920s and early 1930s was supplying farmers' needs for management advice. He offers among his conclusions the following: "Increased professionalism, besides giving much greater operational skills to decision makers, has (i) encouraged segmentation of the subject as it stood, (ii) created an interest in the academic aspects as such—in the pursuit of knowledge and not in application. . . . These tendencies have led to the formation of various specialists' societies and journals (e.g. in connection with labour, farm management, rural sociology, administration, history, food policy) developments which seem to have been viewed with fairly unalloyed approval as a contribution to high professional standards" (p. 293). Hunt concludes that these and other developments have resulted "in British agricultural economists being unsure of the proper boundaries of their work—either subjectwise (e.g. toward politics) or in the field (e.g. toward food industries)" (p. 293).

The "concerns" (both meanings: a business and solicitous regard) of agricultural economists have become broader and more diverse (Hunt). Most members still acknowledge being agricultural economists but add an individual, specialized identification. The glue that held the profession together has become less sticky.

Benefits and Costs of AAEA Membership

At the same time that the diversity within the profession has increased, the services provided by the AAEA have remained quite general and collective in nature; that is, most of its services are available to members and nonmembers alike. Thus, it has become difficult for many members of the profession to identify closely with the Association. It is not surprising that most individuals question the value of being a paying member, since as nonmembers they can gain most of the benefits.

What are the benefits and costs of Association membership to individual agricultural economists? The costs are relatively easy to determine. They mainly consist of dues of $25 per year for regular members.

There are certain costs for those who become active in the Association as officers and committee members. However, these latter costs need not concern us a great deal, as the individuals would not become active in the Association unless the benefits, however measured, were greater than the cost to themselves.

The benefits from the Association vary from individual to individual. When the question is raised as to the benefits of joining the Association, the response that comes forth early in the conversation is the *American Journal of Agricultural Economics*. What benefits does the *Journal* provide the members of the Association? It is a source of new ideas in the field of agricultural economics. The *Journal* provides an opportunity to publish and so have one's ideas subject to peer review. An article in the *Journal* is an important factor in promotion and tenure for university economists. Another benefit from having an article in the *Journal* is an increase in self-esteem above the tangible promotion and tenure benefits. The *Journal* can also be put on the shelf for later reference; it also may be put on the shelf for the status it gives by having it on the shelf for others to see.

The benefits from participation in annual meetings are often mentioned in discussing the Association. The benefits are diverse and often subtle. The annual meeting is a very large information exchange with the content ranging from highly technical to rumors. The annual meeting provides a chance to see your classmates from graduate school and also their families—as long as the Association meets on campuses with low-cost facilities. The annual meeting provides a meeting time and place for technical committees as well as committees planning other activities in the profession.

A major service of the annual meeting is related to the role of the Employment Committee. One of the benefits of Association

membership is the market for jobs it provides at the annual meeting, and during the year through the efforts of this committee and the employment registry. This service is of considerable importance to graduate students, members of the Association who wish to change jobs, and employers desiring to hire agricultural economists. If the Association were disbanded, the function of recruitment and job hunting probably would be quickly institutionalized in some other form.

The services provided by the *American Bibliography of Agricultural Economics* is directly useful to some members. The small subscription list when it was published in hard copy is evidence that the number is limited. Since the *Bibliography* has been "on line" only a short time, it is difficult to determine how much use has been made of it. Approximately thirty departments of agricultural economics have access to the information through their university library terminals. It has a large potential for the profession as well as individual members.

A very real benefit to the individual member is contained in the belief that the Association contributes to the general good of the United States and world society. Many individuals may receive few tangible benefits from their membership in the Association, but they are convinced that the growth and development of the profession is important to society, and they wish to have a part in supporting that kind of contribution to society.

In summary, it may be helpful to think of AAEA as a system of five services to its members: *(a)* information services such as literature retrieval, search and documentation center, and news notes; *(b)* educational services like papers at annual meetings, *Journal* articles, seminars and conferences, and book reviews; *(c)* legitimating services like publication in *Journal,* awards program, and use of Association credentials; *(d)* employment services such as the registry and job market at annual meetings; and *(e)* fraternal services like social events (formal and informal) at annual meetings, some aspects of awards program. The system is not completely specified. Some items, such as the *Journal,* have a long history; others, such as the employment registry, are developing.

How could the Association improve its services to members? Examples include increasing the coverage and use of the services of bibliographic search and documentation center, especially international literature, and publishing more abstracts in the *Journal* (informational services); developing alternative subject matter publications of interest to specialized subject matter groups and holding seminars and workshops for specialized subject matter groups (educational services); developing a program to certify agricultural economists and accredit departments of agricultural economics, and increasing the opportunity to publish *Journal* papers by an alternative publication or expansion of the *Journal* (legitimating services); developing a year-round job market, in addition to the registry and annual meeting job market (employment services); and offering insurance to members, providing tour and travel services (fraternal services).

Another set of issues deals with the roles of agricultural economists discussed earlier. How can the Association better serve agricultural economists in the roles of participant in decision making, doers of subject matter analysis, and doers of disciplinary analysis? How can the Association promote and develop the better use of economic theory and contribute to theory development? How can the Association assist the very specialized subject matter analysts who are members of the Association to gain knowledge and insight from theory as well as the experience of participants in decision making? How can the Association improve the distribution of the results of subject matter analysis and disciplinary analysis?

The present and possible set of services are broad and diverse. In addition to the level of services provided, questions of the mix of services exist. Decisions about the level and mix of services are related to resources available to the Association.

Public Good Aspects of AAEA Services

Many of the services of the Association have public good aspects for members of the profession. The usual characterization of a pure public good includes indivisibilities in production, as well as jointness of supply and inefficiency of excluding others from its consumption, once it has been supplied to some members of the community (Mueller). It is difficult to exclude nonmembers from the user benefits of the *Journal,* the annual meeting, the registry, and the general society good produced by the Association. It would also be difficult for an individual member, depart-

ment, or organization to produce these goods. While Association services are not pure public goods, they are close enough for public goods analysis to be useful.

The property of difficulty of exclusion raises the probability that purely voluntary methods for provision of the public good will break down because of freeloading. As the size and heterogeneity of the community of potential users increases, freeloading increases. Faced with some deterioration in the financial state of the Association and increased awareness of this logic, the Board in 1976 adopted the following policies governing services: *(a)* the AAEA should, in general, limit committee membership to AAEA members; *(b)* higher registration fees are to be charged nonmembers registering to attend the annual meeting; and *(c)* the privilege of presenting contributed papers, as well as presenting and discussing invited papers at the annual meetings, should be limited to AAEA members, except in special cases in which the condition is waived by the president. These moves, as well as other items under study, would make a careful and thoughtful transformation of what have been collective goods available to all into selective goods available only to members or at preferential rates to members.

Publication in the *Journal* has private good aspects for the author's organization. The decision in 1975 to institute page charges is a recognition of this fact, as well as the need for income.

The literature dealing with public choice also discusses quasi-public goods. Pure public goods require some voting process for revealing preferences. For private goods, the entry and exit of buyers and sellers perform the same function. However, quasi-public goods require a mixture of entry, exit, and voting processes.

Two methods that have been suggested for dealing with quasi-public goods are "voting with the feet" and "theory of clubs." The voting-with-the-feet process is useful when the assumption of joint supply is dropped. The preference for the quasi-public goods is revealed through the silent voting with the feet of individuals exiting and entering communities producing the various combinations of quasi-public goods. Voting with the feet groups individuals together in communities of homogeneous tastes.

The theory of clubs operates when exclusion is possible and the addition of a member lowers the average cost of a good. A club of people with homogeneous preferences is formed to take advantage of economies of scale. In regard to clubs, Mueller concludes, "The voluntary formation of clubs to allocate public goods is efficient only when the optimal club size is relatively small, i.e., when the quasi-public goods have a limited degree of publicness" (p. 413).

Thus, both methods result in a group with homogeneous preferences producing a quasi-public good. The growth of new journals in areas of consumer affairs, recreation, natural resources, operations research, etc., may well be examples of these ideas. The formation of regional associations is also a weak example. It would be possible for the Association to adopt a structure that would foster within the Association small groups with homogeneous preferences, such as farm management extension economists, undergraduate teachers, etc. Such a course of action would create a snug harbor for the diverse interests with opportunities for venturing out to the larger sea of agricultural economics.

Financial Resources

Present and potential services to society and members are constrained by financial resources. The AAEA, while a not-for-profit organization, is clearly a not-for-loss one. It is instructive to examine membership and financial data of the Association for recent years. The total number of members and subscribers reached a high point in 1975 (5,966) after a low point in 1973 (5,478) and some recovery in 1974 (5,775) (Redman). As will be reported, the total in 1976 was 5,841. The dip in membership in 1973 was caused by a substantial decline in regular members. Regular members increased from 3,282 in 1975 to 3,497 in 1976; the year dues increased from $15 to $25. Foreign members and subscriptions have remained a fairly constant percentage of total members and subscriptions: about 33%.

The issue of market penetration, the number of potential members compared with membership in the Association, is often raised. In 1975 the Membership Committee concluded that only one-half of all U.S. agricultural economists are members of the Association. Further analysis will be forthcoming from the Membership Committee.

Turning to the financial affairs of the Association, the balance of income and expenses

was negative in 1974 and 1975 (Redman). The balance for 1976 was positive; we are back in the black. Income rose in 1973, 1974, and 1975, but costs rose faster during this period. Since the books are kept on a cash basis, the numbers for one year do not necessarily reflect the income and expense of that year's activity. An accrual accounting system would give more information.

The structure of costs of the Association is similar to that of a motel or hospital. Practically all of the costs are fixed within a one-year period. A decrease or increase in membership of 500 to 1,000 would have little effect on the expenses of the Association. The only variables would be postage and paper for the *Journal* and the secretary-treasurer's office expense. All other costs remain relatively fixed. Thus, increases or decreases in membership have great effect on the financial position of the Association.

There is a reasonable probability that the Association can equate income and expenses over the next few years with present activities. *Journal* costs probably will not increase as rapidly as in the past. Expanded membership would assist the income side. The Association will have to manage carefully to equate income and expenses, but it likely will be achieved.

The AAEA and Society

U.S. society sanctions the AAEA by providing special status to it as a nonprofit organization. In beginning a discussion of the Association and society, it may be useful to ask why this is so. The answer appears to be found in society's views toward professional associations, not just our Association. Through its various and diverse decision units, society acts as though development of knowledge in a professional field is a good thing. The Constitution of the AAEA recognizes this point of view. Article II states: "The object of the Association is to further development of systematic knowledge of agricultural economics" (*Handbook-Directory*, p. 10).

Just as the membership of the Association is heterogeneous, so is U.S. society. It is made up of many publics that have an interest in agricultural economics knowledge. Listed among these publics would be consumers, farmers, firms selling to and buying from farmers, food processing and distribution firms, managers of natural resources, community and local government officials, students, professionals in related social science and agricultural fields, and universities. Each group views the Association and the related profession of agricultural economics from a slightly different perspective. However, it is likely that the various publics see the affairs of the Association as a means, not an end.

The systematic knowledge developed as a result of Association activities enables society to understand and predict phenomena in agricultural economics as well as develop and evaluate alternative courses of action for decision. The AAEA is a means for the improvement and development of agricultural economics knowledge, which, in turn, is a means of dealing with the many and varied problems faced by the society and its parts.

The Value of Agricultural Economics Knowledge

The increased demand for agricultural economics (and other social sciences) knowledge by a society facing a larger number of interdependent problems is one of the major foci of relations among society, the profession, and the Association. In thinking through the relationship between the Association and society, some concept of what the publics desire from agricultural economics knowledge is helpful. Ruttan holds that the demand for knowledge in the social sciences comes from a concern for the efficient performance of institutions. He states: "Advances in knowledge in the social sciences can lead to more efficient performance of existing institutions and to the innovations leading to the development of new and more effective institutions" (p. 4). Among the examples he gives are quantification of commodity supply and demand relationships, which leads to more effective functions of food procurement and distribution programs (either by private firm or public organization), and knowledge of the effects of land tenure or group farming arrangements, which might lead to institutional innovations, in turn causing more equality in access to resources and thus increased productivity.

Many of the future problems of the Association and the profession may well be due to certain elements of society placing a high value on our past performance. To the degree that they continue to value the present activities highly, the demand on the profession

will continue to increase as problems become more complex and numerous.

Legitimacy of Agricultural Economics and the AAEA

Legitimacy is related to the value placed by the units of society on agricultural economics knowledge. The profession of agricultural economics and the Association are given legitimacy or status by its publics.

Legitimacy is a rather sensitive subject. Without legitimacy, neither the profession nor the Association could sustain themselves in a social system. Should the various publics deny legitimacy, the profession and the Association would be unable to keep themselves alive. No individual or group can continue to perform a role unless that role is accepted by those who are affected.

Boulding, in discussing the legitimacy of central banks, distinguishes at least six legitimating elements for an organization: payoff, willingness to make sacrifices, age, mystery, ritual or artificial order, and alliances with other legitimacies.

The units of society granting legitimacy appear to value payoff highly; that is, they all accord more legitimacy to the profession of agricultural economics and the Association to the degree that it produces and delivers knowledge that leads to more effective performance of existing institutions and innovations in institutions. The point to be made is that the Association is granted legitimacy by many of the units of society, in large measure, to the degree that it furthers the "development of systematic knowledge of agricultural economics."

How the AAEA Serves Society

There are two major routes through which the Association can serve society. The first is the provision of a set of services for its members and the agricultural economics profession. The services will enable the individual members of the profession to provide information for improved performance of economic institutions and better use of resources. The second major route is for the Association to provide this information directly to the various elements of society. Although the development of normative policy statements by the Association is prohibited by the AAEA Constitution in article II, the Association can provide economic information on policy alternatives and consequences as well as other economic information that would improve the performance of institutions in society. Farrell suggested this kind of activity in last year's presidential address.

The Association does little to deal directly with the various units of society. Should the Association expend more effort to produce and distribute knowledge directly to the various publics, or should it continue to work mainly through its members to improve the production and distribution of knowledge? Among the ways the Association could produce and distribute knowledge to society would be *(a)* to join the Council on Agricultural Science and Technology (CAST) or develop the means itself to make statements as does CAST; *(b)* to provide accreditation services for undergraduate and graduate curricula; *(c)* to change the *Journal* into more of a communications device for users of agricultural economics research; *(d)* to devise an alternative publication aimed at users of agricultural economics knowledge (an example might be *Crops and Soils,* published by the American Society of Agronomy); *(e)* to devise sessions at the annual meeting for the interested publics; *(f)* to hold special symposia for consumer groups, legislators, firm managers, students, farmers, etc.; *(g)* to develop statements of needed agricultural economics research for use by agricultural research planning and funding organizations; and *(h)* to make special efforts to communicate with general publics. Analysis and debate of costs and benefits to society and the Association on each item would be required before action could be taken.

If the Association were to order its services with the goals of improving the performance of the profession from the point of view of certain publics, priorities could well change. To achieve this ordering, a good deal of thought and discussion would be required. For example, what mix of services would improve the ability of economists to do research, teaching, and extension work useful to society? How could the Association provide incentives for agricultural economists to communicate more clearly and usefully the results of their analyses? Should the Association direct its efforts toward an elite group of the best agricultural economists or should more effort be put to improve productivity of all agricultural economists?

It is easily conceived that the Association could and should challenge agricultural economists. An example is the statement of T. W. Schultz, in his Leonard Elmhirst Memorial Lecture, that there is increasing opposition to economics in social and political thought as well as debasement of economics by government. Schultz charges that there is an unwillingness and inability on the part of economists to challenge this adverse drift. He points out that the opposition to economists is not restricted to a particular kind of government, or officials from high- and low-income countries. He states: "The hard realities of the cost of producing goods and services are not abolished by either national or international politics. Herein lies not only the hope, but the necessity of economics" (p. 4).

Many difficult and emotional issues lie in these thickets. I do not have easy solutions to them. But the issues need to be faced if the Association is to better serve society.

Some Opportunities

I now discuss some persistent issues and opportunities that appear to transcend the specific suggestions made earlier. I do not present a detailed plan for the future of the Association. Its future will be determined by the action of the Board and the membership. Significant steps have been taken recently to exploit opportunities for the Association. Examples include appointment of new committees to study and make recommendations about alternative publications, business organization and management of the Association, evaluation of the annual meeting, and professional registries. The reinstitution of the Professional Activities Committee also serves to bring useful examination to a number of issues. The actions coming from the reports of these committees will serve the Association well. However, unless the membership cares about the Association and actively supports improvement, little change will occur.

The Journal

Controversy continues to swirl around the *Journal*. In the early years of the profession, the *Journal* was virtually the only medium available for published communication among agricultural economists. Now other publications exist but interest in the *Journal* remains high, as it is a very visible activity.

W. G. Tomek, present editor, in an interesting piece titled "Is There a Disequilibrium Between Supply and Demand for Articles in the Journals of Agricultural Economics?" lists the following complaints of readers: "articles are too mathematical; topics covered by the *Journal* are not sufficiently diverse; the topics covered are too narrow and specific; i.e., the big issues are not discussed; articles tend to be methodological in emphasis rather than concentrating on policy issues; too much emphasis is placed on articles derived from theses, and this conveys an image of a necessary methodological content for publication, and this in turn discourages ideas or issue-oriented manuscripts; readers also want articles reflecting the judgment of mature members of the profession on policy questions; articles allegedly do not cover topics of interest to extension economists, undergraduate teachers and business economists; and readers see a need for more literature review articles" (pp. 1–2).

Tomek points out that not all the papers are methodological or mathematical; e.g., the 1975 *Journal* published 147 pieces of which 20 emphasized methodology. He concludes "The problem is the lack of enough high quality, important things to publish" (p. 8).

There appears to be disequilibrium between supply and demand. Why? The *Journal* articles published are a selection from the manuscripts submitted. Apparently, not sufficient "high quality, important things to publish," as viewed by the readers, have been submitted. I reject the position that the editors have a bias against "high quality, important things." Why are such manuscripts not submitted? Two possible reasons occur to me. One, agricultural economists are not doing high quality, important analysis. Two, if they are doing such analysis, they are not submitting the manuscripts to the *Journal* for publication. Both are possible, but I tend to accept the second reason as more important. If I am correct, commissioning of articles by the editor, alternative publications, and the creation of an environment that will bring submission of important and high quality manuscripts are in order. Thought, concern, and work by the editor, Alternative Publications Committee, Executive Board, as well as members will be required to make improvements on this complex issue.

Involvement of Members

Many members view themselves as second class citizens in the Association. The expressions of concern, sometimes near violence, varies over time. I have heard such views from agricultural economists in the South, Northeast, West, and North Central regions. I have heard complaints from teachers, extension workers, and people employed in industry. Members from non-land-grant and small land-grant universities have voiced concern.

Two avenues exist to deal with this issue. One is for the president and Executive Board to continue to improve opportunities for an "open," as opposed to "closed," style in the affairs of the Association, e.g., committee appointments, annual program, etc. The second is for the members who feel anguish to become usefully assertive. Sending suggestions to the president and the Board and volunteering for activities and developing feasible alternatives would help. Both avenues need to be traveled.

Membership

The ability of the Association to provide improved services to society and its members is constrained by its income. The nature of costs discussed earlier, as well as need for new income for new services, makes an increase in membership a high priority item. The recently increased efforts of the Membership Committee and the secretary-treasurer need to be continued. Often failure to join or renew membership is an act of omission rather than commission, so presenting multiple opportunities, i.e., "hitting them often," will yield results.

But the members also have an opportunity and responsibility. Personal contact is probably the most effective of all sales techniques. It appears logical that, if you think membership is worthwhile, you should attempt to persuade others to belong to the Association.

Two Strategies

I have difficulty in defining clear-cut alternatives for decisions about the future of the Association. The affairs of the Association are complex and subtle. Two major strategies can be identified. One is to determine what the central core of the profession of agricultural economics should be and to meet the needs of society and members having preference for working in this central core. The second strategy is to recognize and foster the diversity and lack of homogeneity. This strategy would have the Association become a "federation" or a holding company of "clubs" or interest groups.

Among the consequences of the first strategy is the necessity to determine the central core of agricultural economics. A similar issue was debated early in the 1900s. Taylor and Taylor, in the *Story of Agricultural Economics*, report the cleavage between rural economics and farm management. The Committee on Instruction in Agriculture, chaired by T. F. Hunt, recommended in 1911 the use of the term "*rural economics* as applicable to the general field of economics in its relation to agriculture and rural communities" (p. 95). The acceptance of this report by administrators in colleges of agriculture and the USDA led to the formation of departments of rural or agricultural economics and the consolidation of the American Farm Management Association and the Association of Agricultural Economists under the title of American Farm Economic Association in 1919. The debate on the central core continues. A number of departments have changed or added to the name of agricultural economics and proposals are often made to change the name of the Association.

Whatever the definition of the central core of agricultural economics, it is likely a definition would lead to a reduced number of members. The Association would probably continue to operate as in the past, with one *Journal*, an annual meeting, and other services. Some attention would have to be given to styles of decision making and involvement of members, but with agreement on and commitment to the central focus, these problems become less intense. A major uncertainty is obtaining a definition of agricultural economics to which a sufficient number of agricultural economists would be committed to continue as an Association.

The question: "Can diversity become strength?" is crucial for the second strategy. The arguments for diversity that apply to firms do not apply well to organizations that produce public goods for their members and attempt to serve society. Arguments for diversity in markets and private goods production relate to serving the various interests of users or the buyers. Even here, unless there is some common bond, the market or organization dis-

solves. What is the "tie that binds" professionals with diverse concerns who produce and distribute agricultural economics knowledge?

I hold that there is a bond consisting of three elements. The first element is the set of interrelated problems analyzed. The problems focus on the food system as well as rural communities and resources. The problems were more closely related in the past. Most of the activities of the food system took place in rural communities and used rural resources. Now the activities of the food system involve urban people and resources and have an international dimension. Even though the relationships of the food system and rural resources are not as tight as in the past, rural areas are indispensable. The second element is the relationship to economic logic. Agricultural economics analysis often draws from other disciplines but almost always draws from economics. The third element is an empirical emphasis. Throughout the history of agricultural economics, conclusions have been expressed largely in numbers as opposed to conclusions based on logic only.

It appears to me the diversity and specialization in the profession can be placed under these elements and the elements serve to differentiate the profession of agricultural economics from other professions. The users of knowledge produced and distributed by agricultural economists will benefit from intellectual interaction and even friction among members with various concerns. The member who is in a decision-making role will better serve his organization and society by discussion and argument with the subject matter analyst and the discipline analyst. The subject matter analyst will do better analysis from interaction with decision makers and discipline analysts. So also will the output of the disciplinary analyst be more useful as a result of interaction with the decision maker and the subject matter analyst.

Concluding Comments

There is a common thread in the fabric of this discussion that may not be as apparent as it should be. The Constitution states the goal of the Association is furthering the development of agricultural economics knowledge. This statement implies the development of high quality agricultural economics knowledge. Excellence is important. Both society and members will be served to the degree that the Association stimulates, fosters, and indeed demands excellence. The different users of agricultural economics knowledge have varying perceptions of excellence. This suggests two major tasks for the future. One is helping user publics develop high standards of excellence concerning agricultural economics knowledge. Another is to raise all members' appreciation of excellent performance in teaching, research, extension, and decision making.

Let us join in assaulting the barriers to excellence in the development of agricultural economics knowledge.

Natural Resource Economics: The Upsetting Discipline

M. M. Kelso

Robert Solow, in his 1974 Richard T. Ely lecture, remarked that "it is easy to choose a subject for a distinguished lecture like this, before a large and critical audience with a wide range of interests. . . . It has to be, because twelve people, counting me, have done it" (p. 1). Much the same thing can be said about this, our annual "distinguished" lecture, though but ten, including me, have done it. Of course, what really makes it easy is that the president calls you on the phone and says, after the usual introductory niceties, "Hey! How about you doing the fellow's lecture this year?" After a certain amount of hemming and hawing and sparring around, you say, "What do you want me to talk about?" to which he replies instantly, "That's entirely up to you! That's *one* thing I don't have to worry about in putting this bloody program together!" So there you are. It is easy!

My discussion will be more a personal testimony than an intellectual performance. I trust, of course, that my testimony will contain intellectual nourishment. It would be out of place before an august assembly of intellectuals like this if it did not. But its intellectuality may be somewhat hidden because it will not be couched in intellectually brilliant analytics nor in soaring conceptual hyperbole. But I take comfort in Adam Smith's oft-quoted remark about the "invisible hand" and hope that the intellectuality in my personal testimony may lead you, as by an invisible hand, to new insights into your unconscious biases, hence recognition of what may be restraining unconscious assumptions in your conceptions of society and the world. I hope the result may be that you will then play leading roles in what I shall argue are imperative changes in our economic view of man and his world if we are to help our society to avoid the apocalypse.

Fellow's lecture.

M. M. Kelso is a professor emeritus in the Department of Agricultural Economics, University of Arizona.

Intellectual Background

Some forty-five to fifty years ago I came into what then was called land economics almost coincidentally, quite, even, by accident. I see myself as then, a naive, idealistic, intellectual youngster who had just received his B.S. degree in agriculture, with a major in animal husbandry, from the University of Minnesota and who had accepted a research assistantship in agricultural economics at what was then Connecticut Agricultural College (now the University of Connecticut). I was to assist in economic research in land utilization on dairy farms in the eastern highlands of Connecticut. That experience whetted my interest in, and appetite for, study of the economics of land utilization in agriculture. The University of Wisconsin was at that time preeminent in its offerings in land economics, so I went there in 1930 to pursue graduate work leading to the Ph.D. degree in agricultural economics with a dissertation topic in land economics, minors in sociology and constitutional law, and with a sizable dose of institutional economics administered by John R. Commons, then approaching the end of his illustrious career.

From the vantage point of maturity and experience, I look back on those college years and the twenty years of professional work in land economics in the New Deal's Resettlement Administration, in the Division of Land Economics of the "old" Bureau of Agricultural Economics in the U.S. Department of Agriculture, and at Montana State College with a profound sympathy for what was then a nagging worry, sometimes conscious, more often subconscious, but always with me, a worry that concerned the conceptual and analytical relations between land economics and the accepted body and conventional wisdom of the rest of agricultural economics and its parent economic theory.

My naive idealism, born of the conventional wisdom and accepted economic dogma of the

times, assumed intellectually that maximized aggregate welfare would flow from maximized individual welfare were it not for the aberrations of monopoly and monopolistic elements in the economy, the humanness of the all-too-human actors in the drama, public interference in the market system, and the like. I know now that my association with those great iconoclasts, Veblen and Commons, and my experiences in the droughts and great depression of the 1930s generated within me gut feelings of skepticism regarding that intellectual idealism. It was, I can testify, a period of intellectual and philosophical discomfort for me. But I was not aware quite why.

I know now I was trying to accommodate my conceptions of land economics (we now call it the economics of natural resources) to the accepted body of conventional wisdom of agricultural economics and economic theory. But I could not bring it off—not that I tried very hard. It was sort of like a chronic nagging discomfort lived with so long and so intractably that one sort of accepted the notion unconsciously, even rationalistically, that it is the natural state of things, common to all persons similarly situated, part of the inevitable burden of living—and intellectualizing.

I came closest to resolving the paradox or, maybe more accurately, came closest to grasping the sources of the paradox through my intellectual association with the Wisconsin institutionalists, notably John R., as we students affectionately called him, and from my New Deal experiences during the depression that, in fact, were but the application in practice of much of John R.'s intellectual insights, though most of us, including me, did not then quite realize it!

I well remember my first intellectual insight that brought land economics and conventional agricultural economics together in one very small way. It was soon after I went to Montana State College in 1946 as an agricultural economist specializing in ranch and public land management. That was a time of ferment among western federal public land ranchers over their relations to the public lands, to the federal bureaucracy, and to federal land managers. I had been working with a Committee of the American National Cattlemen's Association on the question posed naively and dichotomously by it as to whether the public grazing lands should be privately or publicly owned, the Committee biased in favor of the former because its members were "fed up" with the difficulties and frustrations of the latter. I, like the Committee, had been viewing the problem dichotomously as one or the other. I was trying to think my way through the issue in order to find some way to resolve the conflict. Emotionally, I could accept the graziers' frustrations but intellectually I could not accept the dichotomous solution of universal private ownership of all the then public grazing lands.

One day (it would have been in 1946 or 1947) I was driving from Bozeman to eastern Montana on some mission I do not now recall. As most of you know, distances in Montana are vast; traffic in those days was light. So to relieve the boredom of uneventful hours behind the wheel, I let my mind mull over the public land problem that was so much in my thoughts. It came to me suddenly as an intellectual insight so clear that I could without much trouble, if only I were of a religious turn of mind, have attributed to divine inspiration, that what we were dealing with here was a problem of landlord-tenant relationships on the public lands versus private ownership of those lands, that the solution was not an either/or choice between what we had and something totally different but between what we had and a reformed system of public landlord-private tenant relationships and between that and private ownership, and, further, that because it would be impossible to persuade the public to divest itself totally of ownership rights in much, even most, of the public grazing lands, the solution for the private grazier users was to recognize and accept their status as tenants on much of the public lands and to work for improved landlord-tenant relations between themselves and the public landlord. Immediately all I had learned in land economics about improved landlord-tenant relations in agriculture came to bear, and I began to click-off mentally a multitude of logical and feasible changes that would give tenant graziers security of expectations with compensation for disturbance and improvements and that would protect the public landlord in the conservation of his land holdings.

I regret to say that nothing came of all this except my own intellectual growth. But even that growth, such as it was, still left me with my feeling of inadequate conceptual merging of land economics and conventional agricultural economics. I found my land economics useful in conceptualizing the role of the government as landlord and of the rancher as ten-

ant and the nature of the rights, duties, liberties, and exposures that characterized their relationships as well as possible changes in those institutionalized relationships that would presumably improve efficiency and equity for both. But, whereas I was correctly conceptualizing the rancher as a private individualized firm as required by conventional economic theory, I was, for purposes of the same theory, incorrectly conceptualizing the public landlord as if it, too, was a private individual firm. What continued to bother me was what is or ought to be the structure, role, and behavior of a public landlord in the governing analytical theory? I never figured that one out and, so far as I am yet aware, no one else has either.

I know of only two exceptions to that statement. One is our colleague, a fellow of this Association, Marion Clawson, who, in his 1951 book, *Uncle Sam's Acres,* extensively analyzed the role and conduct of the federal government as land owner and manager but gave only passing attention to its role as landlord. The other exception was the Public Land Law Review Commission, which in its monumental task reported in 1970 gave some attention to the federal government-private user relation on the federal lands.

It was at least a dozen years later that I had my next illuminating experience contrasting conventional economics and my land economics. I was traveling in Australia in the early 1960s. I struck up an acquaintance with a senior agricultural economist in the Australian Bureau of Agricultural Economics. We were visiting about a variety of professional matters of mutual interest revolving around policy issues related to land economics. We got into a discussion of agricultural product price supports, particularly the issue of whether or not one should and, if so, how one should incorporate land values into the "base" from which the magnitude of such supports should be calculated. He related his unsuccessful experiences in trying to convince the Ministry, the Parliament, and producer groups that land values should not be included in the base. The gist of his argument was that (*a*) such a land value is usually taken to be a "fair market value" for each individual producer's land such as might be generated by a willing seller and a willing buyer negotiating in a land market, these individual parcel market values then being extrapolated to all agricultural lands of similar economic qualities. But (*b*) such market land values are derived from the "private rents" the parcels generate, capitalized to a private myopic time horizon at private individual discount rates, the land's rent being affected by private individual opportunity costs for the operator's management, labor, and capital and by the prices received for the land's products and prices paid for inputs. However, the level of product prices, hence the land's rents, will be affected by the very supported prices the level of which the supports are designed to maintain, usually even to increase. Thus, (*c*) the aggregate value of individually determined land values will be affected by the circularity between the level of supported product prices and the underlying land values, each augmenting the other without any clearly determinable limit. Thus, (*d*) to break that circularity, it is necessary to separate the land value base from individually realizable rents and capitalized values generated in the market place.

But, upon breaking that relationship between supported price, level of rent, and individual land parcel value, what value do we put in its place in the support formula for product prices? Seemingly, such a value would be some aggregate social value of the national aggregate of agricultural lands related to some optimal or improved level of aggregate well-being capitalized to some "long-view" time horizon at some "social" discount rate.

That raises difficult, maybe even impossible, conceptual as well as operational problems. Just what is the socially relevant level of aggregate agricultural land values? What is the value of a homeland, of the socioeconomic base for a society? We did not know then, and I do not know now. But the impact on me was, I think for the first time, a clear realization that the "value" of the social aggregate is not simplistically the simple aggregate of individual values; the aggregate is not, likely, the simple sum of its parts. But what is it?

Not long after, again in Australia, I again ran into the same paradox in a much sharper and more revealing context. The island of Nauru in the Southwest Pacific has been found to be composed of highly rich phosphates. The technical development of fertilization in agriculture led to a fantastic growth in market demand and in price for this natural resource. So, of course, the Nauruans were quick to take advantage of it and entered into contracts with Australian, New Zealand, and other Southwest Pacific governments to sell their

phosphate in the ground at a negotiated rent price that has greatly raised the level of living and welfare of the Nauruans. Until, as you may surmise, they realized that their island homeland would fast become a hole in the sea! What then? Well, of course, they began raising to ever higher and higher levels their asking price (and getting it) per unit of homeland removed. But that has not exorcised the devil. For after all, they either must sell their homeland piecemeal, in order to live as they have become accustomed to live, ultimately moving to some other as yet unacceptable and unlocated alien environment or, by protecting the permanence of their homeland, to live in previous poverty.

Is the aggregate value of their homeland the tonnage of phosphate they "own" times its market price per ton? If not, what is its value? Again, the maximization of the market value of their natural resource is not necessarily, is probably much less than, the aggregate social value of the homeland. Here again, the aggregate is clearly not the market sum of its individualized parts. What "support price" for phosphate should the Nauruans adopt? I still do not know the answer. I am not yet sure I even know how to conceptualize an answer.

Over the years I have enjoyed telling the story of the "Nauruans' Dilemma" to confound my classes, but not until I read Kenneth Boulding's 1966 paper "The Economics of the Coming Spaceship Earth" did I begin that restructuring of my conception of natural resource economics that pointed the direction that resolution of the paradox must take and began that intellectual process that ultimately allayed my intellectual frustrations by finding how to merge the conceptualizations of natural resource economics with the conventional wisdom of economic science. This was the climax point in my intellectual evolution. During the ensuing decade I have been filling in and filling out that conceptual amalgamation.

Just what did Boulding say that brought about in me this intellectual revolution? I quote:

> We are now in the middle of a long process of transition in the nature of the image which man has of himself and his environment. . . . The image of the frontier is probably one of the oldest images of mankind, and it is not surprising that we find it hard to get rid of.
>
> Gradually, however, man has been accustoming himself to the notion of the spherical earth and a closed sphere of human activity. . . . Even now we are very far from having made the moral, political, and psychological adjustments which are implied in this transition from the illimitable plane to the closed sphere.
>
> Economists in particular, for the most part, have failed to come to grips with the ultimate consequences of the transition from the open to the closed earth. . . .
>
> The closed earth of the future requires economic principles which are somewhat different from those of the open earth of the past. . . . [The open economy is characterized by] the illimitable plains . . . associated with reckless, exploitative, romantic, and violent behavior. . . . The closed economy [on the other hand is one] in which the earth has become a single spaceship, without unlimited reservoirs of anything, either for extraction or for pollution, and in which, therefore, man must find his place in a cyclical ecological system which is capable of continuous reproduction of material form even though it cannot escape having inputs of energy. The difference between the two types of economy becomes most apparent in the attitude towards consumption. In the [open] economy, [of the conventional wisdom, i.e.,] consumption is regarded as a good thing and production likewise; and the success of the economy is measured by the amount of the throughput from the 'factors of production,' a part of which, at any rate, is extracted from the reservoirs of raw materials and noneconomic objects, and another part of which is output into the reservoirs of pollution. . . .
>
> By contrast, in the [closed] economy, throughput is by no means a desideratum, and is indeed to be regarded as something to be minimized rather than maximized. The essential measure of the success of the economy is not production and consumption at all, but the nature, extent, quality, and complexity of the total capital stock, including in this the state of the human bodies and minds included in the system. . . . This idea that both production and consumption are bad things rather than good things is very strange to economists, who have been obsessed with the income-flow concepts to the exclusion, almost, of capital-stock concepts. . . .
>
> There are problems here which the economics profession has neglected with astonishing singlemindedness (Boulding 1966, pp. 3–11).

Elsewhere, Boulding (1970) elaborated this theme further:

> . . . the real measure of economic welfare is not income at all. . . . Income is just the unfortunate price that we have to pay because the state [of the person or of society] is corruptible. . . . Consumption is a bad, not a good thing; production is what we must undergo because of consumption. . . .
>
> Much more fundamental is that all of economics, the whole GNP [gross national product] mentality, assumes that economic activity is a throughput, a linear process from the mine to the garbage dump.

> The ultimate physical product of economic life is garbage . . . a great deal of man's activity is directed toward what we might call desired pollution. . . .
>
> If the earth is to become a spaceship, we must develop a cyclical economy within which man can maintain an agreeable state.
>
> Under such circumstances the idea of the GNP simply falls apart. We need a completely different set of concepts for that eventuality, and we are still a long way from it technologically because we never had to worry about it. . . . Suddenly, it is becoming obvious that the Great Plain has come to an end and that we are in a very crowded spaceship. This is a fundamental change in human consciousness, and it will require an adjustment in our ethical, religious, and national systems which may be quite traumatic (pp. 161–64).
>
> Economic development is the process by which the evil day is brought closer when everything will be gone (p. 166).
>
> I have recently discovered the real name of the devil, which is something terribly important to know. The real name of the devil is *suboptimization,* finding out the best way to do something which should not be done at all. . . .
>
> The problem of how to prevent suboptimization is, I think, the great problem of social organization. The only people who have thought about it are the economists, and they have the wrong answer, which was perfect competition. Nobody else has any answer at all. Obviously, the deep, crucial problem of social organization is how to prevent people from doing their best when the best in the particular, in the small, is not the best in the large (pp. 169–70).

So, according to Boulding, the conception of earth as spaceship rather than as limitless plain will require traumatic adjustment in our ethical, religious, and cultural systems—and, according to me, in our relevant intellectual systems as well, which includes conventional economic wisdom and will be equally traumatic to us! But paradoxically that conceptual shift set in motion within me the evolution in my intellect that relieved the unconscious traumatic tension I had lived with for decades. Why had it not been possible all along to integrate neatly land economics as I knew it with the conventional economic wisdom that I also knew?

Incompatibility Between Natural Resource Economics and Conventional Economic Wisdom

If one defines "land" (in land economics) or "natural resources" (in natural resource economics) as semantically equivalent to the "natural environment" or to "nature" (which I do) and if one conceives nature as a closed system (which it is), then natural resource economics stands conventional economic theory and the conventional real world wisdom of the economy on their respective heads—upside down, which is very upsetting indeed—and the intellectual trauma migrates out of my mind to enter the minds of those who espouse the conventional economic intellectual wisdom. Why?

Conventional economic intellectuality posits individual economic units as producers and as consumers acting within a system constrained by conventional economic institutions of which the market, competition, prices, and individualized property are the principal elements. That conventional intellectuality sets as its objective function the maximization of income, of throughput, per capita per unit of opportunity cost. In that conventional intellectual construct, the preference sets of the individualized actors and the environment of institutions that constrain and direct their actions are posited as exogenous constants. The aggregate of incomes, which is to be maximized, is taken to be the sum of the optimal individualized net gains generated within the interacting system of individualized actors choosing within the constraining envelope of exogenous preference sets and market institutions.

It is just here that the closed system conception of nature as interpreted and imposed by natural resource economics gets in its upsetting licks, its upside-down trauma on the conventional system. Maximization of throughput within constant exogenous parameters of preferences and institutions and within an individualized myopic time frame is no longer the relevant desideratum. This is Boulding's suboptimization devil. In its stead, maintenance or improvement in the state of the capital stock and of the bodies and minds of the aggregate system within a long-run (even infinite) time frame wherein there is no "outside," only "inside," is the required desideratum.

Even what we economists have known since Keynes as "macroeconomics" is not truly "macro" as defined by natural resource economics. The Keynesian "macro" is concerned with behavior of aggregate throughput of the conventional system, which is composed of interacting "micro" units guided by the conventional system of relevant preferences and established institutions. It has noth-

ing to say about the physical constraints of a spaceship nature on the macro system nor about the conventional sets of preferences and institutions other than as they are fiscal, financial, and market related.

Defining the problem of economic well-being viewed through the lens of natural resource economics in addition to that of conventional economic wisdom shifts the analytical "line of sight" away from exclusive concern with system throughput to concern for well-being state of the system, away from exclusive attention to preference sets that emphasize satisfactions derived from marketable products to concern for preference sets that emphasize satisfactions derived from inner resources of the person, derived from consumption of marketable products from flow rather than stock resources, and toward satisfactions derived from magnanimous sacrifices made to keep the society's future options open. It also shifts the "line of sight" away from exclusive concern with exogenous conventional institutions of property and away from exclusive concern with structure, conduct, and performance of the competitive market. Natural resource economics also shifts the "line of sight" of economic analysis away from research, education, and the adoption of technology to enhance throughput of marketable products derived from the conversion of resources to garbage and towards research, education, and the adoption of technology to enhance the state of well-being of the system derived from production and consumption based on flow resources and on the reconversion of garbage into productive inputs, together with minimization of the entropic dissipation of energy.

A big order? It is a terrifyingly big order, but one on which nothing less than the permanent viability of mankind as humankind, even possibly as a biotic form, depends absolutely. I am not so brash as to argue that the upside-down conversion of conventional economic wisdom that this formulation of the problem implies must be effected today—or even tomorrow. But the time horizon of tomorrows within which the inversion must be effected is frighteningly close. Apocalypse is too close for comfort!

Imposing the structure of ideas that is natural resource economics upon the conventional economic analytical wisdom requires that preference sets and the institutional environment of the conventional wisdom be transposed from exogenous analytical constants to endogenous variables, that problem resolving analyses focus on the means whereby purposeful change can be effected in those preference sets and in that institutional environment, that research, education, and technology increasingly deal with the structure and role of relevant institutions, and with means for their purposeful reformulation that will guide "as by an invisible hand" improvement in the well-being state of the system.

No Need for Natural Resource Economics in Conventional Economic Wisdom

I now know that my past intellectual discomfort over the relations between land economics and conventional economics arose because there is no need or place for natural resource economics as a distinguishable body of ideas within the conventional structure of economic analytical wisdom. In that conventional structure there are only capital and man; there are only production and consumption economics and the market economy; there are only firms, consumers, and financial and fiscal institutions; there are only individualized entities interpersonally related through competition.

Our late colleague, a former president and fellow of this Association, Karl Brandt, has said, "A further factor that determines the effective capacity of an economy is popularly called natural resources. Their nature, their role in economic growth, and the importance of specific types of resources change with the progress in science and technology and the shifts in domestic and foreign demand. Contrary to popular notions, these resources have no value as such. They represent opportunities to apply management, labor, and capital to them for the purpose of deriving energy or materials from them. Once public or private capital or both have made natural resources accessible or productive, these resources become valuable" (p. 33). In that last sentence, Brandt might have said that natural resources so conceived become capital. For, in the analytical construct within which he was reasoning, that of conventional, individualized market-oriented, throughput economics, that is what natural resources are—capital goods.

Our eminent colleague, Earl Heady, also a fellow of this Association, has said, "Land, as a factor of production, has no unique charac-

teristics which should cause it to be set aside by itself in economic analysis. . . . Land differs from certain other factors in respect to legalistic and institutional characteristics. . . . Analysis which relates to institutions *per se* has come to be known as land economics. Most institutions do, however, have impacts which lend themselves to analysis via economic tools drawn from the basic principles of production, distribution, pricing, and consumption. No new principles unique for land can or need be formulated. . . . Land perhaps takes on unique importance only in respect to its use and allocation over time . . ." (p. 763).

Brandt and Heady are both correct in what I have quoted given the conceptual economic analytic framework within which both were working. Both are here concerned with questions of "production, distribution, pricing, and consumption" (to quote Heady) as they emerge in an individualized actor, competitive market system from which maximized throughput efficiency can be analytically deduced. Heady correctly states that "land" as a factor of production has no unique characteristics for analysis, that it differs from other factors in legalistic and institutional ways, and that land economics embraces analyses of "land" that relate to institutions per se. As production economic analysts, he and Brandt were right when one recognizes the implicit framework of conventional "classical" economic maximizing or optimizing of throughput employed by both. But this is Boulding's partial optimization "devil" again if and insofar as it is used to analyze alternative economic policies as handmaiden to the social process of policy making for natural resources to enhance the state of well-being.

As Heady correctly observes, natural resource economics is uniquely (I would say inherently) institutional. So soon as one incorporates the uniquely institutional natural resource economics together with the uniquely "spaceship" conception of nature into the conventional economic analytical construct, the conventional system experiences a transformation—it becomes applied institutional economics; it concerns itself first with maintenance or improvement of the well-being state of the system rather than with maximization of the throughput of the system and, second, with minimization of natural resource input in state maintenance or improvement rather than with optimization of natural resource input consonant with efficient throughput maximization. To paraphrase Boulding, it stands conventional economic wisdom on its head.

Reverting to the story of my personal frustrations, the Boulding thoughts (quoted above) provided the intellectual cue that put me on the path to my tension relaxation. I do not mean to imply that I did it all on my own following the Boulding cue. For that was but the cue that gave me the conceptual insight that opened my eyes and mind to the significance of the flood of writings by many others over the past two decades—on externalities and market failure, on Pareto-relevant and Pareto-irrelevant criteria, on property rights and economic behavior, on "collective action in control, liberation, and expansion of individual action" (to quote Commons 1934, pp. 69, 73, 902; 1950, pp. 15, 21, 26, 343) relative to the development, depletion, use, and transfers of use of natural resources as they affect the state of aggregate economic well-being over time.

Policy Analyses, Uncertainty, and Conventional Economic Optimizing

Policy making for natural resources, or for anything else for that matter, is indubitably future looking. Hence, it is inherently uncertain. Policy making and any economic analysis meant to assist it must recognize this fact of futurity uncertainty. There can be no operational analytical optimum for the long run. There can be only suboptima for the short run constrained by the promise—or hope—that they will improve well-being in the long run. Such inherent futurity uncertainty dictates that greater importance be given even in the short-run objective function to reversibility of any policy actions posited than to their optimization. Ability to "back up" and try something else in the succession of short runs is more important than is a constraining demand for optimizing even in the short run, let alone for the long run.

This demand in policy making and its underlying economic analyses for short-run improvement in well-being rather than for optimizing and for reversibility of actions as a constraint on short-run policy choices led Lindblom (1959a, b) to conceptualize policy making as marginal incrementalism and to his characterization of the process as "muddling

through." The reversibility constraint upon policy choices is necessary, else over time some options will be closed, some future alternatives denied, some opportunities for improvement in well-being destroyed forever. Thus, economic analyses useful to policy action must formulate their objective functions in improvement or betterment terms and must build into their analytical models the opportunity costs of any irreversibilities in the array of alternative policy actions explored.

Property in Natural Resources, Monopoly, and Competition

An economic system containing individualized ownerships of natural resource parcels is inherently a monopolistic system. It introduces into conventional individualized economic optimizing implicit monopolistic aberrations in the economic results of the system due to the ubiquitous presence of externalities and public good elements, the nonreproducibility of stock resources consumed in production, and the presence of those unearned, surplus incomes called rents, which are not eliminated and may even be accentuated by competition. Serious questions can and have been raised regarding the private maximization and capture of these natural resource rents that are at bottom monopolistic returns. Individualized property clothes the holders of individualized natural resource parcels with rights and liberties that give them economic power and freedoms of action vis-à-vis others relating to each particular unit of space, the resources it contains, and the products it can be made to generate. Obviously, the degree of monopolistic power with which individual natural resource property holders may be clothed is widely divergent in magnitude and often is very small. But whether such monopolistic power bestowed on parcel owners is large or small, to that degree it distorts both economic efficiency and equity outcomes from what they would be if the idealized competitive conditions of conventional economic theory were to prevail instead.

But of greater implication for economic policy and more upsetting to purist purveyors of the conventional economic wisdom, the solution for such monopolistic aberrations in aggregate well-being growing out of individualized property in natural resource parcels will not be found in the elimination of those monopolistic elements but rather by their extension to more inclusive collectives. Such extension of monopolization is the real meaning of actions taken to "internalize externalities" and to further the production of "public goods." Maximization of the state of well-being of the society often requires a "monopoly solution" of the natural resource problem. Since monopolization of natural resources by private individuals is politically unthinkable given our present social values, such monopoly solutions require collectivization solutions that range from private collectives such as cooperatives to quasi-public and truly governmental monopolies. Here, again, the natural resource-based problems of aggregate well-being stand the conventional solutions of economic wisdom upside down. Rather than the perfect competition of conventional economic wisdom, natural resource problems often require the opposite—broadened collectivist, monopolistic solutions!

The intriguing thing about this is that John Stuart Mill and Henry George saw it clearly 100 to 150 years ago! Why have their insights been so universally ignored, so single-mindedly ignored by economists (to paraphrase Boulding)?

The answer likely lies in what the historian, Walter Prescott Webb in his book, *The Great Frontier*, refers to as the 400-year boom in modern history:

> What was the essential character of the frontier? *It was inherently a vast body of wealth without proprietors*. . . . When this great area was made available to the crowded and impoverished people of the Metropolis [by which he means western Europe], they swarmed out like bees to suck up the nectar of wealth, much of which they brought home to the mother hive. *This sudden, continuing, and ever-increasing flood of wealth precipitated on the Metropolis a business boom such as the world had never known before and probably can never know again. . . . Assuming that the frontier closed in 1890 or 1900, it may be said that the boom lasted about 400 years.*
>
> . . .
>
> Assuming that there was a boom, and that it lasted 400 years or more, it follows that a set of institutions, economic, political, and social, would in that time evolve to meet the needs of a world in boom. . . . [T]hese boom-born institutions, economic systems, political systems, social systems—in short, the present superstructure of Western civilization—are today founded on boom conditions.
>
> . . . scholars will look back on the age when the Golden Door opened, and men marched out to the Great Frontier to create the greatest boom that the world has known; they will make myths and legends

about it, and in poetry and literature express their poignant yearning for New Frontiers. They will see the frontier as the great factor in the age called modern, see it clearly as the lost factor which they would so love to find (pp. 13–28).

Conventional economist writers today sound that "poignant yearning," though they express it in economist's rather than historian's language. They call it "economic growth."

Natural Resources and Economic Growth

It is some (but not very much) exaggeration to say that ever since man emerged as a human animal, and particularly during the 400-year boom, economic growth has been the prime solver of his economic welfare problems and has constituted one of the primary foci of public policy and social inventiveness. Economic growth provided the additional real—or throughput—income for additional persons as populations grew, provided the throughput surpluses from which flowed expanded investment in nonhuman and human capital alike, and financed technological change as well as the leisure time for pursuing philosophy, science, and the arts. Economic growth fueled explorations both in the domain of the mind and of the world; it provisioned the efforts by which newly opened vistas of mind and of world were occupied and developed. Economic growth made possible the explorations of mind and world and the exploitation of that which these explorations discovered.

Seldom has the value of economic growth to man and to his quest for a better and happier life been questioned. So basic has it been to man's beliefs that the philosophical systems that underlie his value systems and the social, economic, and political institutions that he has developed and that guide his modes of living are all designed to rationalize, facilitate, and glorify economic growth. It has been the great problem solver and the values and institutions of organized societies have been designed to insure that it will remain so.

Primary among these values and institutions have been democracy, capitalism, and individualism and the individualized private property in nature, the free markets, and the competition that characterize our conventional economic wisdom. These values and institutions of the 400-year boom were entirely consistent with man's view of the world as if nature's storehouse of productive resources was infinite and the capacity of her dumps and sinks to receive, store, and recycle waste products was also infinite. These values and institutions were wholly consistent with the goal of maximized throughput. Economic growth was the perfectly logical desideratum of the good and right.

Small wonder that the penetrating insights of Mill and of George—insights that saw nature as a limited and closed rather than as a limitless and open system, that saw the shortcomings in individualized property and competition in the resources of nature, that saw the dangers in, even the impossibility of, endless economic growth and the inevitability of lesser, even stationary growth—were joyously ignored in the tumultuous excitement of the 400-year boom.

As so well and succinctly put by Barkley and Seckler in their excellent little book, *Economic Growth and Environmental Decay—The Solution Becomes the Problem*, the conventional solution to the well-being problem—economic growth measured in throughput terms—has itself become the problem demanding solution if we are to realize the well-being maintenance or enhancement goal in the face of natural resource depletion in the spaceship that is nature.

I, too, was an intellectual creature of that boom. But my land economics had generated in me a nagging schizophrenia, a dual personality, together with, if not discord, at least dissonance between those dual sides of my intellect. I well remember the intellectual euphoria I experienced a dozen years ago upon first reading that trenchant work by Barnett and Morse, *Scarcity and Growth: The Economics of Natural Resource Availability*, from which I superficially gleaned the conclusion that natural resource scarcity need be no restraint on continuing economic growth given all the many ways that our economic system, even in the absence of technological change, can and will mitigate, even eliminate, resource restraints on growth. In defense of Barnett and Morse, I hasten to add that a more careful reading of their work—particularly in the context of a more encompassing natural resource economics on my part that recognized the basic and fixed restraints of space and energy in the spaceship earth, together with a greater awareness of the quality of life parameters in the objective function—destroyed my euphoria but led me to see that amalgamation of natural resource economics with the conventional economic wisdom upsettingly altered the latter, not the former.

Then in our western society came the upsetting environmental revolution of the 1960s and the more upsetting energy crisis of the 1970s. Now, not only I and numerous other intellectuals but increasingly numerous citizens have been jarred out of their complacent euphoria with economic growth and the limitless quantitative expansion of mankind and his consumption. Not only intellectuals but many citizens, too, suddenly confront the closed spaceship reality that is nature and the devastation that that confrontation inflicts on the conventional economic wisdom and its derivatives—democracy, capitalism, and individualism particularly as they relate to individualized property rights in nature and to free markets and competition in natural resources and their primary products.

I do not argue that all economists should be natural resource economists. That would be inexcusably smug egocentrism. I intend no more here than to describe how natural resource economics led me to a clear and critical appraisal of the future usefulness of the conventional economics on which I and all of us have been nurtured. Remember that I said this paper is a personal testament.

But I certainly do argue that all of us in our economic analyses, especially where and when they have public policy relevance, must incorporate in our analytical structure the conception of the closed spaceship earth, improvement in the well-being state rather than maximization of the throughput of the system, together with all relevant preference sets and institutional elements as endogenous variables rather than as exogenous parameters. Doing so places clear restraints on conventional economic wisdom as a vehicle for optimizing well-being or improving the state of the dependent society.

Doing so will not be easy, nor always comfortable. I close by quoting the closing paragraphs from John Kenneth Galbraith's book, *Economics and the Public Purpose*:

> . . . the future of economics could be rather bright. It could be in touch with the gravest problems of our time. Whether this is so—whether economics is important—is up to the economists. They can, if they are determined, be unimportant; they can, if they prefer a comfortable home life and regular hours, continue to make a living out of the infinitely interesting gadgetry of disguise. . . .
>
> Or economists can enlarge their system. They can have it embrace, in all its diverse manifestations, the power they now disguise. In this case, as we have seen, the problems of the world will be part of their system. Their domestic life will be less passive. There may be a contentious reaction from those whose power is now revealed and examined. And similarly from those who have found more comfort than they knew in the fact that economists teach and discuss the wrong problems or none at all. But for a very long time to come economists will thereby escape the fate that Keynes foresaw (pp. 323–24).

The Economics of Agriculture and Agricultural Economics

Emery N. Castle

During this past year those of us who work at Resources for the Future (RFF) were stimulated by the external Research Advisory Committee to identify the most important problems that will face society in the next twenty-five years. The RFF experience provided background for the preparation of this paper. My end objective is to assess agricultural economic's professional posture relative to the environment in which we find ourselves. But that is the second part. In the first part my purpose is to say something about the social environment itself. Of course, this is really only another way of describing the most important social problems that I expect to dominate the next quarter century.

Social Environment

I have found the work of my colleague, Edgar S. Dunn (1971, 1975), to be exceedingly useful in describing the social environment. According to Dunn, the bulk of species adaptations in bioevolutionary history has been specializing; that is, they bring about a highly specialized correlation of population behavior with the requirements of a restricted environmental niche. In contrast, adaptive generalizations occur less frequently and widen the environmental range within which the species operates. The unique feature of the genus *Homo* is that it has made a series of generalizing adaptations. Organized markets, the city, and the alliance of institutional science with technology are examples of generalizing adaptations. The reason that humans have made generalizing adaptations, rather than specializing in response to the natural environment, has been because of learning processes that have amplified the productivity of human behavior.

While little may be known about the process that gives rise to successful adaptations, a substantial amount is known about some of the adaptations themselves. Economists, for example, know a great deal about markets and their operation. The market is one of the most powerful of the generalizing adaptations that has been made by modern man.

I now identify four characteristics of the contemporary scene that will have influence on the economics of agriculture and the practice of agricultural economics. These four characteristics are global in nature. Therefore, much of what follows is presented in an international context.

The Presence of Social Irreversibilities

Although the concept has been around a long time (Ciriacy-Wantrup 1952), current environmental awareness has stimulated interest in distinguishing among decisions with respect to whether or not they are reversible and, if so, the cost of reversibility. The concept may have even greater relevance as applied to social processes.

The benefits of modern technology, that is, successful adaptations of knowledge, have been enormous. Individual mobility, individual development, and an increased life span are examples. Those who have achieved these benefits will not yield them easily or willingly. Those who have not achieved them, but who observe that others have, aspire to them.

For this reason past successful adaptations cannot be reversed. New adaptations, yes, but a reversal, no, unless there is a major social collapse. This is why much of the writing on life style, no growth, and "small is beautiful" is intellectually barren. Those who argue for these alternatives to present adaptations fail to deal with the loss of these real or perceived

---

Invited address.

Emery N. Castle is senior fellow and vice-president, Resources for the Future.

The author is greatly indebted to Theodore Schultz, Sterling Brubaker, and Kenneth Farrell for their reviews of an earlier draft of this paper. While he gives them credit, they should not be held responsible for shortcomings, many of which probably stem from the author's unwillingness to accept all of their suggestions.

benefits (American Academy of Arts and Science).

For the same reason, some of the discussion about world agriculture is unrealistic. Attempts to develop and force the adoption of technology tailored toward a subsistence agriculture, a solution of the problems of the poorest of the poor, or energy "extensiveness" is not well grounded in either fact or logic. The technology that is found to be useful reflects relative factor costs, and technology that does not hold the prospect of obtaining for the adapters the benefits of general economic progress does not have a bright future (Hayami and Ruttan; Darmstadter, Dunkerley, and Alterman).

Yet we are foolish if we believe there are no problems to be encountered by extrapolated past growth (Brubaker 1972, 1975). The undesirable side effects of continued application of particular technologies, the exhaustion or more complete utilization of certain resources held in common for which there are not ready substitutes, the possibility of diminishing returns in some productive processes, and the existence of people bypassed by economic change cannot be dismissed out of hand. The fears and concerns that have led to talk about "no growth" and "life style" reflect legitimate concerns even if many of the proposed solutions are unrealistic (Cadell).

The Divergence of System Objectives and Performance

Both bureaucracies and markets are ubiquitous in contemporary life. Yet not all of the responses from such social creations are socially desirable (Bator, Niskanen).

Social control is made difficult by the fact that the best utilization of a certain technology often requires that it be applied over wide areas affecting many people. But effective participation in decision making increases in difficulty as the number of people increase. This is a current fundamental problem. On the one hand, the utilization of certain technology or knowledge requires large organizations, such as a national government, a multinational corporation, or an international research and information exchange network. On the other hand, the full consequences often cannot be effectively dealt with at this level because of the inability of social control mechanisms to reflect general understanding and interest.

The Divergence of Anticipated and Realized System Performance

As noted, contemporary society is distinguished by various kinds of large social organizations that interact and intersect at many different points. Yet, the performance of this complex cannot be predicted with confidence. This lack of confidence in our ability to predict threatens social cohesion. I break this problem into two parts to make the meaning clear.

The construction of large system computer models has progressed rapidly in recent years. These models typically incorporate knowledge from many disciplines about various cause-and-effect relationships, but the results obtained are often counter to the expectations derived from disciplinary theory. It can be argued, quite logically, that something like this can be expected because no one intellectual discipline can represent all of reality. In addition, the integration of knowledge, with a reflection of appropriate interdependencies and with an accounting of recursive relationships, should lead to better predictions. There are also many reasons why such models may not be accurate predictors of system performance. Furthermore, adequate tests of such predictions cannot be made. Thus, a situation exists where there is good reason to doubt predictions made either on the basis of disciplinary knowledge or the most complex of computer models. (For a most thoughtful discussion of this general problem, see Day and Koenig.)

But the world is not in the hands of experts, disciplinary or otherwise. The lay person who is called upon to make a political judgment must also have a hypothesis about cause-and-effect relationships, which may or may not conform to actual performance. In response to a question, Patrick Cadell, President Carter's pollster, said, "But you are right; in the world I deal with, perception is reality. What the public believes is what is operable." Thus, the expectations that social scientists and other experts have about complex social systems often differ from the expectations of the lay person, and neither may be in accord with reality. While the phenomenon itself is not new, the consequences become more serious with

increase in size and complexity of social organizations; the impact on social stability is obvious.

The Intersection of Social and Natural Systems

The agricultural production function has at its base biological science. This has long been recognized in farm management and production economics, and to their credit agricultural economists have done pioneering work integrating production functions with the economics of the farm firm.

This work does not, however, touch the essentials of the emerging issues that impinge on sustained economic production. So long as aggregate effects could be ignored, production relationships could be expressed in terms that were relevant to firm decision making. Thus, new knowledge and capital could be substituted for "land" over a relevant range, and it was not necessary, indeed it would have been foolish, to have concerned ourselves with the possibility of finiteness of natural resources.

The scarcity of those natural resources that are priced in the market place is not the most pressing concern. Rather, the greatest threat comes from a different direction. Numerous resources are not priced in the market place, and these resources are typically referred to as common property. Because they are not priced, incentives do not exist for the development of technology that can be substituted for such resources. It is these resources that are becoming limiting to improvement in human welfare. Examples are the atmosphere, open space in urban areas, and certain natural systems.

This signifies that social science theories need to reflect more adequately natural systems. The relevant formulation of the aggregate production function may need to be in terms of the fundamental concepts of biological and physical science.[1] Until this reformulation occurs, I am not optimistic about scientists developing appropriate institutional devices for common property management. Of course, society may discover such devices through adaptation processes independent of organized social science.

[1] Georgescu-Roegen's *The Entropy Law and the Economic Process* is an attempt to provide a more general formulation of production relationships.

Summary

Dealing with the four characteristics of contemporary society discussed above constitutes the most important problem facing us for the next quarter century. But what has been said to this point that is of value in understanding the nature of contemporary economics of agriculture?

(*a*) Agricultural production around the globe will become increasingly commercialized. This commercialization will not solve the problems of the poorest of the poor except indirectly.

(*b*) Economic progress, made possible by agricultural improvement, will continue to cause social disruption. Unless there is a social collapse, however, society will not turn its back on large firms if it is economically efficient to be large. The benefits of economic development are such that those who are now deprived will strive for them; those who have the benefits will not willingly surrender them.

(*c*) Two types of negative side effects of economic growth will demand increased attention. One is social disruption; the other is reflected in insults to the environment. The identification of the most appropriate techniques for reflecting those side effects in decision making will be an increasingly important social problem.

(*d*) An international responsibility for hunger exists largely because of the transmission of information across national boundaries. National agricultural policies will be subjected to greater international scrutiny, and it will be difficult to isolate these policies from international relationships.

(*e*) The economics of contemporary agriculture will continue to be concerned with multiple objectives. Income distribution objectives will be counterproductive if production incentives are ignored. There are many agricultural examples of this from around the world, but if one does not wish to look abroad, U.S. energy policy provides an excellent example close to home.

Agricultural Economics

This section is normative. Here, I evaluate the performance of a profession and offer recommendations. Agricultural economists currently face some of the most severe problems we have had since I have been a member of

this profession. The trends and problems described above demonstrate that the economics of agriculture is becoming increasingly interdependent with other social problems. The result is that many groups, other than the agricultural economics establishment, are concerning themselves with the economics of agriculture. There is a real danger that agricultural economists may become the technicians for microeconomic problems but that we will lose our preeminence in policy matters. The remainder of the paper elaborates this concern.

In the following pages an attempt is made to evaluate an institution, to do what economists talk about so much but for which they have inadequate methodology. Ad hoc criteria used in this task are described in detail in the appendix. To summarize, these criteria are (*a*) the adequacy of the institution in defining its domain of performance (this criterion is concerned with who is included and excluded from the performance of the institution); (*b*) the precision of the institution in specifying the relation of those who make decisions to those who bear the impact of decisions; (*c*) the effectiveness of the incentive system of the institution in bringing about desired behavior; (*d*) the capacity of the institution to respond to change; and (*e*) the ability of the institution to generate relevant information.

Capacity to Define a Domain of Performance

During the past two decades agricultural economists have become applied economists by working on a wide range of problems. If one believes that what agricultural economists do is more important than what they call themselves, we can take justified pride in our willingness to tackle new problems. This proceedings issue, for example, reflects urban planning, agribusiness, marine economics, and international affairs as subjects of interest and emphasis.[2] Furthermore, the planning of annual AAEA meetings better reflects the wishes and desires of the current membership than did the meetings of an earlier time because of a few, relatively simple, changes in institutional devices.

[2] George Tolley and Irving Hoch, agricultural economists, are two of the most respected researchers in the subdiscipline of urban economics. The proceedings of this meeting will reveal the leadership of agricultural economists in marine economics. There is evidence that forestry economics may be on the verge of a renaissance. If it is, the efforts of an agricultural economist, Marion Clawson, will prove to be significant.

There are those who argue that agricultural economists have encompassed greater breadth than can be adequately accommodated and that the traditional fields of agricultural production, distribution, and policy have been neglected. Without doubt these central problems of agriculture should be readdressed. However, questions can be raised as to whether a continuation of the studies that dominated the 1950s and 1960s would have left us significantly better off than we were in the early 1970s. Indeed, it may now be easier to reorient our research and education to the contemporary economic problems of agriculture than it would have been if we had continued to work within the paradigms of the 1960s.

The research approach used by agricultural economists has been far more stable than the problems that have been addressed. The essentials of this approach have been a concern with the empirical and an appreciation of both the power and the limitations of economic theory. These dual characteristics have supplied our unity and permitted us to work effectively in fields ranging from urban to marine economics.

I am pleased with the domain of agricultural economics subject to the institutional framework within which we operate. We have been pragmatic in the problems studied, but we have been unified with respect to the way they have been studied.

Relation of Decision Makers to Those Who Bear the Impact of Decisions

Agricultural economics as a subdiscipline owes its development to the nurture provided by the land grant universities and the U.S. Department of Agriculture. The nature of the extension and research program insures a degree of responsiveness and accountability to clientele needs. The nature of these institutions also establishes and circumscribes clientele groups to a very considerable extent. While the impact of research and service extends beyond these clientele groups, our principal area of accountability has been to them. The evidence suggests that the profession has been commendably responsive to the needs of these clientele groups in research and service. It is not clear that we have been as responsive to the needs of other groups who have been affected by the total agricultural research and education establishment.

There are some special problems, however, that exist with respect to graduate education. Of all of the activities of the typical department of agricultural economics in a land grant university, graduate education most nearly approaches the concept of the autonomous university; yet the research that is being performed by such departments is becoming increasingly short run and applied in response to "accountability" needs. Does this form a satisfactory base for graduate education?

Breimyer recently said we may be guilty of glamorizing certain subareas of agricultural economics with the result that these are overloaded while others are undersupplied. Breimyer's view of graduate education seems to be sharply at variance with that of Ruttan, who wrote that the most able graduate students tend to gravitate away from those areas that are experiencing consolidation and refinement and toward those experiencing new bursts of insight. This divergence of view turns on whether graduate education can or should be manipulated and molded in response to applied research needs or whether it will be more valuable if it is conducted in a more autonomous fashion.

As stated above, the elements that provided the unity of agricultural economics are a concern with the empirical and an appreciation of economic theory. If this unity is to be preserved, graduate education needs to continue to provide for such an orientation. In this connection, I raise two warning flags.

First is the failure to distinguish between quantitative techniques and an empirical orientation. The purpose of empirical work in science is to permit the researcher to better analyze reality, but many of our quantitative techniques have no relation to this role. They may be normative, as in the case of much programming work, or they are futuristic, as is true of many system dynamics models. Such results are often incapable of being tested against past or future experience. Even where some testing might be done, it often is not. Thus, the technique, instead of being a more powerful tool for analyzing experience, in effect isolates the researcher from reality. While agricultural economists have a justified reputation for empirical work and confronting their conjectures with reality, preoccupation with quantitative techniques does not assure this. Indeed, overemphasis on techniques with built-in normative assumptions may preclude it.

Second, the analytical framework of economics properly qualifies it as the social science of the greatest value in policy analysis. Yet the mechanical application of economic theory to the kinds of issues and problems identified in this paper is not likely to be fruitful (Roberts). To maintain their traditional appreciation of both the power and the limitations of economic theory, agricultural economists may need to follow more closely than they have developments in the mainstream of economics. Most agricultural economists do have a fairly good command of microeconomic theory through their graduate training. Too frequently, their association with general economists is minimal after that. Both groups are the poorer as a result.

Educational experience at the graduate level can be classified into four major groups: (*a*) economics and agricultural economics, (*b*) subject matter outside economics to facilitate research and reading in economics (examples are quantitative techniques and mathematics), (*c*) subject matter that provides an alternative view of phenomena considered by economists (the other social and behavioral sciences and the law should be included but to the extent the economist deals with biological and physical phenomena, these subjects may also be considered), and (*d*) subject matter that assists in putting economics, economic problems, and social phenomena in perspective in space, time, or concept (examples are geography, history, and philosophy). No one can have a comprehensive mastery of all these areas, but a case can be made that all professional workers should have an appreciation of each. Such an appreciation can be obtained in many ways other than by formal course work because subjects vary greatly as to whether they can be more efficiently tackled at the graduate level by course work or by individual study.

The following recommendations are made for strengthening graduate education in agricultural economics. First, greater reliance should be placed on problem solving and application of analytic techniques in workshops, seminars, and the presentation of individual research in reports and papers. Data collected during my tenure as graduate dean at Oregon State University demonstrate that agricultural economists tend to be in graduate school a shorter period of time than most disciplines (which is probably good) and spend a higher proportion of their time in coursework and less in research (which is probably not so good). One set of data that I have shows that Ph.D. chemistry students devoted 40% of their

time in graduate school to course work, but doctoral students in education and agricultural economics spent 81% and 70%, respectively.

Second, agricultural economics graduate education needs to be greatly strengthened in macroeconomics and economic policy generally. Few agricultural economists are at home with the macro concepts underlying monetary and fiscal policy, international trade, and economic development. Yet, as noted above, the source of many of the public policies and trends that influence the economics of agriculture lies in these forces.[3]

Third, agricultural economics graduate education is generally weak in areas (*c*) and (*d*) above. Graduate students in agricultural economics seldom are able to appreciate the approach of another discipline to the phenomenon of concern, and we are generally deficient in the perspective provided by geography, history, and philosophy. The remedy of these weaknesses poses a nice problem in resource allocation. How can we put such work into an already overcrowded graduate program? It is possible (and I have seen it done) to move in this direction by an appreciation of two facts: extensive coursework is unnecessary to obtain the viewpoint of another discipline (one or two courses or individual study with some direction can stimulate a lifetime of reading and growth) and the subdiscipline of agricultural economics does not warrant extensive series of courses in the subfields of marketing, management, finance, and resources. The emergence of the post-World War II literature reviews provides the graduate teacher and student with a marvelous opportunity (Martin). A serious student with some faculty guidance can obtain the essence of these subfields by pursuing these literature reviews with diligence.

Effectiveness of Incentives in Bringing about Desired Behavior

There has been considerable discussion in recent years about the impact of the academic incentive system on the way professionals use their talents (Heady). I focus on a different facet of this general problem.[4] Agricultural economics has been nurtured by the land grant universities and the USDA. On the positive side, this provided a clientele and a structure for activities and encouraged a truly superior tradition of service and application. On the negative side, it tended to separate us from the basic disciplines and the liberal arts. The current emphasis on accountability, usefulness, and relevance directs attention away from fundamental problems that arise in connection with applied work. Proposals for a competitive grant funding in agricultural and forestry research are an attempt to break away from the parochial nature of much work in the land grant universities and the USDA.

Part of the difficulty may result from the use of false or irrelevant dichotomies. An illustration is provided by Gordon's presidential address before the American Economic Association. The implication of the title "Rigor and Relevance in a Changing Institutional Setting" is that a choice needs to be made between rigor and relevance. A disservice is done by stating the issue this way. The most relevant problems are, by definition, difficult. To suggest that they are somewhat amenable to nonrigorous examination is illogical. To the extent that we succeed in promoting this kind of nonsense, neither the best minds nor the best methods will be attracted to applied problems.

The Capacity of Agricultural Economics to Respond to Change

Most public institutions have been subjected to numerous exogenous shocks during the past decade, and agricultural economics has not been excepted. As noted earlier, the subject matter of agricultural economics has changed significantly, but another and perhaps more fundamental change has occurred about which there has been relatively little comment. Two decades and even as recently as a single decade ago, the profession was dominated by the large agricultural economic departments of the Midwest. Today, there are departments located throughout the country that are contributing significantly in many different ways. Why has this occurred?

Since World War II, increased resources have been available to the profession even

[3] The work of Schuh on the effects of devaluation on agriculture is an example of the kind of research that needs to be emphasized.

The time has probably come when agricultural economics departments should cease hiring just agricultural economists. Only by confronting people who have in-depth education in the areas in which we are the most deficient are we likely to get the dimensions needed in our work. When these dimensions are reflected in our research, they will enter graduate training in a most significant way, rather than as just another course in economics. Even in departments where economics and agricultural economics are combined, this kind of integration still seems to be lacking.

[4] Neither do I discuss here the AAEA awards program as an incentive. My opposition to this program is on the record elsewhere (Castle 1970, 1973).

though the share of the federal agricultural budget to economics has been relatively stable. Furthermore, state appropriations have grown, and other sources of funds have developed. This has increased the pool of educated humanpower available because of the close relationship between research and graduate education.

Because of this expansion in humanpower, it has been possible even for the smaller departments to attract two, three, or more quite productive people who constituted the nucleus of the necessary critical mass to do outstanding professional work. Coupled with this has been the manifestation of many interesting social problems related to agriculture outside the Midwest. The rapid development of agriculture in the South and Southeast, the urbanization of the Northeast, and the resource problems of the West provide examples. Thus, there has been an increase in resources, humanpower, and new problems since World War II. It will be unfortunate if this should spawn a new orthodoxy. The variations in conditions and problems in the nation suggest that departments should be different. Dilution of quality will undoubtedly result if scarce resources are used to try to be equally strong in all of the many subfields that populate our subdiscipline.

The Ability to Generate Relevant Information

Two major concerns exist because appropriate information is not being generated, although the fault lies other than with agricultural economics. However, the capacity of agricultural economists for social analysis may make it possible to compensate for some of the inadequacies of the institutional framework within which the profession must operate.

First, agricultural economics is the major social science servicing agriculture. While there are a smattering of sociologists, anthropologists, and political scientists involved, only agricultural economists have the sustained nurture provided by substantial recurring funding. The trend toward competitive grants may assist the other social sciences attain comparable depth, but I do not believe it. Animal science does not depend on competitive grants for work in animal genetics, nor do we use competitive grants to develop depth in plant pathology. A comparison of the development of agricultural economics with other subdisciplines in economics that have not had recurring sustained support makes the same point.

In the long run, we should work for something approaching comparable support for our sister social sciences. Unless we do, we will continue to encounter technical solutions to the social problems of agriculture. In the short run, we should exercise self-discipline and not pretend that agricultural economics is capable of dealing with all social problems. Our modest success in analyzing the economics of organizations and rule making should make us humble about tackling even more complex problems. If the first part of this paper has validity, it is apparent that the scope of economics will be sorely tried. While I am not among those who are critical of the relevance of economics, I must also record my belief that it cannot be expected to encompass all social phenomena and problems.

Second, agricultural economics, as it is currently organized, is inadequate for the analysis of the macroeconomics of domestic and international agriculture. Farrell's paper details institutional inadequacies with respect to our capacity for policy analysis of the economics of agriculture, and there is no need to repeat these arguments here. However, I believe there are some supplemental comments that can be made.

At various times there has been strong work in agricultural economics at Harvard University, Vanderbilt University, Stanford University, and especially at the University of Chicago. Our subdiscipline would be very different if these efforts had not existed. While the states were properly concerned with state and local problems, these private university efforts provided us with overarching concepts and synthesized fragmentary studies (Jones).

As compared with the need, I see relatively little of this occurring on the international scene despite excellent work of people such as Mellor, Ruttan, and Schuh. Should the work in agricultural economics at the University of Chicago diminish and nothing comparable replace it, the situation will be even worse.

The institutional pressures are in the opposite direction. Agricultural economists are typically expected to do technical assistance within the developing countries. This usually involves education or research on problems as perceived and defined in the institutional complex of the country. Agricultural economists may also be expected to serve as a member

of a multidisciplinary team to develop new technology for particular locations. Yet I see little to resemble the scaffolding that Schultz provided for the economics of agriculture on the domestic scene. In view of the interdependence of nations and cultures and in view of the need for generalizing adaptations, the value of this kind of work is great. Unless this need is met, the danger is substantial that international agricultural economics will become increasingly fragmented. If this occurs, agricultural economists cannot expect to play the leadership role in international agriculture that they have in domestic agriculture.

Concluding Statement

Agricultural economics is currently being subjected to powerful competing forces. One set of forces are immediate and real and pull in the direction of great emphasis on the micro with short-run payoff in a narrow cost-effectiveness sense. But there are another set of forces in operation that suggest agriculture will no longer be the exclusive province of the land grant universities and the USDA. This set of forces denies the uniqueness of agriculture and stresses interdependencies within and between economies.

The institutional framework within which agricultural economics operates generally reflects well the first set of forces, and the profession has reflected these needs in its work. The institutional framework is less well suited to the needs stemming from the second set of forces.

The profession has little choice, indeed it has a responsibility, to be responsive to the first set of forces in its research and service. The existence of a significant graduate program, however, provides an opportunity for a better understanding of the second set of developments. If agricultural economists are to remain preeminent in the policy arena affecting agriculture, they must constantly reevaluate their graduate education. That which is happening in our graduate education today will have great impact on our professional performance a decade hence.

Appendix

Criteria for the Evaluation of Institutions

Society has many institutions, which may be formal, informal, structured, nonstructured, for accomplishing social ends by influencing individual or group behavior. The objectives or ends are typically multiple in nature. Thus, judging the adequacy of an institution in achieving a single objective usually results in an incomplete evaluation.

The criteria suggested for the evaluation of institutions consist of five parts. Examples can be found of literature that bear on each criterion. However, at a minimum, all five considerations must be taken into account in judging performance. Further, no single body of literature can be relied upon for developing all of the above, and a heuristic approach is needed to utilize the theory that is available.[A.1]

(*a*) First is the adequacy of the institution in defining its domain of performance. This criterion is concerned with whether it is possible to know who is excluded, as the institution performs its role. An institution may fail because there is misunderstanding regarding who it serves. A small privately endowed, liberal arts college with highly selective admission criteria is less likely to be faulted for its failure to provide mass education than is a general purpose state college or university. Economic theory has something to contribute to the development of this criterion, although sociology and political science are useful as well. Externality theory is relevant to the boundary question, but, as has been noted, institutional statements about boundaries must do more than simply reflect physical conditions even though such realities must obviously be taken into account.

(*b*) Second is the precision of the institution in specifying the relation of decision making to the impact of those decisions. An institution needs to be specific with respect to who makes decisions and who bears the consequences of those decisions. The more democratic the system, the closer the correspondence between those making and those bearing the consequences of decisions. Regardless of the system of government, the situation is basically unstable unless the relationship is specified. The instability results from the always present prospect that the relationship will be discovered and made known but will not be to the liking of the populace generally (Dahl). Social psychology, political science, and economics all advance or accept the hypothesis that there is a relation between participation and behavior. The social choice literature on representation and appropriate jurisdiction is obviously relevant.

(*c*) Third is the effectiveness of the incentive system in bringing about desired behavior. Item (*a*) is neutral with respect to political norms; it pertains primarily to the degree of certainty that exists with respect to the sphere of operations. Item (*b*) permits one to relate the location of decision making to the impact of decision making, assuming the sphere of operation is known. Item (*c*) is more precise. The application of the criterion implies that social objectives can be discovered, that the relation of the two can be hypothesized and then tested. In practice, something less than ultimate social objectives may be pursued in order for the institution to be operational. When this happens, the institution may yield results that will not be consistent with more ultimate social objectives.

The neoclassical theory of economics is based on the normative assumption that the maximization of national income is desired. Conditions have been deduced that must exist if this is to occur. One such condition is that the incentive to incremental production reflects the social costs and returns of that production. The violation of this condition raises the presumption of market or institutional failure. Much of the recent literature on environmental economics has been concerned with the discovery and correction of such "failures" in economic activity. Such efforts demonstrate only that a single objective has not been optimized. More than this is needed to demonstrate that criterion (*c*) has not been met.

Fundamentally, of course, this item involves all of behavioral science. Even so, there is much important work that can be done on a quite pragmatic level. The work of Niskanen in demonstrating that, upon creation, the objectives of the bureaucracy become different than the objectives of the creators provides an illustration.

(*d*) Fourth is the capacity of the institution to respond to change. Many of the current questions about institutional performance stem from concern as to whether an institution has the capacity to respond to new information. In other words, does it permit social learning? New information can be accommodated in a variety of ways. Objectives may be adjusted, incentives may be changed, the domain of performance may be modified, or the demise of the institution may be anticipated (Dunn 1971).

(*e*) Last is the ability of the institution to generate relevant information. The making of decisions requires information. Institutions can provide for the generation of

[A.1] The economics profession has not been deficient, especially in recent years, in calling attention to the importance of institutions (Downs, Schultz, Shaffer). Further, there has been significant response to this need (Ciriacy-Wantrup 1956, Buchanan and Tullock, Olson, and Niskanen provide examples). Yet if the criteria suggested here have validity, the journey has not yet been completed.

information either explicitly or implicitly. The accuracy and relevance of the information that is generated has much to do with the quality of decisions that are made.

At this stage no one body of social theory can be utilized for the evaluation of social institutions. While I believe certain aspects of economic theory can be put to good use, it has obvious limitations. As noted, most or all institutions have multiple social roles. Because it is not possible to optimize more than one objective at a time, that part of the economic theory based on optimization may have limited value in institutional evaluations. Criterion (*d*) obviously pertains to nonstatic situations. While analyses based on static assumptions may have value, they cannot provide a definitive evaluation of institutions.

The AAEA—Issues and Answers

Paul W. Barkley, Charles E. Erickson, Bernard F. Stanton, Stephen C. Smith, and William W. Wood, Jr.

The American Agricultural Economics Association (AAEA) is a voluntary organization with about 4,000 members. The membership is extremely diverse. The only requirements for membership are an interest in agricultural economics and a membership fee of $25. The organization was formed in 1919 by a merger of the American Farm Management Association and the American Association of Agricultural Economists. As recently as the early 1960s, being an agricultural economist was equivalent to being a member of this Association. Since that time, the growing number of subspecialties and the increased remoteness of agricultural economists from agricultural policy has perhaps weakened the Association. Some observers feel that only about half of all practicing agricultural economists in this nation are members of the AAEA.

Recent AAEA presidents have made concerted efforts to increase the effectiveness of the Association so that all practicing agricultural economists will perceive some identifiable personal gain stemming from membership. These efforts have been thwarted by an amazing gulf that separates those who manage the Association from the dues-paying members.

The Association is managed by a volunteer, elected president and a volunteer Board consisting of six elected members, the immediate past-president, the president-elect, an appointed secretary-treasurer, and an appointed editor of the Association's journal (*American Journal of Agricultural Economics*). The Board is assisted by a number of standing and special committees. The lines of communication between the Board and the members are well defined but narrow; the linkages between the committees and the membership at large is very tenuous. Some committees operate with almost no input other than the experience and intuition of their own members. Other committees use extensive surveys to gather information and input.

The late 1970s will be a time of introspection and action for the Association. This session provided an opportunity for members to make an input into questions and ideas that maintain and run the Association. The session was conceived in 1976 at The Pennsylvania State University when President Farrell approached the Professional Activities Committee to ask if it would supervise a segment of the program during which members could raise questions and talk about their concerns for the Association.

Issue: Alternative Publications

The Association has been considering a publication outlet other than the *Journal* for some time. One possible alternative to the *Journal* is a newsletter that would carry information on meetings, semiprofessional activities, changes in employment, calendars of events, and the like. This newsletter could also include items that deal with contemporary economic issues and economic outlook information. Some organizations, the American Statistical Association, for example, have had something called *AmSTAT*, which does not look as if it would be very expensive to imitate. Can the AAEA publish this kind of document?

The Alternative Publications Committee has recommended that the materials that now appear in the back of each issue of the *Journal* be deleted and published separately as a newsletter. A recent survey indicated there was large support for this kind of separation and publication of the "soft" material. We do not at the moment know the exact cost of revising the Association's publication package in this way. There is also some concern regarding the ap-

This paper summarizes a session in which panel members responded to questions from the audience. The format of the paper is to state the issue and then characterize the answers given by the panel members. Paul W. Barkley was the panel moderator.

Paul W. Barkley is a professor of agricultural economics, Washington State University; Charles E. Erickson is with Cargill, Inc.; Bernard F. Stanton is a professor of agricultural economics, Cornell University; Stephen C. Smith is the associate dean of agriculture, University of Wisconsin; and William W. Wood, Jr., is an economist with the University of California, Riverside.

propriate contents for a newsletter. Should we take the material out of the existing *Journal,* or should we expand this material to include the dates and purposes of various meetings that may be of interest to agricultural economists? What kinds of information would be productive? These are important questions, and the Board or the Alternative Publications Committee would be interested in hearing from members about them. Many members have already participated in a mail survey related to this issue. By December 1977, the results of the survey and cost estimates for either a monthly, bimonthly, or quarterly newsletter will be available.

Issue: Service to Economists in Extension and Business

Agribusiness and extension economics are sometimes considered subsectors of the general profession. Since there are these recognized differences in areas of professional application, why is it thought to be more effective to target publication of the *Journal* to narrow interests of researchers rather than maintaining comprehensive treatment of the subject matter of economics and agricultural economics?

Annual meetings are sometimes divided into sections for special use by subgroups, but this kind of use should not negate the professional's basic interest in his profession: agricultural economics. The annual meetings should be a meeting of professionals, and it should reflect a high degree of professionalism. It should be useful to all agricultural economists whether they are employed by extension, research, resident teaching, or a private firm. The oft-cited division is an artificial one that has created more problems than it has solved.

The *Journal* raises similar problems. Some agricultural economists employed in extension have been critical of the *Journal* because it does not deal specifically with the problems they are investigating. Industry people have expressed a number of concerns about the professional publication. Although many members are concerned, it is likely that no two of them would agree about what should be done to improve the *Journal.* This disagreement is the real problem. It has been easy to be critical, but not so easy to make positive suggestions about improving things. The newsletter is the kind of thing that might attract some attention and solve some problems, but it can never be a perfect substitute for the *Journal.*

Issue: The *Journal*'s Clientele

Members of the AAEA may be making a mistake when they attempt to differentiate various clienteles for the professional journal. The real concern is how the *Journal* can provide a means for professional development. It should help readers understand and interpret the things that are at the cutting edge of agricultural economics. It should deal with the issues that are of major concern among agricultural economists. The *Journal* can be very important in terms of professional development. Comparisons are not always apt, but perhaps we can learn a great deal from the *American Economic Review.* It provides access to some of the current and more important economic thought—much more, perhaps, than the *Journal.* Can the *Journal* provide more material related to professional development?

All AAEA members should go back and reread Farrell's presidential address to learn the general change in orientation of materials that come out of this professional association. There have been significant changes in the sort of material that is taught and is in research programs. There is a great deal more "relevance" to the profession now as opposed to a decade ago. This increased breadth and relevance is beginning to show in the programs of the annual meeting and the *Journal.*

Issue: Membership in CAST

The Council on Agricultural Science and Technology (CAST) was established in 1973. Since then, the AAEA has been asked continually to join CAST and to assist in preparing reports for use by the Congress and by citizen groups. Many individual agricultural economists have served on CAST committees and task forces, but to date the AAEA has not participated as a sponsoring group. Why not?

In 1974–75, the Association appointed a committee to prepare a recommendation regarding the AAEA's potential membership in CAST. The three-member committee submitted a lengthy report that included arguments for and against membership. The same argu-

ments still apply so it can be assumed that the issue of membership in CAST is still controversial. (The committee report appears in the December 1975 *Journal.*) The Board tried to reflect the desires of members when it voted not to become a member of CAST. The Board and the membership perceived CAST to be an organization that takes political positions. Such positions are expressly forbidden by the AAEA's Constitution. Individual agricultural economists can and should continue to participate in preparing the reports issued by CAST, but that is a different issue than whether or not the Association should become an active member.

The nature and public posture of CAST may be changing, and it undoubtedly is a matter that should be monitored. Agricultural economists have had a great deal to do with changing the nature of some of CAST's positions. The Association has always cooperated in supplying people for task forces. Before the Association reconsiders joining, however, someone must study CAST's bylaws very carefully to learn the stated objectives of the organization, the composition of its executive Board, and the way in which decisions are made by that Board. The AAEA may have a greater influence on CAST by maintaining its stance outside the organization. Sometimes an outsider can have more influence than an insider.

Issue: Midwestern Dominance of the AAEA

The AAEA sometimes appears to be dominated by those agricultural economists working in the Midwest. One way to help open the Association to others would be to have the regional associations elect members to the Board of Directors. Another way is to have economists from extension and from industry play a more prominent role in managing the Association.

The Board of Directors has inquired into the question of regional representation on the Board. The majority decision, almost always a unanimous decision, is that we want a national association, not a federation of regional associations. To allow for regional differences, however, the presidents of the regional associations are asked to serve as ex officio members of the AAEA Board.

The issue centering on participation in the AAEA is more difficult. Hildreth's presidential address mentioned making the Association more open, but the openness must come through individual members becoming more assertive and more willing to take responsibility. Regardless of their place or type of employment, agricultural economists must be professional and must take the initiative in asserting that professionalism. This requires a commitment of time and energy, and often the individual member must take the first step in order to be recognized by the leadership of the Association. It is almost impossible to name an instance in which a recent president has refused an offer of assistance.

Issue: Participation in the Annual Program

The annual program appears to be dominated by people from land grant universities and the USDA. They seem to talk, moreover, about academic themes. Those agricultural economists employed by industries cannot find places on the program or even useful sessions to attend.

Industry economists have consistently complained about the Association. The *Journal* was at the top of the list for many years. More recently, there have been numerous complaints about the program. However, if industry economists have a complaint about this year's program, they should look to themselves. All members, including industry economists, could have submitted an "organized symposium."

The most persistent complaint among agricultural economists in industry is simply: "Why should I join?" If you cannot find an affirmative answer to that question, obviously it is unwise to join. Many have never had any difficulty deciding that membership has a positive payoff. Those who continue to doubt the value of joining should know that the Association is increasingly open to industry problems and industry participation. One caution is in order. In the past, industry economists have been heard largely because they opened their mouths. If they do not speak up, they will not be heard.

The Association seems to be made up of individuals with very selective skills. How can the Association arrange for meetings of agricultural economists who have such high degrees of specialization?

There are three ways. First, the president can arrange invited papers sections to accom-

modate the needs of a specialty. Second, the specialty group can develop a contributed papers session, or if the practice is continued, an organized symposium. Finally, the specialty group can ask the Association to sponsor a special meeting. This last alternative is possible under a policy adopted by the Board in January 1977. Under any of these plans the specialty group must take the initiative.

Issue: Membership Growth

The AAEA does not seem to grow as rapidly as degree conferrals and employment opportunities indicate it should. Many individuals and institutions are not joining.

As in so many cases, the answer to this problem lies in individual reaction. The Association has no mechanism to learn of potential members. Individuals who are already members must act as recruitment agencies for the group. Chairmen of academic departments and leaders of units in the USDA have often been asked to recruit from within their own units and have been very cooperative.

Recruiting in industry is more tedious. Industries must be aware constantly of the antitrust considerations that make it difficult for people in the same industry to talk to one another. Nonetheless, there are many individuals who should be contacted and asked to join.

The institutional membership is a related issue. The Association has not perfected means of gaining and maintaining the sponsorship of institutional members. It is possible that as many as 500 firms could be attracted into the organization to serve as institutional members or sponsors. Some agricultural economists now employed by industries are attempting to compile lists of firms that might become targets for institutional recruiting.

Closing Comment

In closing, we would like to recall Hildreth's presidential address, which mentioned and discussed many of the issues and themes that have come up in this session. It is good to hear someone who cares about the Association with that degree of intensity. By participating in this discussion, members, too, have indicated their care about the Association. We hope that care continues, and we hope that future presidents, future committee chairmen, and future program chairmen will find opportunities for members and others who are active agricultural economists to become active in this Association and to make the Association the important vehicle that it can be.

Potential of Research on World Food and Nutrition Problems

Charles E. French

This paper draws on two years of experience with the World Food and Nutrition Study (WFNS) of the National Academy of Sciences. I give some background about that study, but my comments are not restricted to it. Primarily, I define a professional issue, namely, that our profession lacks a meaningful and exciting research agenda for tackling world food and nutrition problems. Moreover, we are failing effectively to communicate both our skills and our needs. I am not discussing a new topic, e.g., Farrell provided a scholarly paper on many of these issues. Certainly the fellow's lecture by Kelso (this issue) will be a classic in our literature. My contribution lies especially in the chance to discuss a case study that involved substantial input from our profession.

The World Food and Nutrition Study

President Ford requested the WFNS study in December 1974 following the World Food Conference in Rome. He asked the National Academy of Sciences to assist. The issue specifically focused on how the U.S. scientific community could give leadership.

The Academy interacted with about 1,500 of the outstanding food, nutrition, and related scientists in the United States and throughout the world. The study was organized around twelve teams of experts covering the various subject matter areas; two "blue sky" teams to look at the unusual possibilities (one primarily of physical sciences emphasized supply and one primarily of social sciences emphasized consumption); one team to look at organizational changes; and one overall team to exercise some priority assessment of the research proposals of the other teams. The teams had both general and applied scientists. Two hundred and one people served directly on the study teams with eighty of those being social scientists, predominantly agricultural economists. The social scientists were diffused throughout the teams. Often they were limited to specific subject matter. To some extent, they may have been taken for granted and probably were not given as much attention as the others. This was particularly true with regard to defining their own specialized areas of research. A steering committee, several of whom were social scientists, gave overall supervision to the study. The dominant professional background of the staff was social science.

The team members were asked detailed versions of three questions. First, they were asked to delineate areas of research that their talents could address to alleviate constraints on availability of food and nutrition worldwide. The idea was to tackle both frontiers of science—external and internal (Weisskopf). They were to avoid presenting a shopping list but rather selected priorities that were head and shoulders above others they might list. Second, they were asked to evaluate the effects expected from this research, particularly in giving U.S. leadership to aid in solving the global problem (Arndt and Ruttan). Third, they were asked to lay out the institutional, financial, and policy considerations relevant in getting the job done. They were not constrained by resource limitations, but they were expected to justify their choices. Most teams came up with a rather short, substantiated, and well-defined list of priorities.

The study has resulted in two reports prepared by the steering committee—an interim report (National Academy of Science 1975b), accompanied by a special National Academy of Science study (1975a) on U.S. research pri-

Invited address

Charles E. French is with the National Research Council, National Academy of Science, Washington, D.C.

The author especially would like to acknowledge the ideas and support from colleagues on the staff and study teams of the World Food and Nutrition Study. Charles E. Hanrahan and Emery N. Castle gave helpful reviews of an early draft of this paper. Yet, in no way does this paper purport to represent them or the findings of the WFNS per se.

orities, to President Ford and a recent final report to President Carter (National Academy of Science 1977). These are being followed by five more volumes containing the specific reports to the steering committee by individual teams, including a social science volume. The two reports to the White House have been made public; the others will be soon.

Let me make two, probably unnecessary, caveats. These refer to an editorial technique that I will use but would avoid if I knew how. That technique involves comparison of social scientists with their counterparts. First, no attempt is made to downgrade social scientists; they compare favorably by traditional peer evaluation techniques regarding knowledge of subject matter and method. Second, no attempt is made to show disappointment with any social scientists who worked on the teams; they represented their disciplines effectively and accurately. All comparisons are made to suggest tangible things from other disciplines that agricultural economists might observe and possibly emulate. Suggestions for improving our discipline do not deal primarily with professional stature; they deal mainly with the modus operandi by which we can more effectively help tackle the global problems of hunger and malnutrition.[1]

Urgency in Research

The age of complacency for our profession is gone. We talk about professional direction at every AAEA meeting. For the most part we come out saying, "Tomorrow we must get organized!"[2] That is not good for morale. Compared with other scientists in the WFNS, agricultural economists lacked pride and scientific camaraderie, our frustration level was higher, and our satisfaction level lower.

Our potential emphasizes the urgency. The scientific community in general has been subjected to a catharsis. Scarcity, human rights, social justice, and challenges to the scientific method have laid clean some broad opportunities for research. The problems are complicated. But we have a comparative advantage for many of them. We are dealing with interscience, interpolitics, and international issues, particularly involving resources, food, and policy making. Farrell says it is "increasingly difficult—if not impossible—to analyze and understand agriculture and related public policies except as an integral part of national and world economic, social, and political systems" (p. 786). Warley indicates the point forcefully saying, "now foreign economic policy is the core of foreign policy" (p. 820).

A profound and effective paper by Castle has done much to stimulate me both by its forthright evaluation of our past contributions and by its definition of an important new direction. I listen when he concludes on the realities of adapting to technological change as follows: "Obviously, social adaptations are needed on a global basis to these realities. Social adaptations and social control mechanisms are needed to cause individual behavior to be consistent with social objectives. These mechanisms have been modified indirectly by natural science through the widespread adaptation of technology and they have occurred as a result of social experimentation and learning, stemming from technical change. They have not been changed to any significant extent, I believe, because of knowledge advance in the social and behavioral sciences although Adam Smith, Karl Marx, and J. M. Keynes might be cited to the contrary" (p. 8).

Such is his dire evaluation. But as usual Castle does not leave us there. He goes on to offer some new direction:

> Let us assume that the research succeeds in doing what the scientists say it holds the prospect for doing. . . . The question then becomes—how will this be viewed by the millions around the world who make the crucial decisions on family size, education, human health, production, harvesting, and distribution? Will it be viewed as a permanent expansion of the opportunity for even greater populations and even greater consumption of material 'things'? Or, will the increased output carry with it appropriate incentives for future adjustments? . . .
>
> A major re-orientation of research, primarily but not exclusively, social and behavioral in nature, is recommended. Such a re-orientation need not be highly expensive, as compared to natural science research efforts. . . .
>
> At the present time much of the social and behavioral science research and technical assistance is of a narrow scope on production and problems within the developing countries.
>
> . . . wants, desires, and hence, consumption, are largely 'givens' rather than variables to be explained

[1] Among the job specifications assigned me in the WFNS was staff responsibility for the economic input. This acknowledgment should make clear the ultimate responsibility for any concerns about such input.

[2] This overstatement, of course, is unfair to many fine papers given at this meeting in prior years, especially the papers by Farrell, Soth, Schuh, Barkley, and Warley.

in many social science investigations. This needs to change (pp. 7–15).

A sociologist, Philip Olson, recently gave a paper in which he surveyed recent sociology literature emphasizing these same ideas.

The Current Situation

Food and nutrition are much in the limelight. Energy is the spectre of weakness of the commercial world, but hunger is the spectre of the poor, and that is most of the world (International Food Policy Research Institute). U.S. policy has put food to the front starting especially with the China-Russian compromises. Terms of trade and population trends portend an emphasis on food. This is not so much to say that hunger and malnutrition are more urgent than in the past. The difference lies in the fact that, for the first time in history, we have a good chance to do something about hunger and malnutrition, and both the third world and we know that. Warley speaks of the "success of the developing countries in shifting the subject of their poverty from the periphery of world affairs to the center" (p. 825). Also, the newer emphasis on the adverse effects of poor diets on health have added concern (U.S. Congress).

A cohesiveness of concern about food problems has evolved worldwide. We all know about the Rome World Food Conference of 1974 and the follow-up conferences. Most major countries have programs of research and assistance (Cordaro). In the WFNS, we found sincere concern and evolving commitment worldwide to do something about this problem. This ebbs and flows, but it has solidified and has a permanence.

The basic conclusion of the WFNS was one of scientific and technological optimism. The consensus of the scientists was that they could meet the challenge laid out by President Ford if other members of society handled their part effectively. They particularly were concerned that the political and social problems be handled; otherwise, they laid no bets on the chances of success. Wharton also held that this was his view.

Probably the most innovative and substantive contribution of the WFNS was the couching of this problem in much broader terms than usual. The study discusses the political will of the poorer countries, joint programs with scientists worldwide, and social science research with special emphasis on poverty and the myriad of debilitating effects that poverty and hunger have on people. This is much more than the second-, third-, and fourth-generation problems of technical advance. This broader orientation does nothing to play down the importance of technology. It merely reorients it in a broader formulation. The press has emphasized this difference, and the reaction has been favorable. It is consistent with the current mood. President Carter in his special address worldwide on inauguration day highlighted hunger and poverty in his human rights pledge (Overseas Development Council).

In the WFNS, the need for priority assessment in research came through clearly. The public is tired of hearing scientists merely asking for more money. They want convincing arguments from scientists as to what taxpayers can expect if resources are given to the scientists. This study probably consolidated the largest consensus judgment ever by scientists to justify their existence. But methodologically, the scientists demonstrated time and time again that, unless one disciplines them and forces priorities, they simply will not make these choices.

A healthy respect was demonstrated for agricultural research by the general scientists and policy makers. Also, a healthy optimism about the contributions to be made by social scientists was evident. This was optimism as contrasted with outright respect. Most general scientists did not doubt that social scientists could do the job. The applied coworkers (primarily from the USDA-land grant complex) of the social scientists were doubtful but mainly supportive. The attitude was basically one of "wait and see."

The Academy report recommended 20% increase in real terms immediately and 10% per year increase the next four years. Several factors add strength and momentum for food and nutrition research. General scientists can get research funds out of the broad public concern budgets, e.g., space, health, energy, and environment. They will do so, often by incorporating the food and hunger problem into their research proposals. The agricultural scientists have gained respect (e.g., for the upgrading of personnel and for the way scientific knowledge has helped farmers handle the corn blight problem, to adjust to recent weather changes, and to make an important impact on foreign trade and the level of food prices). Science

maturity in this country is recognized. An important scientific international network is evolving, from the international centers to a growing community of science.

The role of the universities in research may well increase. The Title XII Program formalizes the potential in the world food and nutrition areas, but the story is broader. The universities need the money, and research funds are probably their most attractive potential source for increases. Also, some evidence shows that the private sector emphasis on research may be declining; the public may need to pick up that slack.

Having said all this, the case put forth for social science research in the research in the WFNS was not exciting to the other scientists, the staff, and the steering committee (table 1). The proposed research on national food policies and organizations gave the impression of a massive, and possibly an impossible, undertaking. The need and importance of it were accepted, but counterpart scientists expressed concern about its acceptance by the policy makers and openly admitted failure to understand what was to be done. They understood the trade policy research better, and the food reserve research was well received.

The management work had support but mainly as service to a host of other people. This was true of the benefit-cost work as well. Moreover, the benefit-cost work was often thought of as something to be done *ex post facto*. The work on information systems was an exception—the proposed information management work was substantive; also, that interdisciplinary report itself was strong. (I did not include it in table 1 as being specifically social science in orientation.) The marketing and food science work did not impress many as being scientific or important and mainly was considered only as an extension of production.

The nutrition policy makers expressed interest in the social science input, but they viewed a rather narrow range of social scientists as being helpful.

The foregoing may be unnecessarily pessimistic. It may put too much emphasis on the attitude of the counterpart scientists, the staff, and the steering committee as proxies for the scientific community and the policy makers. Yet one has to be honest; the agenda failed to impress these groups relative to the support they gave other areas.

The social science proposals put forth were from several sources. The study team reports usually were from teams that had two social scientists among possibly a dozen or more counterpart scientists. Several teams were predominantly social scientists, but often their work was circumscribed, e.g., to research needs on methodology, trade, information systems, or food availability. Various conferences on social science input were held with public and private groups and individuals. Much staff and steering committee effort was devoted to the subject. The basic problem was not that we did not have good ideas and many of them. The problem was lack of a well-defined, finite set of priorities that were understood by, and excited, others.

Professional Implications

The study design and organization may well have put the social scientists at a disadvantage. Yet, concern about professional orientation is not limited to this study or to me. Thus, what can we learn?

Six things about the posture of social scientists stand out. All six made the job of the social scientists in the WFNS more difficult.

First, their professional opinions were more varied than those of their counterparts. They spent much more time arguing among themselves, particularly with regard to what constituted their most important research opportunities. They had more difficulty in compromising for their common good. Interestingly, the most outspoken critics of the social science input were other social scientists. This was not generally true in the other fields. Diversity of thought is a cornerstone for scientific goals and objectivity but can be overdone. We may have outgrown the need to "discuss" everything to death. For example, several of us have long thought the inordinate use of discussants at AAEA meetings is an anachronism.

Second, the scope of the subject matter, and probably method, spanned by social scientists was wider than that of their counterparts. The other scientists were thrown off guard by the lack of specialization of the social scientists and the quickness with which the social scientists would claim their proficiency and the feasibility to research so many areas. The fact is that our study asked specifically for priority recommendations, the best foot forward, of the social scientists. Relatively, this came

Table 1. Recommended Social Science Research Priorities, World Food and Nutrition Study

Priority Area	Nature of Research Effort	Major Effects	Sources of Support[a]
Policies and organizations			
National food policies and organizations	Improve policies and organizations affecting food production, distribution, and nutrition in developing countries: (*a*) human performance in food systems; (*b*) comparative studies to identify transferable improvement factors (decentralization, local participation, staff development); (*c*) interactions of income distribution with food production and nutrition; (*d*) methodology of sector analysis	Early results in improving effectiveness of policies and organizations relating to food systems and orienting selection and implementation of other biological and physical research; give farmers incentives for production and provide prices that will give more effective distribution	AID, NSF, USDA
Trade policy	Improve effects of trade policy on food production and nutrition: (*a*) studies on effects of trade liberalization; (*b*) consequences of international management of trade; (*c*) optimum trading patterns	Early effects on orientating country food policies for balance between own production and reliance on trade; improve diets, incomes, and national economic performance	USDA, AID, DOS, DOC
Food reserves	Improve role of reserves in relation to other measures for stabilizing food supplies: (*a*) improving developing country food reserve practices; (*b*) identifying improved mixes of reserves and other measures to stabilize food supply	Relieve hunger and malnutrition due to production instability	AID, USDA
Management			
Farm production systems	Improve production systems, particularly for small farms in developing countries: (*a*) methodology for identifying appropriate farming systems; (*b*) multiple cropping; (*c*) soil and water management; (*d*) equipment-labor relationships	Realize potential for two to four times present production in humid tropics; more modest increases in semiarid tropics	AID, USDA, EPA, ERDA
Management services to other groups	Improve the functioning of technical areas by giving management services: (*a*) pest management (*b*) tropical soils (*c*) water and irrigation (*d*) aquatic systems (*e*) weather and climate variation (*f*) information systems (*g*) food losses	Much more efficient use of resources in many other special areas and when interdisciplinary effort is needed	AID, USDA, NASA
Benefit-cost analysis	Assess the expected returns from other programs: (*a*) chemical fertilizers (*b*) animal diseases	Orientation of programs of research and use for these two areas	AID, TVA, USDA, NSF
Marketing			
Market expansion	Extend market scope for consumers and farmers in developing countries:	Stimulate production and consumption and cut food losses	AID, USDA

Table 1, cont.

Priority Area	Nature of Research Effort	Major Effects	Sources of Support[a]
	(*a*) enhancing purchasing power; (*b*) transportation; (*c*) marketing institutions; (*d*) managing marketing flows of major commodities		
Nutrition Policies affecting nutrition	Improve effects of full range of government policies: (*a*) effects on nutrition of policies and practices usually formulated with no consideration of possible nutritional consequences	Nutritional improvement in short run; in long run dietary changes may benefit health and life expectancy of large population segments in United States and developing countries	NIH, NSF, USDA, AID

Source: National Academy of Science 1977.
[a] AID is Agency for International Development; DOC is Department of Commerce; DOS is Department of State; EPA is Environmental Protection Agency; ERDA is Energy Research and Development Administration; NIH is National Institute of Health; NSF is National Science Foundation; TVA is Tennessee Valley Authority; USDA is U.S. Department of Agriculture.

much harder for the social scientists than it did for their counterparts.

Third, the social scientists are understaffed and poorly resourced. The other scientists often asked whether or not the social scientists had a "critical mass." The counterpart scientists were serious in saying what they could do, but they were just as serious in saying what it would cost and how many more scientists would need to be trained if society expected them to do the job. The social scientists seemed to be willing to take on things much more quickly, and dollar and manpower costs were often an afterthought.

Fourth, social scientists do not delineate well between their service role and their specialty competence. Their versatility causes confusion about the role that is expected of them by both other scientists and policy makers. Also, it probably relaxes the priority assessment pressure on them when they are deciding what they can do specifically on their own. Social scientists have a pride about their interdisciplinary competence. The WFNS organization put emphasis on interdisciplinary work; this made it difficult for the specialized competence areas to evolve. The problem is inherent in our profession. The service demands are immense, and they are competitive with other things. We must do something to delineate the service role, decide how we can handle it, and articulate our professional policy about it to others. Confusion on this point clouds our respectability. Johnson has proposed a troika of problem-solving research, subject matter research, and disciplinary research. This is a start. Our key social science study team sorted their recommendations along this line, but it has not sold too well. But this notion deserves consideration.

Fifth, social scientists were more resistant than their counterparts in trying to estimate the impacts of their work. This may have been a more difficult role for them, or they may be more knowledgeable about the pitfalls in such activities. But the WFNS is unique in the degree to which scientists did attempt to justify their existence. So far, policy makers and funding agencies are impressed with this aspect.

Sixth, social scientists had more trouble communicating with their counterparts than the others did among themselves. This probably could have been expected. But it caused at least two problems. It tended to be used as an excuse for not ironing out mutual scientific notions between social scientists and the others. Also, it resulted in the burden of communication being placed upon the social scientists. The counterpart scientists had the social scientists on the defensive, e.g., they would ask, "how do you research an institution—anyway, what is an institution—a farm, a court of law, a family, a marriage?" By then the social scientist was frustrated, if not mute.

Thus, we are too opinionated, too broad, too poor, too overworked by others, too cautious, and too hard to understand! In addition, there were times when I thought the agricultural economists must be professional orphans. The family disciplines for most counterpart scientists were the bases for their un-

derpinning and often the stimulants for their pragmatism. Kelso demonstrated how essential this is. This problem came to me many times when counterpart scientists asked me or other social scientists what we considered to be our basic research needs, and so many times we mumbled a nonanswer. I wonder if the general economics profession is pushing us hard enough, but that is the basis for another paper.

The Opportunity

The time has now come for someone to lay out the research agenda. So, I will list eight areas. Unfortunately (or fortunately), their discussion must be brief.

This list may verify my own inability to avoid the generic dilemma—so many exciting things for us to do and so little willpower to say "no!" But the list attempts to use the experience of the last two years; the thought, work, and frustration of my many colleagues who struggled with this subject; the broad picture of what other scientists are doing; my inability to explain my professional colleagues to many others who wanted to support us; and my attempt to select research that could be additive and hopefully holistic.

Allow me to return a moment to Castle's new direction. He said:

"Examples of the kind of research issues I believe should be on the agenda for high priority examination are: a. Investigations which will lead to a better understanding of population growth under a variety of conditions. . . . b. Comparative analysis among nations and states of adjustments to particular resource endowments. . . . c. Investigations which will lead to better understanding of the compatibility of systems and organizations with the objectives of the larger society. . . .

"These investigations will have the following characteristics: 1. They are concerned with social control mechanisms. . . . 2. They will be concerned with the linkage and the flow of information between large systems and individual decision makers. . . . 3. They will constitute a significant change in perspective. . . . they will tend to concentrate on the determinants of consumption over time . . ." (Castle, pp. 12–15).

Resource economists are making important contributions to the formulation of this type of problem. Kelso has now given us an exciting personal testimony that intellect, insight, hard work, and great patience actually can integrate a piece of our integrative science. The trick is to avoid Boulding's devil of suboptimization—a theme that my management research has twisted in my gut much as Kelso's land economics twisted it in his.

Meaningful problems in food and nutrition characteristically are broad. Optimization equipment is difficult to construct. Too often an important part of the problem is assumed away to fixed constraints; we did this with early linear programming formulations involving the divisibility problem on fixed costs. The paradox of optimization lies in its increasing power as the problem is expanded. This is the thrill that motivates the large model optimizer.

Kelso and Castle scare me as they expand our definition of consumption in such problem formulations. This becomes especially troublesome in world food and nutrition research with its geographic and time-dimension variations. But I am convinced that we must try. We may need the leavening effect of some of the notions of Lindblom's "muddling through," but we do have a chance of surrounding these massive problems.

Now for my list of eight.

People around the world need help on policy evaluation. We have techniques and tools, such as sector analysis, for such evaluations. Also, we have some understanding of policy implications, part of which might help others, especially on policy dealing with technology. Policy evaluation is an area of strength. In policy evaluation research itself, we need more work on food reserves. We might do some method work on the potential of business management planning techniques as a way to assist developing country governments to avoid policy by crises. Many other possibilities exist. The areas outlined in table 1 are researchable.

Trade is essential if we are to avoid the temptations so attractive to technologists and others to make every country self-sufficient. Interregional trade research within countries and among groups of closely aligned countries is a need. The appropriate emphasis on self-sufficiency is a major problem. The profession has delineated the trade problems effectively, and judgments are reflected in the WFNS. But overall we are not staffed and organized well to do an outstanding job on trade. Some good

trade work is being done, but we need critical masses at more institutions and more collaborative work with analysts abroad, including emphasis on our traditional markets as well as developing competition (Krause).

Global models for coordination of production and consumption decisions are needed. These are more than current world models. We assessed the world model work in selecting the methodology for the WFNS. These models must be strengthened greatly if they are to do the job. Such research also may give the profession an opportunity to do more with the theory of holism. Currently, scientists use it as a buzz word to replace "scenario," which we have run into the ground. As I understand holism, the theory does not merely state that synergism gives a total greater than the sum of the parts. It also contends that a holistic component is identifiable in and of itself and should be the focus of the conceptual notions. Statisticians did more when they decided to look at the error term for what it was than they did when they handled it as a nuisance. Possibly we have another handle for big problems. The thrust of the world modeling effort is certainly not in our professional hands. If we are to do much about that, we have much work ahead of us.[3]

Research on institutions and their place in development was much discussed in the WFNS. The need for such research is dramatized by a crucial decision in the WFNS. It concluded that current knowledge was inadequate to design a food and nutrition institutional arrangement that would assure a high priority research agenda. So we were forced primarily to tackle the agenda itself. Some think that the WFNS approach was frivolous, but we considered it the best alternative.[4] A growing body of literature on institutional analysis has evolved. But we do not have a solid social science institutional research thrust, and a dire need for it exists.[5]

Farm management may be in for rebirth. Many questions asked in the WFNS had to do with some of the simple concepts of farm management and where farm management fits in the total development process. A serious adaptation will be needed to improve our knowledge about economies of scale, especially for the small farm in the myriad of settings in which it is found worldwide. The WFNS makes a strong assumption, along with many other studies, that we must get world production up substantially through smaller farms. It may be sacrilegious, but I hold that social scientists have significant responsibility to test that hypothesis. The emphasis on small farm development in the centrally planned countries is a special problem of note (Lazar). Hopefully, the farm research can be coordinated with needed research on household economies.

Technology diffusion research has had some inputs from this profession, but mostly it has been done by sociologists. Also, my impression is that the amount going on currently is nominal. Probably the most asked question in the WFNS was whether or not social scientists could explain why we were not getting more adoption of science and technology findings. Some in-house assessment of the value of social science research generally might be quite important and cathartic.

Marketing and business management research will be needed for improved world food and nutrition and is probably already overdue. The research in this area relevant to developing country problems was not impressive. Work at Michigan State University and Harvard University is encouraging but inadequate. The private sector work gave signs of declining, and it is too sketchy to be a major factor. Research on the role of the market as a link between commercial systems and agrarian development is recommended.

The poverty problem, as viewed by many including the Steering Committee of the WFNS, is nearly an identity with the world food and nutrition problem. Problems of the poor are obviously intertwined with the problems of hunger. Will social scientists do much about this problem? Our track record on poverty has been miserable in our own country and in our profession. We should make a decision as to whether we want to gear up for this worldwide. If we do not register a disclaimer,

[3] At least one recent analysis holds that we should be more involved in the world modeling effort as it is now evolving, such as at the International Institute for Applied Systems Analysis in Austria.

[4] We did make important organizational recommendations in the WFNS, but at best we compromised and worked on both organizational and subject matter priorities. I have elected specifically to avoid discussion of the organizational recommendations. (I am pleased that they are discussed elsewhere in the 1977 AAEA meeting.) Another proposal was that we wait and have the social scientists make the priority assessment, but we thought urgency foreclosed that possibility.

[5] See the forthcoming report of study team 7 of the WFNS where one classification for institutional research is proposed.

we will be held responsible for research in the area.

Conclusion

The WFNS adds support to a strong public and scientific expectation for social science research. Agricultural economics can lead the way for this research on world food and nutrition problems. The profession has the potential, especially in its own scientific personnel and in external support. Ironically, the biggest problems of the profession currently are in applying its own expertise in better managing its own profession. But doctors' wives die young, and psychiatrists' kids are often truants or delinquents!

Discussion: Research Needed to Increase Food Production

R. H. Wellman

As the World Food and Nutrition Study (WFNS) points out, the United States must increase its support of certain high priority research areas now if the people of the world are to be free from hunger in the year 2000. With adequate support and selection of priorities, it is almost a certainty that the people can be fed. In the areas of crop and animal production, insect control, and aquatic food sources alone, the study teams appointed by the National Academy of Sciences have identified seven high priority areas, which if pursued vigorously could easily double or triple the world's food supply within the next twenty-five years.

These areas are integrated pest management, nitrogen fixation by soil microorganisms, increasing photosynthetic rates, genetic manipulation, breeding resistance of plants to such stresses as drought and acidic soils, increasing livestock carrying capacity of grazing lands, controlling diseases such as sleeping sickness or East Coast Fever in livestock, and reducing the waste in fish processing. They offer major new pathways for the increase in food supplies. If research proved successful in the areas listed above, and if research findings were translated into farming practices in the developing countries, the food supply could essentially be doubled again by the year 2000 as it was in the developing countries between 1950 and 1975. This earlier doubling, the only gain of its magnitude in history, resulted primarily from increased use of fertilizers and pesticides and from traditional plant breeding.

It may be instructive as an example to describe in more detail the research proposed for one of these major areas, that of plant stress. Until now most efforts to overcome the effects of plant stress have been to supply the missing ingredient if it were in short supply or to avoid it if it were in long supply. This means irrigation where lack of water causes plant stress and not using land where acidity makes aluminum toxicity a serious problem. The world must get an increasing portion of its food from problem soils and from areas that have been considered too hot, too cold, or too arid for crop production. It is customarily the poorest farmer that has the worst land and the least chance of irrigation. He also has the problem of having no reserve resources. He must raise a crop every year in order to eat; yet the lack of an adequate monsoon may make his potentially high yielding strain shrink and produce no grain.

There are seven fields of research proposed to lessen the effects of plant stress in food crops: (*a*) developing rapid screening methods to determine resistance of cultivars to various stresses; (*b*) incorporating resistance to aluminum toxicity and other stresses into high yielding varieties of crop plants; (*c*) breeding crops for a shorter growing season to avoid drought or frost; (*d*) breeding for wider and deeper root penetration so that the cultivar can make maximum use of the scarce water or mineral nutrition; (*e*) improving the symbiotic relationship between soil fungi and plant—in the case of mycorrhizal association, the resultant complex functions as if the plant had a larger root system; (*f*) breeding for higher resistance to salinity—plants with good resistance could withstand the use of brackish water for irrigation; and (*g*) modifying farming methods so that stress is prevented or reduced (for example, shading of a lower crop by a taller one). While these problems can be solved only if some very fundamental work is done, the approach to all of them is mission oriented (i.e., if successful, more food will be produced).

The WFNS has made a great contribution toward setting the priorities of research. At Boyce Thompson Institute we have reordered research to put maximum efforts on three of the priority research areas recommended by the WFNS: biological nitrogen fixation, plant

R. H. Wellman is the director of the Boyce Thompson Institute, Yonkers, New York.

stress, and integrated pest management. We have also established interdisciplinary collaboration between ourselves and other interested parties, such as Cornell University and the International Rice Research Institute. All of us believe that the most important and exciting work we can do is to help solve the food problems of the future.

I have been somewhat surprised that the social scientists appear not to have participated in the studies leading to the recommendations of the WFNS to the extent that the biological scientists have. I say this in spite of the very valuable contributions made to the study team I chaired by two of your distinguished colleagues, McPherson and White, and, of course, French was also most helpful. But it seems that the agricultural economists should be leading the effort to quantify the importance of various research approaches. All together, twenty-two research areas have been defined in the WFNS report, and all have been given equal importance. No one has said which crops, in which countries, are most important. If the biologists attempt to cover all the problems in these recommendations, they will spread themselves too thin. Cannot agricultural economists point out the bull's-eye and let the biologists shoot at it? Were agricultural economists to undertake such a project, they probably would need all the quantitative skills they have. Finally, as biologists approach success in making the plants perform as they should, could agricultural economists tell them, and more importantly the farmer, what their efforts are worth? Do agricultural economists need to develop any new analytical tools to help when the time comes?

At the very least, it seems that in this day of interdisciplinary research, biologists must continue to work with economists and with sociologists and other social scientists as integral members of a team attempting to solve the food problems of the world.

Discussion: Nutrition and Food Science Implications

Doris Howes Calloway

A previous speaker has noted that there were only thirty agricultural economists involved in the World Food and Nutrition Study (WFNS). Even though "Nutrition" is half of the title, there were only five and a half nutritionists involved and, incidentally, only six women. Our study team 9 had two and a half nutritionists (one did double duty as an anthropologist) and half of the total women involved in the study. It is no wonder, then, that issues relating to women received little attention and that, apart from team 9's efforts, neither did nutrition.

Nutritionists must assume much of the responsibility for the fact that issues concerning food and its relation to human sustenance have been neglected by other professionals. Nutrition scientists have tended to remain in their laboratories, developing basic information on what substances are essential in the diet, what amount must be taken daily, and what metabolic purpose is served. "Basic research" workers have not spoken out on the societal consequences of failure to meet nutritional needs and, in fact, many may not even be aware of them (any more than an organic chemist, for example, might know about and speak to issues stemming from the use of pesticides). People working in applied nutrition might be expected to know these things, but applied nutritionists have for the most part been women who are often shy of speaking or whose remarks go unheard by those in a position to act, to make change.

More recently, the most prevalent form of malnutrition—that due to inadequate food intake, to limitation of food energy—has been seen to be unnecessary and capable of elimination. Many people have urged that a concerted effort be made to do so, and the United Nations is committed to this effort. Economists have looked to justify it as economic, not simply humanitarian. Assessment of economic costs relates to present views that short of death severe malnutrition leads to permanent impairment of physical and mental development so that society is burdened with the underproductive survivors. Sadly, the nutritionist is unable as yet to give definitive answers as to the individual and social consequences of less than severe malnutrition. Sadly for the economist, it is difficult for him to justify increasing the productive capability of someone who, in fact, will be unemployed and unproductive. Yet there is no doubt that these consequences are profoundly undesirable. Even our mutual security is threatened by the existence of malnutrition elsewhere.

Study team 9 was drafted to be interdisciplinary, with the sanction of the Academy but largely under advisement of Alan Berg, our chairman. His stance was consistent with a view that has been emerging among international and bilateral agencies (under the urging of a handful of key professionals, mainly economists) that sustained improvement in nutritional state of deprived people will not result from conventional nutrition/health sector interventions but will, rather, require that general governmental policies and programs be designed specifically with nutrition objectives in mind. Team 9 took a new view of nutrition research, seeing it as needing to provide the information required to indicate what the policy choices are, to provide the criteria for selecting among alternatives, and to suggest measures of effectiveness. This new kind of nutrition research obviously requires the involvement of many specialists, notably agricultural economists and nutritionists. Food scientists should review their research priorities in the same light.

Five research profiles in nutrition and food science have been selected by the Academy Steering Committee as deserving immediate attention. These are the functional significance of malnutrition or nutrition-performance rela-

Doris Howes Calloway is a professor and chairman of the Department of Nutritional Sciences, University of California, Berkeley.

tions, the role of specific dietary components in the context of total diets, the nutrition impact of governmental policies, evaluation of nutrition intervention programs, and reduction of food losses between production and consumption. Several other profiles have nutrition/food science content, but none of these offers the hope for immediate nutrition gains as those cited. Of all works proposed, the Steering Committee gave its highest priority to the research needed to link food intakes with nutritional states and to determine the biological and societal consequences of failure to meet needs. I agree.

Discussion: Enhancing Natural Resource Use to Increase World Food Production

Jan van Schilfgaarde

The natural resources available to grow food—land, water, and energy—are finite in extent, and their use for agriculture is often in competition with other uses. Recent inventories suggest that 3.4 billion hectares, or 25% of the world's land surface, in principle could be cultivated; at present the cultivated area is less than 11%. The potential for expansion of cultivated area is substantial, but much of this land is not where the people are; furthermore, its development could readily lead to drastic and irreversible resource deterioration both on site and off. A similar situation prevails for water. The currently 170 million hectares of irrigated land could be doubled but not without tremendous investment and substantial risk. The obvious alternative for increasing food production is to increase production per unit of land. Both avenues must be pursued.

Two divergent, yet related, concepts are often advocated: to transfer the technology of U.S. commercial agriculture to other regions and to greatly expand basic biochemical research—photosynthesis, nitrogen fixation, genetic engineering—in "pure" academic institutions. Both have their proper place in increasing food production, but they must be placed in perspective. I propose that higher priority be given to learning to use natural resources effectively and conservatively by adapting known principles imaginatively to existing ecological and socioinstitutional circumstances and by further developing these principles to aid in constructive development. This approach is less direct and more difficult than transferring large-scale mechanization and less glamorous than biochemistry. It calls for inputs from more than the physical and biological sciences—from economics, if you wish, but not for myopic benefit-cost analysis.

Some examples may clarify the issue. In Nigeria, it is not uncommon to encounter 50 plant species that make up a farming system for a small community. Introducing monoculture techniques would be socially and agronomically disastrous, as well as exposing the land to severe erosion. But the recent development of a hand-operated drill for precision planting in mulch or sod can greatly increase labor productivity. Combined with a back-carried herbicide sprayer that applies 10 liters per hectare (as compared with the more usual 500 liters per hectare), the energy required for planting is reduced more than tenfold, while production is increased by improving the existing multiple cropping system.

Pereira related an experience in Kenya, where some twenty years ago forest vegetation was transformed into a tea plantation, using the best conservation practices known. Peak runoff flows quadrupled during clearing and planting and still were double those from forested watershed after a full canopy was established, even though consumptive use was equal. Brazil is committed to developing 3 million hectares of Oxisol savannahs of their Cerrado by 1979 and 50 million by 2000; Peru plans to develop 2 million hectares of its Amazon jungle by 1990. Do we know how to avoid adverse consequences? If we do, can we implement the proper measures?

In Puerto Rico, intercropping a new planting of coffee with plantains the first two years, and taniers the third, increased net income more than $8,000 per hectare over the three-year period. Furthermore, imaginative management practices resulted in subsequent annual coffee yields ten times the regional average. Thus, the potential has been demonstrated of significant impact on production by adapting imaginative concepts to existing farming systems. So have the dangers of large-scale changes without full realization of the consequences.

Within this framework, exciting possibilities exist for research to realize the full potential of

Jan van Schilfgaarde is the director of the U.S. Salinity Laboratory, U.S. Department of Agriculture, Riverside, California.

Reprints purchased by Agricultural Research Service, U.S. Department of Agriculture, for official use.

the available resources, natural and human. The thrust of such research should be to help the independent, generally relatively small farmer improve his productivity with a minimal dependence on capital-intensive external inputs. This certainly does not obviate the need for sophisticated and basic research.

A key problem, especially in the tropics, is to provide adequate plant nutrition. In view of dwindling (and high priced) supplies of petrochemicals and phosphate rock, one valid approach involves accelerated research to manufacture ammonia more efficiently and from feedstocks other than natural gas and to improve the inexcusably wasteful methods prevalent in the phosphate mining industry. An alternative, of at least equal merit, is to use the resources at hand to reduce the dependence on artificial fertilizer. The amount of major nutrients in organic wastes in 1971 was eight times that in the fertilizers sold. In the United States, the nitrogen excreted by animals in confinement was about two-thirds that sold as fertilizer. Clearly, the potential for improved waste recycling techniques is large. Furthermore, research on the use of bacteria (rhizobia) to enhance nitrogen fixation and fungi (mycorrhizae) to increase phosphorus uptake by roots has tremendous potential for improving plant nutrition without dependence on expensive or even unavailable inputs; such research requires a high level of sophistication, but the results lead directly to simple field application.

Another opportunity concerns the adaptation of crop plants to environmental stresses. Historically, plant breeding has emphasized selection to fit an environment in which stresses—nutrient deficiencies, water, salinity—have been minimized. The selection of grains for aluminum tolerance and some preliminary results showing a wide range of salt tolerance among barley strains indicate the potential of fitting the plant to the environment rather than the reverse.

Considering irrigation, the need is for efficient use of water in the first instance. Current practices result in substantial waste of both water and energy and unnecessary degradation of land and water. The problems are partly technical, but, as illustrated by Reidinger, institutional and economic issues frequently dominate.

Space does not permit further examples, but clearly there are tremendous opportunities as well as many problems in increasing productive use of limited natural resources within the framework of socially acceptable farming systems—problems that require technical innovation but, just as urgently, imaginative inputs from social scientists. Some of these are close at home, like the need to provide adequate incentives for academicians to address multidisciplinary real world problems; others focus elsewhere, where textbook economic analyses have often aggravated rather than resolved unhappy situations.

Discussion: Social Science and Related Implications

Lowell S. Hardin

What we are discussing is a U.S. public policy document. Its message reinforces and is complemented by the rising concerns of nonfarm groups. The right to food is discussed as a component of the human rights package. The World Food Council, some think, may become a serious forum for north-south dialogue. There is hope that Public Law 480 may become a food for development program with decreased emphasis on surplus disposal and diplomatic leverage. More importantly, international interdependencies among nations and societies are increasingly understood. Thus, a variety of forces is at work to place at least part of the World Food and Nutrition Study's (WFNS's) recommendations on the national policy agenda.

In an effort to improve the performance of development aid, donors are demanding more sophisticated and rigorously prepared projects and programs. The capacity of many less developed countries (LDC's) to meet these standards is still limited. As a result, there has developed an increasing flow of development aid searching for suitable programs and projects. Equation of demand and supply cannot rely in the long term on transitory expatriate expertise. Rather, domestic LDC capacity to meet this need and tap into the global community of science, technology, and governance must increase. Much of what the WFNS recommends is intended to speed this process. But the new aid resources coming on stream will have to show at least some results rather soon if desired momentum is to be sustained.

Against this background, I have four observations. First, as agricultural economists we may well be challenged to provide more than we are prepared to deliver. Scientific and technological advances of biophysical and engineering types, while exciting, critically important, and likely to be forthcoming, are in themselves insufficient to the task. Nontechnological constraints may well be the critical ones. Involved are proper public policies in the rich as well as in the poor countries and development of the institutions, programs, and projects they foster. Biophysical scientists frequently speak with conviction when they say: "We have the technological package right. All that is holding it back is wrongheaded price, trade, tax, land tenure, exchange rate, or investment policies." Often economists are the first to agree. We also know, however, that much technology has been unsuccessfully promoted because it was not well tailored to the agroclimatic and socioeconomic circumstances of the intended users.

Second, what we seek and what our fellow social and biophysical scientists are urging upon us is joint involvement in capacity building and research. In this connection the experience of the International Agricultural Research Centers is instructive. Through high-quality biophysical research, much of it adaptive, some key technological advances are identified. At the national level, however, changes in the nontechnological components of the production/distribution system are required in order to take full advantage of the improved technology. At the invitation of national programs, the centers' social and biophysical scientists work with the nation's scientists and policy makers to put the nontechnological components into the total package. Thus, the initial technological advance catalyzes institutional and policy changes. Such technology-led changes are part and parcel of an imperfect institutional development process. They often make it easier for the right questions to be asked, heard, and acted upon. Effective participation by social scientists requires familiarity with the technology at hand and understanding of what is in the pipeline.

Third, for effectiveness, agricultural economists and social science colleagues need to enter the scene on an *ex ante* rather than an *ex post* basis. Biophysical scientists seldom take kindly to the social scientist who, absent

Lowell S. Hardin is a program officer for agriculture, the Ford Foundation, New York.

at preimplementation stages, comes in for the evaluation and tells everyone else what they did wrong. Of course, social scientists are involved in diagnosis, planning, and *ex ante* assessment of the consequences of change, but my plea is for even greater *ex ante* responsibility bearing and involvement.

Fourth, as social scientists we almost instinctively invest heavily in self-examination. Generally, the outcome is constructive. But to my view we should not let this process deter us from getting on with the job. Given the inadequacies of development theory and the limited knowledge of how to induce desired institutional change, we still have to learn by trying, by ferreting out what works and why.

Concluding, I view the study as a successful interdisciplinary effort. Having worked on the PSAC World Food Study of 1967, I have learned not to expect miracles. I do think, however, that international food and nutrition research and development is being made more legitimate, mostly for the right reasons. As this occurs, we may have to run to catch up. That is precisely what I would like to see happen.

Farm Family Response to a Negative Income Tax
(D. Lee Bawden, The Urban Institute, Chairperson)

Purpose and Design of the Rural Income Maintenance Experiment

D. Lee Bawden and William S. Harrar

The Rural Income Maintenance Experiment (RIME) was the second of four major experiments to test the behavioral consequences of a universal income-conditioned cash transfer program. It followed closely its predecessor, the New Jersey Income Maintenance Experiment, in objectives and design. Of the four experiments, it is the only one focusing on the rural sector (farmers and those in towns with population less than 2,500).

This paper describes the setting that spawned experimentation with a universal income-conditioned transfer program (commonly referred to as the negative income tax), gives the rationale for the RIME, and sets forth its objectives and basic design.

Origins of Negative Income Tax Experimentation

The negative income tax experiments originated in the mid-1960s. Public assistance programs in the United States had come to be regarded as illogically conceived, poorly administered, and inequitably applied. Over half of the poor people in the United States were receiving neither public assistance nor food stamps. Of those that were—mainly from Aid to Families with Dependent Children (AFDC) and Old Age Assistance (OAA)—some families were receiving eight times the assistance of other families of similar size and pre-transfer income merely because of regional location. Except for a meagerly funded and unpublicized AFDC-UP program in about half the states, households headed by able-bodied males under 65 years of age—the so-called working poor—were ineligible for public assistance; yet two out of every five poor people in the United States were in such households.

Out of this dissatisfaction, interest grew in an income maintenance program that was open to all poor people and that had simplified eligibility requirements. A universal negative income tax emerged as the most promising alternative among several, partly because of its ability to more efficiently channel funds to the low-income population and partly because of its inherent logic as a downward extension of the positive income tax. In its simplest form, a negative income tax embodies two principal features: a guarantee or basic benefit, which varies by family size and is available to families who have no income, and a tax rate, which is the rate by which this basic benefit (guarantee) is reduced per dollar of other income received by the family. (Thus, a 50% tax rate means that benefits are reduced by $0.50 for each $1.00 of income received by the family from other sources.)

The major reason for experimentation was that a negative income tax—because of its relatively high "tax" on earnings—would likely have some negative effect on work effort. But no one knew how much. The cost of any given negative income tax program is dependent on the amount of work disincentive that it would induce. Moreover, the choice of the appropriate parameters of such a program (the guarantee and tax rate) depended in part on the relationship of work disincentive to those key parameters. A large-scale experiment would permit identification of the effect of alternative negative income tax programs on work effort, as well as on the attitudes and other behavior of low-income families.

These were the major reasons that the Office of Economic Opportunity in 1968 ini-

D. Lee Bawden is the director of Human Resources and Income Security, The Urban Institute, Washington, D.C., and William S. Harrar is self-employed in San Francisco, California.

tiated an experiment in urban areas of New Jersey and Pennsylvania that focused on families headed by able-bodied males between 18 and 58 years of age.

Rationale for the Rural Income Maintenance Experiment

The New Jersey experiment was expected to yield a great deal of information about the effect of various negative tax plans on behavioral and attitudinal characteristics of urban wage earners. But these results were not expected to be directly applicable to the rural sector, in which over one-third of the nation's poor reside.[1] Differences between rural and urban residents in their work responses to such a program were expected because of differences in alternative employment opportunities and in the proportion of self-employed people. An accurate estimate of the magnitude of disincentive, both rural and urban, was necessary to estimate the cost of a nationwide program.

Also, it was not clear whether some features of a program most effective for addressing urban poverty problems were best suited for addressing rural poverty. For example, a large number of rural residents with low incomes are operators of farms or businesses in small towns. Determination of annual income as well as the appropriate timing of payments for the self-employed are different than for wage earners. This is especially true for those farmers who receive their entire annual income at harvest time.

These needs for experimentation in a rural setting in conjunction with the urban experiment in New Jersey led to a planning grant from the Ford Foundation to the Institute for Research on Poverty, University of Wisconsin. Under the Ford grant, ten staff members at the University of Wisconsin, all affiliated with the Institute for Research on Poverty and representing the disciplines of economics, agricultural economics, sociology, political science, law, and social work, combined in an interdisciplinary effort to design the rural experiment. The experiment began in late 1969 and extended over a four-year period, with payments made to families for thirty-six months. The total cost of the project was about $5.5 million, financed initially by the Office of Economic Opportunity and later by the Department of Health, Education, and Welfare.

Description of the Experiment

The primary objective of the RIME was to measure the effect of alternative tax rates and minimum guarantees upon the work behavior of rural residents, both wage-earners and farmers. Of secondary importance were a host of other objectives, among them being to learn the effect of payments upon (*a*) the children of the poor—their health, school performance, peer and reference group involvements, attitudes towards authority, delinquency rates, vocational aspirations, and numerous other characteristics; (*b*) changes in expenditure patterns—the distribution between savings and consumption, marginal expenditures on medical care and housing, and credit versus cash buying; (*c*) job search behavior; (*d*) farm production and financial decisions; (*e*) nutrition; (*f*) family structure (separation and divorce rates); (*g*) geographic mobility; (*h*) psychological well-being; and (*i*) political involvement.

Two locations were chosen for the experiment. The alternative of taking a nationwide rural sample was rejected in deference to administrative ease and a smaller operating budget. By selecting two locations, regional and ethnic differences in work incentives and other behavioral characteristics could be tested. The South was chosen because it contains a higher incidence of rural poverty than any other area in the United States and because over half of the rural poor reside there. The Midwest was selected because it is, as classified by the U.S. Department of Agriculture, a relatively affluent area with a poor white minority.

The sample was drawn from Duplin County, North Carolina, and two contiguous counties in the more sparsely settled Midwest (Calhoun and Pocahontas Counties, Iowa). Criteria for selecting the counties included the size and number of rural towns, their proximity to large cities, density of the farm population, diversity of agriculture, and representativeness of the entire region with respect to incidence of poverty, unemployment, racial mix, age distribution, and educational level.

Families were selected randomly from the

[1] In 1969 the rural population represented only 26.6% of the total U.S. population but contained 35.5% of the poor people.

predesignated areas and were deemed eligible for the program if their incomes were less than one and one-half times the established poverty line. Eligible families were then randomly assigned to a control group or to one of five treatment plans, involving combinations of three tax rates (30%, 50%, and 70%) and three guaranteed minimums (50%, 75%, and 100% of the poverty level). The plans are shown in table 1 along with their 1969 minimum dollar guarantees and breakeven levels for a family of four. Families remained on the plan to which they were initially assigned for the duration of the experiment, and they were eligible for payments for the thirty-six-month period regardless of their subsequent geographic location, as long as it was within the United States.

A total of 809 families were selected; 54% were assigned to the control group, and 46% were distributed among the five treatments. The sample was stratified by income level, age of head, and region. Sixty-two percent of the sample was allocated to North Carolina, 38% to Iowa. Seventy-two percent of the families were headed by an able-bodied male age 18 to 58, 13% were headed by a female of the same age range, and 14% were headed by a person of either sex over age 58.

Payments were based on income and number of members of the "filing unit." The central family of the household (husband, wife, and minor children) were one filing unit and received one payment; other household members—those over age 20 or over age 17 if married—were separate filing units and received their own separate payment but at a reduced level. If the latter left the original tax unit, they became eligible for the full head-of-household payment level. A family head or spouse who left the original family unit was eligible for a payment of one-half the amount that a head and spouse together were entitled to when both were in the unit. After one year of separation, they each were entitled to a full head-of-household payment.

Income and filing unit size were reported every month to a payments office. Income was defined as total gross income in cash or in kind from all sources minus business expenses. The self-employed also reported depreciation and other noncash costs once a year after filing their personal income tax returns. Ten percent of net capital wealth was added annually to income to represent potential capital consumption. However, the first $20,000 of business assets, the first $10,000 equity in owner-occupied homes, $1,000 in cash or savings, and all personal effects were excluded from net capital wealth for purposes of this imputation. A portion of out-of-pocket medical expenses were deducted from income. Federal and state income taxes were reimbursed on a dollar-for-dollar basis.

All filing units were paid semimonthly, with married heads receiving one check made payable to husband and wife jointly.

The basic accounting plan—the period for computing income upon which payments were based—was the same for both the rural and urban experiments: a three-period moving average, each period representing four weeks (or one month). However, the income accounting procedure in the RIME embodied a "carryover" provision. Earned income in excess of the breakeven level was carried forward for a maximum of one year and was added to income in any period in which such income fell below the breakeven level. Negative income payments were based on earned income plus any amount assigned to that period from the carryover. This was a major innovation in the accounting procedure from the New Jersey Experiment, necessitated by the uneven flow of income of the self-employed.

Adult members of the households (all those over age 15) were interviewed quarterly to

Table 1. Program Alternatives

Guarantee (% Poverty Level)	Tax Rates (%)		
	30	50	70
	Guarantee Level/Breakeven ($/Year)[a]		
50		1,741/3,482	
75	2,611/8,703	2,611/5,222	2,611/3,730
100		3,482/6,964	

[a] Breakeven is the level of the family's own income at which the negative income tax payments become zero. The guarantees were adjusted upward each year of the experiment by the rise in the consumer price index.

gather information on the previously mentioned attitudinal and behavioral characteristics.

Empirical Analysis

A number of researchers, both at the University of Wisconsin and at other universities, participated in analyzing the effects of the experiment. The results are reported in forty-one separate papers, to be published by the Institute for Research on Poverty.[2] The three papers that follow summarize three of the forty-one papers. They are among the most important for they focus on the effect of the experiment on the work and income of farm families and on their business and financial decisions.

[2] Copies of these papers are available from the Institute at a nominal cost. The data base is also maintained by the Institute, and a staff is available to prepare extracts for interested researchers. The cost will vary depending on the size and complexity of the extract.

The Effect of a Negative Income Tax on Farm Business Decisions and Financial Management

William E. Saupe

The purpose of these analyses is to provide a basis for judging the effect of a negative income tax experiment on farm business and financial management decisions. Of concern here are the effects on level and mix of farm production, on changes in asset-debt relationships, and on sources and purposes of farm loans. Theoretical expectations were reported by Meyer and Saupe, Bawden (1970, 1971), and Kerachsky (this issue) and are not repeated here.

Multiple regression analysis was the major analytical device. All models contained a set of theoretically plausible explanatory variables to control for any differences in farm resources or demographic characteristics between controls and experimentals plus variable(s) for the tax and guarantee levels in the experimental plans. Observations from Iowa and North Carolina were not combined in the analyses because of substantial differences in the underlying agricultural production relationships.

Explanatory Model

The analytical models and empirical findings are reported in detail elsewhere (Saupe) and are briefly summarized in this article. An example of the general explanatory model is presented in table 1. In this illustration the dependent variable is the value of all farm product sales in the middle year of the experiment.

William E. Saupe is a professor of agricultural economics and a staff member, Institute for Research on Poverty, University of Wisconsin, Madison.

The Rural Income Maintenance Experiment was conducted by the Institute for Research on Poverty, University of Wisconsin, for the Office of Economic Opportunity and the Department of Health, Education, and Welfare. Additional research support for the author was provided by the Research Division, College of Agricultural and Life Sciences, University of Wisconsin, Madison.

Race of head was included among the demographic variables in North Carolina, where being black was associated with $4,804 less farm sales, a substantial amount relative to the mean of $8,300. In North Carolina an additional year of formal education was associated with $438 of additional sales, but this variable was not significant in Iowa. Being confined to bed by sickness an extra day reduced sales by $78.60 in Iowa but was not significant in North Carolina.

In North Carolina, neither acres of tobacco nor acres of other crops significantly affected farm sales, but the operator's share of the crops produced was significant in both states. In Iowa, an extra acre of cropland added $43 to total sales; a marginal dollar of investment in specialized livestock equipment added 22¢ to sales; and an extra dollar of equity in the base period added 7¢ to farm sales.

Three dummy variables representing the experiment's tax rate-guarantee plans grouped by their approximate "generosity" are included in the example model (table 1). The variable scheme used here was appropriate for the range of income observed among the experimental farmers. The "low generosity" plans were the 50–50 and 70–75 tax rate-income guarantee plans. The 50–75 was the "medium generosity" plan. The 30–75 and 50–100 plans were combined into the "high generosity" group. Other parameterizations tested, but not illustrated here, were a single dummy variable for being in any experimental plan and a set of five dummy variables, one for each experimental plan.

Interpretation of the effect of the experiment does not have to be based on a single model such as table 1. Also of interest are the pervasiveness of an experimental effect over the three years of the experiment, among different parameterizations of the tax rate-guarantee plans, the sensitivity of the effect to

Table 1. A Model for Farm Product Sales in the Middle Year of the Experiment, North Carolina and Iowa

[a] If the operator received 100% of the crops as his share (i.e., a full owner), his farm sales would have been increased by $8,650.
[b] If the operator rented 100% of his cropland on shares, his farm sales would have been reduced by $6,835.
[c] The first six variables pertain to the head of household.

the particular form of the model, to the specification of the variables, and to the addition or deletion of a small number of observations from the groups being studied.

There are relatively small numbers of observations in each cell—from six to fourteen per experimental plan and from thirteen to twenty-four in the generosity groups. The problem of the reduced probability of observing a significant response given a "true" response thus becomes acute. Under these circumstances, the reader may want to accept significance levels of 0.25 or 0.30 that an observed phenomenon is an experimental effect.

Farm Product Sales

The experiment was found to reduce levels of farm product sales in both states but to have opposite and partially offsetting effects on levels of crop sales and on livestock sales (table 2). In Iowa, farmers responded with increased sales of crops, which were more than offset with decreased sales of livestock. In North Carolina, farmers decreased sales of tobacco and other crops, which were not offset by the smaller increased sales of livestock, also for a net decrease in farm product sales.

Table 2 may be considered a summary of many other analyses and tests. Some decisions affecting livestock sales in 1970 had been made prior to the start of the experiment in Iowa, e.g., purchase of fattening cattle and selection and breeding of swine. This would tend to dampen any response in 1970. In Iowa, the decrease in livestock sales associated with the experimentals increased both in magnitude and significance during the experiment (table 2).

Major livestock enterprises in the Iowa counties in the experiment were the farrowing

[a] This includes both the effect of farmers quitting production and the effect of remaining in production but producing less.
[b] Significance level using a *t*-test.

or purchase of pigs and feeding them to market weights and purchasing feeder cattle (generally in the fall) and feeding them to slaughter weights and selling the following year. Being in the experimental plans was associated with a lower conditional probability of selling any market hogs. Among the farms selling market hogs, experimentals sold substantially fewer in all three years, when preexperiment differences were controlled for. Fewer of the Iowa control and experimental farms fed any cattle, and the analyses were less conclusive. The number of cattle marketed appeared to be lower for farmers in the experimental plans, however.

"Minor" livestock enterprises were enterprises that were small relative to the usual size of that livestock enterprise on all farms in the county and also were a relatively minor part of the total farm business on the farms studied. The conditional probability that a farm had any minor livestock enterprises was not affected by being in the experimental plans in any year in Iowa.

In North Carolina, tobacco dominated other crops in gross sales per acre at well over $1,000 per acre, five times greater than for any other crop. Tobacco production was controlled by federal allotments, which could readily be transferred from farmer to farmer. Being in the experimental plans was associated with substantial reductions in tobacco sales and all crop sales in all three years (table 2).

Livestock sales in North Carolina were not statistically different between controls and the experimentals in all three years. Hog production was the most common livestock enterprise and it appeared generally unaffected. The conditional probability of having minor livestock enterprises, and the number of such enterprises, was greater for the experimentals in 1970 and 1971 but the effect on total sales was minimal.

Farm Financial Management

The management of farm business finances and farm family finances are usually intertwined. Every expenditure for consumption, farm-operating expenses, or farm investment draws from the same pool of receipts. For example, a change in total farm family income

caused by being in the experiment may influence farm net worth by a change in farm assets or farm debts. But the change may instead be in current consumption, purchase of consumer durables, or investment in human capital, with farm assets and debts unchanged. Thus, the experimental effect cannot be predicted.

Iowa farmers in the experimental plans increased farm net worth $4,415 less than controls during a forty-five-month period in the experiment from 1969 to 1973, after controlling for the different initial endowment of assets and other control-experimental differences. The *t*-significance level of this coefficient was 0.12; mean net worth at the end of the experiment for experimental and control farmers combined was $33,920. The percentage increase in farm net worth for experimentals was also less than controls. In North Carolina the net worth increases of controls and experimentals were not different in a statistically significant way.

The effect of the experiment on farmers' debt to asset relationships also can be measured but cannot be predicted. In general, the ratio reflects the farmer's and the agricultural lender's view of risk and the expected marginal returns from capital. The analyses gave some indication that Iowa control farmers increased their debts relative to assets more than experimentals. There were no significant differences in the debt-to-asset ratios of controls and experimentals in North Carolina.

Information about sources and purposes of farm business loans was asked for directly in the interviews. Questions were asked about lending institutions, the amount owed, and the reason for borrowing from that institution. Loan companies usually do not provide on-farm supervision or farm management advice with their loans and are often associated with relatively disadvantageous interest rates and repayment schedules. The Farmers Home Administration (FmHA) makes farm loans to applicants who are unable to obtain funds from banks and conventional lenders but who do appear to have farm business potential. In the years of the experiment, the FmHA also provided some on-farm loan supervision and business analyses for their clients.

For the established farm borrower, the improved financial position caused by being in the experiment might permit him to move from less desirable to more desirable lenders. The improved financial position might raise a previously high risk nonborrower to the minimum position where he becomes acceptable to (say) loan companies but not to banks. In Iowa, experimentals reported substantial reductions in the amount borrowed from loan companies between 1970 and 1972 and used this source relatively less than the controls in 1972.

In North Carolina there was a net increase of five experimentals reporting farm loans from any sources from 1970 to 1972 while controls remained unchanged. Regression analyses controlling for between-group differences established that experimentals on average increased their farm business loans $1,145 more than controls from September 1970 to September 1972 (*t*-significance of the controls-experimentals dummy variable = 0.30). Because experimentals started from a smaller base of loans in 1970, their percentage increase was substantially greater than for controls.

The major difference between controls and experimentals in North Carolina was that experimentals increased their use of the FmHA and loan companies relative to controls. The dollar change in borrowings from the FmHA was regressed against a set of relevant explanatory variables, and experimentals increased borrowings from them $996 more than controls (*t*-significance level = 0.19). A regression analysis of dollar change in borrowings from loan companies resulted in a $458 greater increase for experimentals over controls (*t*-significance level = 0.12).

In both states controls and experimentals were little different in their reasons for farm borrowing. Both increased their borrowings for purchase of land, buildings, and machinery. In North Carolina, both groups increased borrowing for automobile purchase and repair, but the changes were more pronounced for experimentals. The number of experimentals borrowing for this purpose increased from seven to twenty-three from 1970 to 1972, and they increased average borrowing for automobiles $587 more than controls during this period, controlling for other relevant differences (*t*-significance = 0.01).

Implications for a Universal Program

There were about 0.6 million farmers with total family income below 125% of the federal poverty level in 1975 (based on U.S. Dep. Commerce). The number eligible for a universal income-conditioned cash transfer program

would depend on the provisions of that program. However, the aggregate farm production responses to any politically feasible program would probably not affect farm production levels or food prices. First, the smaller (presumably lower income) farmers in the United States account for a very small percentage of total farm product sales (Daly). Second, the reductions in farm production noted in the experiment tended to be small and in some cases were shifted to nonexperimental farmers, e.g., tobacco allotments. In spite of a generally inelastic demand for food, the aggregate effect would be minimal.

Associated with the improved financial position of the experimentals, there was a willingness on the part of the farmer and his agricultural lender to begin or increase use of agricultural credit. Avoiding suboptimal use of this new credit would increase the effectiveness of a universal transfer program in increasing the economic well-being of the farm families. The successful experiences of the Farmers Home Administration with intensive loan supervision and of on-farm educational programs in farm financial management for smaller farms suggest that such an opportunity would exist.

Work and Income

Wendell E. Primus

This paper provides estimates of the effect that a negative income tax (NIT) has upon farm work and income. Experimental effects could be substantially different from that of a national income maintenance program for a number of reasons. (*a*) Three years, including an adjustment and learning process, may be too short a time horizon for farmers to completely adjust their farming enterprise to the different prices caused by the experiment. (*b*) There is evidence that families may not have understood how the transfer scheme operated. With a saturated national program, the level of knowledge might be different (Harrar). (*c*) Measurement errors in the collection of the data may result in erroneous conclusions being reached.[1] The theory supporting this analysis has been discussed elsewhere (see Evans; Kerachsky; Primus 1977, 1975).

Conventional consumer theory used in many labor supply models predicts a decline in total labor supplied by a farm operator under an NIT. Among different farm enterprises, the greatest reduction in labor input will be felt where the value of the marginal product for labor is smallest and where adjustment in size of farm enterprise is easiest. Enterprises with large illiquid and inflexible capital requirements should experience the least change in scale of operation.

Estimation Methodology

The prime tool for these analyses was a time-series, cross-section pooling regression program developed from Nerlove. The sample contains all farm families with a male head less than or equal to 72 years of age at the end of the experiment, who farmed each year, had constant marital status, and had at least 400 hours of farm work in one of the years between 1969 and 1972.

Each year of the experiment for each farmer constitutes one observation. This has the advantage of increasing degrees of freedom and allowing the behavioral response to the program over time to be traced. The number of individual farmers in North Carolina is 94: 42 were control and 52 experimental. In Iowa the number of control families for this analysis is 54, while the number of experimental families is 50.

Because of the different production functions and methods of production, the Iowa and North Carolina samples were split. Tobacco growing is primarily a labor-intensive operation, while corn growing in Iowa is a highly capital-intensive operation.

One of the methods for analyzing the effect would be to construct a demand-supply model. A properly constructed model could estimate the treatment coefficients, taking into account the simultaneous decisions, amounts of labor, capital (both long and short run) being allocated to each of several farm enterprises, including off-farm work by various members of the farm family. However, given only income and expense data in monetary terms, the *ex post* nature of the data, the failure to collect input data by enterprise, and poor measures of capital, it is difficult to estimate the structural equations with a sufficient degree of accuracy. Thus, the prime focus of this study is to estimate accurately the treatment parameters in a reduced-form model.

The basic form of the model is $D = f(C, E, C^*E, R)$, where D is a measure of farm income or effort, C are control variables, E are experimental variables, C^*E are control and experimental interactions, and R is a reporting variable.

Control variables are included to insure that differences between the control and experimental samples, which occurred as a byproduct or accident of random sampling, are not included in the coefficients on the treatment

Wendell E. Primus is a consultant to the Office of Survey Development, Office of the Assistant Secretary, Planning and Evaluation, Department of Health, Education, and Welfare.

This paper is based upon analysis done for the Institute for Research on Poverty and at Georgetown University. Complete discussions of the theoretical and empirical work summarized in this paper are available from the Institute.

[1] Measurement errors in the data were significant. Net farm income was changed by an average of $1,312 in North Carolina and $2,633 in Iowa through the editing process.

variables. These variables are often important determinants of the dependent variables. Without their inclusion, the equations would suffer from specification error resulting in biased experimental variable coefficients. These variables included a measure of 1969 work effort, age and education of the farm operator, debt-to-asset ratio, net farm equity, change in off-farm work, and dummy variables representing time.

Experimental variables are different formulations of the tax and guarantee parameters. Interactions are needed between the two groups of variables to test for differences between subpopulations (e.g., race) or as further refinements to determine where the treatment response took place.

A reporting variable was added to explain some of the variation in the experimental group response. A look at the distribution of hours worked for 1970–72 versus 1969 for the experimental group shows a considerable variation. Some experimental families increased their hours substantially, while other families' hours declined substantially. Farmers who intentionally or unintentionally misreport income to the payments process via their monthly income report forms might behave differently. Given the edited estimates of quarterly income (see Primus 1975 for a complete discussion of editing techniques), an estimate of the amount of payments farms should receive can be estimated.[2] Based upon this, some farmers received $1,000 more in payments than they should have received.[3]

Theoretically, these experimental farmers are facing a different marginal tax rate than their assigned tax rate. A change in their true income does not affect their payment as the subscribed mathematical formula underlying the NIT transfer scheme would indicate. Consequently, their behavioral response will be altered as compared with other farmers in the experimental group. The income effect would still be in effect, but the substitution effects would dissipate, the extent to which would be based upon the amount of misreporting and closeness to the breakeven level. As a partial control for this phenomenon, a variable was added that is actual minus predicted payments divided by the mean of the two variables.

Results

The conclusion relating to the experimental effect upon farm effort is sensitive to the measure of farm hours used: budgeted hours and recall hours. Each year, the respondents were asked the number of acres grown in each crop and the number of different kinds of livestock that were sold. By obtaining a coefficient from other published sources, an estimate of the number of hours a particular farming enterprise required was constructed. Adjustments for size and kind of capital equipment and amount of hired labor on the farm were also made. Thus, "budgeted hours" represent the labor input of the entire family to the farming enterprise. The chief disadvantage of using this variable is that farm overhead labor, such as building maintenance, repair of general purpose tractors, or gathering of market information, is not taken into consideration. This may not pose a problem if one assumes that overhead is simply proportional to the scale of operation.

The experimental effects on budgeted farm hours for each region, controlling for preexperimental factors, are summarized in table 1. The percentage differential can be interpreted

Table 1. Percentage Differential in Budgeted Farm Hours

	North Carolina (%)	Iowa (%)
Crop hours	−15.1[a]	−2.1
Livestock hours[b]		−15.8[c]
Total hours	−12.7[c]	−8.0[a]
Adjusted total hours[d]	−5.9	−11.5[a]

Note: Percentage differential can be interpreted as the average change in hours for the experimental group relative to the control group.

[a] This set of differentials for North Carolina is significant at the 0.95 level.

[b] Results for livestock hours are not presented for North Carolina because livestock is a minor enterprise and the analysis is dominated by a few observations.

[c] This set of differentials for Iowa is significant at the 0.90 level.

[d] Adjusted total hours subtracts machine hire and hired labor hours and adds custom work performed by the farm operator.

[2] The same mathematical formula as was used in the actual payments was applied to information collected by the surveys. All components of income and expenses were included. The survey's estimate can also differ because of the accounting period. Actual payments used a one- or three-month averaging period with a twelve-month carryover procedure. Surveys did not collect information monthly, so the accounting period was simply a year with no carryover scheme. This could not have, particularly in the last two years of the experiment, accounted for some of the huge differences in actual versus predicted payments.

[3] Predicted payments were on the average $845 less in North Carolina and $676 less in Iowa than actual payments. The standard deviation of the differences was $845 and $1,030, respectively.

as the average percentage change for experimental farmers relative to the control group.

The operations with small amounts of fixed capital and operations, which could be adjusted easily from one year to the next, experienced the most disincentive. Observe the performance of livestock operations in Iowa and crop production in North Carolina versus that of the capital-intensive crop operations in Iowa. The former had a significant disincentive. Probably, the weakest aspect of this evidence is in the inconsistency in North Carolina between adjusted total hours (removing the effect of machine hire, hired labor, and adding custom work) and total hours. Payment farmers have an incentive to buy hired labor because the price has declined relative to control farmers; one would have expected the disincentive would increase when examining adjusted total hours.

The reporting variable was highly significant and positive in all budgeted hours equations except for adjusted total hours in North Carolina and crop hours in Iowa, where it was insignificant. In Iowa, percentage differentials, calculated at plus or minus one standard deviation of the reporting variable, range from 4% to 6%. The percentage disincentive was always less where the level of payment to farmers seemed to be in the greatest error. In North Carolina, the change was in the same direction and the range was 15%.

During the interviews, which were conducted once every three months, a question was asked about the number of hours worked by the respondent on his farm the previous week. No effort was made to have the respondents keep track of the number of hours worked on a day-to-day basis. By multiplying by 13 and summing over the four quarters in a year, a yearly estimate of recall hours worked could be made.

The chief disadvantage with "recall hours" is a Hawthorne-type effect, in this case, interpreted as a change in reporting behavior resulting from observation. For example, imagine respondents with low levels of education who suddenly begin receiving $1,500 a year. On each opportunity where contact is made with the benefactor, there is probably a tendency to convey an image of a hard-working and industrious individual. There might even be a feeling that the payments are somehow tied to their work effort (i.e., more money for more work), despite statements from project administrators to the contrary.

The experimental effects on farm recall hours are different from that of budgeted hours. The percentage differential is an insignificant, but positive, 4% to 7%. Simultaneous models used by Kerachsky and Evans employing annual recall hours showed a positive incentive of around 10%. In North Carolina, this difference was significant. The reporting variable was insignificant in all equations where the dependent variable is recall hours.

Farm Income

Farm income was also measured in two different ways: net and gross farm income. Net income refers to gross income minus total expenses during a designated time period, usually a year. Gross income is defined as all income during a time period minus the purchase amounts paid for cattle, hogs, or sheep that are sold during the designated time period. Expenses include fertilizer, crop insurance, interest, depreciation, and other similar expense items. Farmers had the option of electing straight-line or accelerated depreciation, consistent with their reporting to the Internal Revenue Service (IRS). In all cases, the net and gross farm incomes were to be on a cash rather than an accrual basis.

From a policy viewpoint, net farm income may be the appropriate variable. This measures a family's ability to attain a decent standard of living. If through the experiment this variable has a treatment effect, it could have substantial cost implications for a national negative income tax program. However, gross and net incomes are influenced by the timing of income and expenses. An experimental farmer has a strong incentive to build inventories of grain and livestock and pay expenses immediately, while delaying the receipt of income. In this way, his payment would be maximized. A farmer with access to credit would not have much difficulty in paying expenses immediately and delaying income and, consequently, would show a larger disincentive for income than what actually occurred.

Reporting of income is probably affected by the experiment.[4] The amount of payments the families received is a direct function of the amount of income that the respondent reports.

[4] There was a significant difference between control and experimentals in reporting from farm records when answering the quarterly interviews with experimentals reporting more frequently from farm account records.

Consequently, an experimental individual has incentives to report all the expenses he can. Furthermore, he may incur expenses within the duration of the experiment that otherwise might be delayed. Examples of this would be major overhauls of tractors or building upkeep. Adjusting the period of analysis would be an attempt to overcome this problem.

If a disincentive in hours did occur, the reduction in hours would be expected in those enterprises where the marginal return to labor is the smallest. Thus, farm profit should decline by a smaller percentage than labor input. If an incentive in hours occurred, one could probably expect that, because of diminishing marginal returns, farm profit would increase, although less than the percentage increase in farm hours.

Again, the actual effect on farm profit is sensitive to the definition of farm profit and the model specification. When profit is defined as gross farm revenue minus variable costs or as the monetary returns to fixed inputs and to farmers' own labor, and the model is estimated in simultaneous equations framework using recall hours, the empirical analysis indicates that the experiment had negative effects upon profit (Evans). These effects are generally large—between 10% and 30%. Furthermore, the percentage effects in North Carolina tend to be larger than those in Iowa. However, the results for both regions are statistically significant at only marginal levels.

When profit is defined as gross farm revenue minus depreciation and variable costs, or as the monetary returns to farmers' own labor, and the equation is estimated as a reduced form controlling for preexperimental conditions, the experimental effect is still negative. However, in contrast to the earlier results, it is insignificant and smaller—between 7% and 10%. Gross farm income had similar results to that of farm profit.

For both results, the experimental effects on profit did not vary systematically or significantly with changes in the tax rate or guarantee. Furthermore, there were no distinct time trends associated with these effects. Generally, the results for farm profits were consistent with budgeted hours as opposed to recall hours.

The reporting variable was again positive and highly significant in the farm equations. The percentage differentials were different by 49% for returns to labor in North Carolina and 75% in Iowa calculated at minus versus plus one standard deviation of the reporting variable. The range in gross farm income was less: around 16% in North Carolina and 22% in Iowa.

Conclusion

The major hypothesis advanced is that work effort should decline with an introduction of an NIT scheme. The answer varies depending upon the variable being analyzed. If recall hours are chosen, one concludes that the experiment had no effect upon hours worked. On the other hand, if budgeted hours are used, the evidence is quite strong that the treatment did affect work hours in a significant negative direction.

An unequivocal answer is highly elusive. A measurement of hours worked for the farmer is the intersection between his labor demand and labor supply curves. It cannot be argued that recall hours represent the supply curve and budgeted hours a labor demand curve. Both variables attempt to measure the intersection of the two curves. To establish which is the better variable, one must determine which measurement technique is best. To argue that economic theory should determine which is correct because one agrees better with the theory is not an independent test of the theory and not a particularly useful way of doing empirical research. Obviously, however, the variable that is judged best by independent criteria, statistical methodology, or whatever will hopefully correspond best to theoretical predictions.

Recall hours are based solely upon a respondent's declaration of the number of hours worked the previous week including overhead hours, while budgeted hours depends directly upon numbers of acres of corn, acres of soybeans, hogs sold, cattle sold, etc. These latter numbers are more likely to be remembered because they influence all subsequent management decisions. This is not to say that there were no errors in the reporting of year-end numbers; but if and when changes to these quantities were needed, the changes could be documented and these changes were relatively small compared with changes in asset or income variables (Primus 1975).

A further argument can be advanced. Presume that one has a number of different productive activities that need to be summarized as one. One immediately thinks of constructing a

linear combination of these different activities. Those weights should represent labor coefficients from other studies. However, because individually most productive enterprises decrease (Saupe), although not always significantly in quantity with respect to treatment variables, all reasonable coefficient sets would show a negative treatment effect. Consequently, if recall hours and budgeted hours are to be reconciled, three possibilities arise. (*a*) A Hawthorne effect does exist and is responsible for the difference. (*b*) While the experimental families have reduced their farm work effort in terms of growing corn or raising pigs, they have increased the number of overhead hours. While this may be true, it certainly is not policy relevant that the farmer must now take five trips to town instead of the previous two to accomplish the same mission. (*c*) An accident of random sampling resulted in experimental families using more labor-intensive techniques of production. This hypothesis is essentially negated, however, when various functional forms of work effort in 1969 (the preexperimental year) are entered in the model.

The results for budgeted hours are roughly consistent with net and gross farm income. Particularly, this is true when a measurement variable (actual negative income payments minus predicted negative income tax payments based upon edited quarterly data) is added to the model. Those families where actual payments exceeded predicted payments by a large amount are affected less by the program parameters (tax and guarantee rates) than families where actual payments equals predicted payments. Consequently, there is more disincentive in families where the latter occurred in terms of hours and income. The fact that the reporting variable was significant in the budgeted hours equation and not the recall hours equation strengthens the case that the budgeted hours are the better measure of farm work effort.

While there remains several disturbing aspects of the data, it seems clear that farm families reduced their crop hours significantly in North Carolina and their livestock hours in Iowa. The overall effect of an NIT on total hours is negative, significant, and on the order of 6% to 13%.

Labor Supply Decisions of Farm Families

Stuart H. Kerachsky

Faced with changing economic opportunities, farm operators have increasingly been dividing their work time between self-employed farm work and the wage labor market—a situation that can be best described as multiple labor market participation. By 1969, the year in which the Rural Income Maintenance Experiment (RIME) began, over 54% of all farm operators in the United States had off-farm sources of income, primarily from wage work (U.S. Dep. Commerce). This figure had risen almost ten percentage points since the end of the previous decade.

Wage market participation rates of the two samples in the RIME are quite similar to the national averages for farm operators with the respective levels of farm sales. Over 33% of the experiment's Iowa farm operators and 58% of the North Carolina operators held wage jobs at some time during the three experimental years. When the labor market activities of both husbands and wives are considered, in almost 50% of the Iowa farm families and 78% of the North Carolina families either the farm operator, his wife, or both held wage jobs. However, wage work provided only a secondary source of income: for families participating in both labor markets, only about 23% of all earned income in Iowa and 48% of that in North Carolina derived from wage work.

These figures for the labor market activities of farm families clearly indicate that a study of their labor supply should focus on both the self-employment and the wage labor markets. Thus, this study analyzes the effects that an experimental negative income tax (NIT) program would have on farm family labor supply given multiple labor market opportunities. Theoretical considerations related to the study are presented, followed by a summary of the actual analysis. The final section of this paper discusses the main findings and places them in the perspective of the overall farm-related analysis conducted as part of the evaluation of the RIME.

Stuart H. Kerachsky is a senior economist with Mathematica Policy Research, Inc., Princeton, New Jersey.

This paper is drawn from the analysis the author performed for the Rural Income Maintenance Experiment as a project assistant with the Institute for Research on Poverty (Kerachsky). His contribution in the RIME final report provides a complete discussion of the theoretical and empirical work summarized in this paper.

Theoretical Overview

In a purely hypothetical world in which a farm operator is paid the value of his marginal product, receives no nonpecuniary benefits or costs from his work activities, faces no market imperfections or institutional constraints, and is not dependent on the labor market activities of other family members, a simple theory underlies multiple labor market participation (Lee): a worker will allocate his labor in a manner that maximizes the value of the marginal product of each hour worked. As a self-employed farm worker, he receives the full value of the marginal product (*VMP*) of each hour worked. As with other resources in the farm production process, the marginal return to labor is a declining function of the quantity used, *ceteris paribus*. In the wage market, on the other hand, labor is paid a constant hourly return (w) in the relevant range.

This distinction between the two markets suggests a particular utility-maximizing ordering of time allocation: as long as *VMP* exceeds w, the individual allocates work hours to the farm, thereby depressing *VMP*. At the point at which *VMP* falls to equal w, he channels his remaining work effort to the wage market, stopping all work when the marginal rate of substitution of income for leisure ($MRS_{l,y}$) reaches w (and *VMP*). Of course, corner solutions in which *VMP* equals $MRS_{l,y}$ at values greater than w are also common. In such cases, farm operators maximize utility by stopping work before they enter the wage market.

According to this simple theory, any change in income that treats the return to labor in each market exactly the same leaves the quantity of farm work unaffected. This result is particularly important for predicting the effects of introducing an NIT program. The income guarantee provision (G) of an NIT program does not alter the return to farm or wage labor at all, while the tax rate (t) alters each return equally. The new equilibrium condition between labor markets, $(1 - t)VMP = (1 - t)w$, implies switching from farm to wage work at exactly the same number of farm hours as before the introduction of the tax. In this case, changes in time allocation result only from changes in the wage-work/leisure equilibrium point, which is dictated by the equality of w and $MRS_{l\cdot y}$. Since w and $MRS_{l\cdot y}$ are altered differently by the provisions of the NIT program, equilibrium can be restored only by reductions in wage work. Of course, if all wage work is exhausted before equilibrium is restored, the residual adjustment occurs as a decrease in farm work. Finally, if the corner solution with no wage work exists, the full burden of restoring the equilibrium rests in reducing farm work.

The conclusion is that the impact of an NIT program on an individual's multiple labor market participation can be discerned if the analysis is confined solely to wage market participation, unless a corner solution is reached. However, this "conclusion" is merely a testable hypothesis and not one that can be defended without prior analysis. The possibility that nonincome utility differences and differential imperfections between the labor markets exist suggests a need for a more general theory.

Nonincome utility differences between farm and wage work are directly associated with the tasks an individual must perform on the farm or at his wage job and with his actual or perceived roles in the job settings. It is commonly believed that farm operators prefer farm work for reasons over and above the income it produces. There is the mystique that farmers have a "love for the soil" and that self-employed persons dislike determined work schedules and supervision. Restructuring the analysis so that the utility-maximizing framework reflects potential utility differences between labor markets leads to the following equilibrium condition:

$$VMP + d = w = MRS_{l\cdot y} - MRS_{wh\cdot y},$$

where d, which reflects the difference in marginal returns resulting from worker preferences, is the difference between the marginal rate of substitution of income for farm work ($MRS_{fh\cdot y}$) and of income for wage work ($MRS_{wh\cdot y}$). If d is positive, operators' utility-maximizing mix of work should include enough farm work to drive VMP below w.

Differential market imperfections can take many different forms. First, tax rules, both experimental and nonexperimental, provide workers with the ability to manipulate, legitimately or illegitimately, self-employment income to their own advantage. Workers may transform such income into a form treated preferentially by the tax laws; they may defer income or expenses to a more opportune time; or they may simply misreport income and expenses. Second, constraints on work schedules can prevent complete hours adjustments. In addition to the usual institutional constraints associated with the length of a wage work day, farm operators are limited with respect to which parts of the day or year they can spend off their farms. Finally, long-term investment activities may inhibit short-run job market adjustments. Such activities are usually associated with the farm, and they may increase farm work above the equilibrium level dictated by the simple theory. However, investment activities could also be associated with careers in the wage market, so they may increase wage work and decrease farm work from the equilibrium level of the simple theory. These examples of market imperfections are consistent with the general theory.

The general theory implies that the ordering of time allocation discussed in conjunction with the simple theory cannot be accepted as a general description of such labor market decisions. Certainly, it cannot be assumed that the guarantee and tax provisions of an NIT program will not affect the level of farm work. Furthermore, labor market decisions may be simultaneously determined, since they may well vary with such factors as the level of farm work, the level of wage work, the ratio of the two, and the level of nonwork income. Since work of any type is usually assumed to be an inferior good, a net decrease in work effort may still be expected. However, the source of this decrease is uncertain. On the basis of the above discussion, the level of farm work may increase for experimentals relative to controls, while the levels of both wage work and total

work decline. Of course, other scenarios are also possible.

This entire situation is further complicated by potentially interdependent labor market decisions among family members. As has been demonstrated (Killingsworth, Kerachsky and Mallar), such interdependence makes the theoretical effects of an NIT on a given member ambiguous.

The Analysis

Due to the theoretical ambiguities, the empirical investigation follows an approach that imposes few restrictions on the estimation of experimental NIT effects. The analysis is based on a four-equation simultaneous system. The three central equations are labor supply equations for the farm operators' farm work, their wage work, and their wives' wage work. (Wives' farm work and other family members' work are assumed to be associated with this system in a recursive manner.) To ensure consistent estimates of experimental effects, the nonexperimental portions of the equations are fully specified, including variables for the marginal return to work, income, life cycle and other demographic characteristics, and the work effort and marginal returns to work associated with participation in the other labor market and the labor market participation of the spouse. The portions of the equations that are designed to capture the effects of the experiment were variously specified as simple experimental status variables and complex interactions of status with demographic characteristics. The fourth equation in the system is a farm labor demand equation that, together with the endogenous marginal return to farm work variable, completes the system. Since the experimental NIT program is not expected to alter the farm production function, there is no experimental component of this equation; therefore, it is not discussed further in this paper.

The ease with which individuals may enter the wage market necessitates that the sample relevant to this evaluation include all farm operators and their wives. However, in both the farm and wage markets, differences exist among age groups, which suggests that these groups be analyzed separately. Because of the small number of young and old sample members, the analysis is confined to the middle-aged group—families in which the head was between 30 and 59 years of age at the start of the experiment.

Additional differences are evident between the North Carolina and Iowa samples. These are associated with farm enterprises and practices, the nature of the wage market, and the stocks of human capital. Consequently, the samples in the two regions exhibit different structural relationships, and they are analyzed individually.

The final samples are three-year panels of nearly 100 families in each region, approximately half of which are distributed among the five NIT plans. An error-components model is used to pool the three annual observations on each family, thereby increasing the effective sample size.

Since not all farm families contained members who participated in wage work, the analysis is divided into two parts. In the first, the annual hours of operators' farm work are evaluated together with the decision of the operators and their wives to enter the wage market. (Annual hours of farm work are constructed from the four one-week observations of hours recorded for each year. The binary wage work variables are derived from individuals' recall of wage work activities for entire quarters.) The second part of the analysis includes only those families in which at least one spouse participated in the wage market, and it evaluates the hours of farm work together with the hours of operators' and wives' wage work. Further refinement of this conditional concept would require a larger sample. While the estimation of equations with binary and bounded conditional dependent variables could be improved with appropriate maximum likelihood techniques, the complications of pooling and simultaneity require that a least squares technique be used.

Several versions of the labor supply equations were estimated with different specifications of both the nonexperimental and the experimental portions of the model. Both parts tend to support the general theory of simultaneous labor market decision making. In the nonexperimental portion, the support is evident in the cross-price and direct-work effects. In the experimental portion, the support can be inferred from the overall patterns of effects, as well as from the relationship between the structural and reduced-form estimates.

The average annual experimental effects on farm operators' and wives' labor supply are presented in table 1. These are calculated from

Table 1. Average Annual Experimental Effects on Farm Family Labor Supply

	North Carolina		Iowa	
	Absolute Differentials[a]	Percentage Differentials[b]	Absolute Differentials[a]	Percentage Differentials[b]
Farm operators				
Hours of farm work	186	13.8	141	5.9
Hours of wage work[c]	−258	−35.1	559	204.5
Employment in wage work	0.011	1.8	0.099	34.2
Total hours of work	−72	−3.5	700	26.3
Wives				
Hours of wage work[c]	72	5.2	−27	−73.3
Employment in wage work	−0.024	−3.9	0.054	17.5
Farm operators and wives				
Total hours of work	0	0	673	24.9

[a] These differentials are calculated as the adjusted experimental group mean minus the adjusted control group mean. Adjusted means are derived from the full sets of regression results and the average sample characteristics. The differentials directly reflect the effect on a "typical" sample member enrolled in the median experimental plan.
[b] These differentials are the percentage change from the adjusted control group mean to the adjusted experimental group mean.
[c] These figures represent changes in employment, as well as in hours of work conditional on employment.

the primary equations without regard to statistical significance. The effects for North Carolina form a reasonable pattern. The trend for farm operators is toward more farm work and less wage work, while for wives it is less pronounced. In all cases, the first year is characterized by generally insignificant effects that counter these trends. Only the underlying coefficient estimates for farm work and wives' wage work show patterns of statistical significance at the 0.10 level or less. The effects on wives' wage hours are the only ones that respond dramatically to changes in the other categories of labor supply: when the indirect experimental effects that operate through operators' farm and wage work are constrained to zero, the average direct effect on wives' hours is strongly negative. While there are strong patterns of experimental effects on individual family members' labor supply, the average effect of the median NIT plan on total family labor supply is zero. Finally, while the average effect on the farm hours of multiple market participants is not summarized in table 1, it is virtually identical to that for the entire farm sample.

The results for Iowa, also summarized in table 1, seem less reasonable at first glance. The only experimentally induced disincentive that is evident is on wives' wage hours, and while it is large in percentage terms, working wives in the Iowa sample report very few hours. The effects on farm operators' farm and wage work are positive, and those on the latter are particularly large and significant. However, two observations help place these results in a better perspective. First, the positive wage effects generally diminish over time. So, as with the North Carolina results, there is evidence that the first year reflects an adjustment to the new program rather than a longer term, normal response. Second, the large positive effects on wage hours result from the indirect effects of changes in farm hours and wives' wage hours. In fact, the average direct effect on operators' wage hours is negative. Thus, while the overall pattern is unusual, it is consistent with the generalized theories of multiple labor market participation and family labor supply. Once again, the average effect on multiple market participants' farm hours is very similar to that for the entire farm sample.

The small number of observations in most nonmedian plans suggests that the estimated effects of changes in the NIT parameters may be unreliable. However, interesting results do emerge. Changes in the tax rate produce no pattern of effects. This is consistent with the standard theory, since such changes should result in conflicting substitution and income effects. Changes in the guarantee, on the other hand, produce a pattern of negative and often significant effects. Again, this is consistent with the theory, since only an unambiguous income effect is produced.

Conclusion

It is important to determine what these results mean and how they fit into the overall pattern of farm-related experimental effects. Because

of the constant hourly return to wage work, the changes in such work can be translated directly into family income and, therefore, families' contributions to their own welfare. However, changes in self-employed farm work cannot be directly translated.

The most direct way to determine the farm-related effects of the experiment on family welfare is to analyze farm profit. The experimentally induced increase in farm work is accompanied by a decrease in profit of 15% to 17% in both regions (Evans). While some of this decrease probably results from the incentive of experimental farm operators to misreport profit and income, the magnitude of the effects and the strong time trends leave little doubt that there is indeed some decrease in profit. Farm-related experimental effects apparently did not improve family welfare and probably reduced it. Together with the wage work results, this implies a certain reduction in families' contributions to their own welfare in North Carolina and an ambiguous effect in Iowa.

One apparent paradox remains: how can the farm hours results be reconciled with the profit results? In his study of profit and hours, Evans also explored the concept of work effort, which reflects managerial ability and the intensity of activity (Leibenstein). He estimates that experimental and control farm operators are equally price efficient (i.e., they are equally profit maximizing in their use of variable farm inputs), but that experimental operators are less technically efficient (i.e., they produce less output from a given bundle of inputs). Consequently, while experimental operators spend more time on their farms, they become less careful managers. A more optimistic view is that these operators may devote time to farm improvements and other investment activities that may increase production and profit in the long run, while having unfavorable effects in the short run. However, there is very limited evidence that the latter may be the case.

Discussion

Wallace E. Huffman

The income maintenance experiments have been unique in terms of public policy development. Prior to the development of new legislation on income-conditioned transfers, Congress was willing to fund an experimental version of such a program, including the analysis of behavioral changes induced by the experiment. The primary reason is the divergence of opinion about the impact on hours of work and earned income of household members covered by such a plan.

The inclusion of a rural experiment in the group of income maintenance experiments has meant that poor rural people have not been forgotten in the planning of new welfare legislation. Also, it has provided an opportunity to develop administrative procedures for handling problems that are somewhat unique to rural areas—a large proportion of self-employed persons and rather thin asset markets. These problems seem manageable.

Given that the primary objective of the experiment was to determine the effect on hours of work, I am puzzled about the small amount of resources that were allocated to obtaining data on the hours of farm work by farm family members. Weekly hours of farm work over a year by farm operators, by their wives, and by other farm household members have a relatively large variance compared with weekly hours by wage workers. Part of this variation is seasonal, but much of it is intraseasonal. Drawing upon experimental design theory, one quickly recognizes that the estimate of mean weekly hours for a quarter based upon a sample size of one has a large sampling error. Thus, one need not fall back on defects of the respondents, as Primus does in suggesting a Hawthorne-type effect, to be skeptical of levels and differences in reported hours of farm work by farm household members.[1] These measurement-error problems with reported hours have undermined much of the empirical analysis that was oriented toward the primary objective of the experiment, including the research reported by Primus and Kerachsky.[2]

The research methodology employed in the three empirical papers troubles me as an economist and an empirical researcher. As scholars, we must carefully blend economic theory and econometric techniques in our data analysis in order to advance knowledge and understanding of systematic social behavior, but the path to this end is not always well marked.

I have three major concerns. First, some empirical relationships reported have weak foundations in economic theory. It may be an interesting question as to how experimental and control farm households differ in their crop and livestock inventory holding (sales) patterns, debt-to-asset ratios, sources of credit, etc., but I see no convincing reasoning behind the so-called control variables included in the analysis or behind the empirical specification of the basic issue. For example, rather than looking at size of farm sales, why not investigate differences in the ratio of farm sales from current production? A negative income tax may give low-income household greater flexibility in the timing of their marketing of products, i.e., lead to an increase in the expected price of farm output and farm profit. Furthermore, the number of explanatory variables in such a regression would be small, and observations might be homogeneous across states. Also, how do experimental and control farmers differ in the ratio of current expenses to the total value of farm production? If low-income farmers are faced with serious credit rationing, a negative income tax program may ease their credit constraint and effectively lower the price of purchased inputs. In addition, a key indicator of a farmer's level of

Wallace E. Huffman is an assistant professor of economics, Iowa State University.

The papers discussed are a very brief summary of much larger chapters of the final report of the Negative Income Tax Experiment. The discussion focuses mainly on the papers. Journal Paper No. J-8938 of the Iowa Agricultural and Home Economics Experiment Station, Ames, Iowa. Project No. 2078.

[1] In addition, there could be a Hawthorne-type effect.

[2] The seriousness of measurement errors does depend on whether reported hours are right-hand or left-hand-side variables in the regression analysis and whether they are correlated with other included variables.

management is the quality of his farm business records. Did the experiment cause experimental families to keep better farm business records than control farm families? Primus' paper, rather than Saupe's, suggests that the answer is yes. If so, this would be a significant finding of the negative income tax experiment, and it has important implications for improving the management of farms operated by these low-income families.

A second concern is that the implications from economic theory about the expected behavior induced by the negative income tax experiment are sometimes not carefully drawn or stated. A household constrained utility maximization model, where household members obtain satisfaction from their leisure time (or "nonwork" time) and a composite market good and allocate their human time between work and leisure, does not lead to an unambiguous prediction of a reduction in hours of work as a result of the incentives of a negative income tax. Consider the case of a household with a single worker. The tax on earned income of a negative income tax plan causes a pure substitution effect toward more hours of leisure by the worker and fewer hours of work, but the predicted change of hours of work from the pure rise in real income of the tax-guarantee combination is ambiguous (Rees). It depends on the sign (and size) of the income elasticity for his leisure. Empirical estimates of the income elasticity for leisure, not theory, are the only guide here. Thus, a negative work incentive effect is unambiguous in a one-worker household only if empirical estimates of the income elasticity for the worker's leisure is nonnegative.[3]

In addition, implications from economic theory have not been fully exploited as a guide for obtaining the variables for explaining hours of off-farm work. Consider the introduction of a negative income tax plan and assume that farm household's maximize utility subject to an endogenously determined income-expenditure constraint, human time constraint, and farm production function constraint. In this model, the household simultaneously determines the quantity of goods and human time or leisure consumed, the hours of off-farm work, the quantity of farm inputs, including the hours of farm work, and the quantity of farm output. The point is the simultaneous determination of the hours of off-farm work and the inputs into farm production (and also farm output). Furthermore, the quantity of off-farm work supplied is the difference between the total supply of work at each implicit wage and the demand for farm work. The quantity of farm work demanded depends on the prices of the variable inputs and prices of farm outputs and on a few truly exogenous factors, but it does not depend on variable input quantities. Few inputs are truly fixed, even land. There is a rental market for land services that is active. Thus, too many variable inputs are right-hand-side variables in Kerachsky's and Primus' analyses of work effect. For an analysis of off-farm work, I suggest that predicted farm output and available prices be used instead of these variables. This change in model specification would also economize on degrees of freedom.

Also, Kerachsky makes a major issue of the fact that reported hours of farm work of experimental household members do not behave according to predictions from a simple work-leisure model of time allocation, so he introduces nonmonetary aspects of working time to get around this problem.[4] I suggest that the total effect of a negative income tax payment may be more pervasive than his simple model permits and that nonmonetary aspects of work need not be introduced to explain a change in hours of farm work.[5] Consider that farmers make production decisions based upon expected farm output prices rather than on actual prices and that negative income tax payments give a farm household a wider range of dates for marketing its farm production, i.e., it causes the expected price of output to be larger than otherwise. This added effect of a negative income tax payment is sufficient to cause hours of farm work correctly measured to change (to increase) as a result of the experiment. There are, of course, other examples that can be hypothesized.[6]

[3] If the estimate of the income elasticity is negative, then an empirical estimate of the size of pure substitution effect is also required before an unambiguous statement about the effect of a negative income tax plan on work incentives can be made. If the labor supply model is further complicated so that there are two workers in the household, the expected effect of the incentives of a negative income tax plan on either worker's hours of work becomes more uncertain and requires empirical estimates of more parameters.

[4] Given the measurement errors in reported hours of farm work, true hours of farm work may be unchanged.

[5] Nonmonetary aspects of work are difficult to measure. Furthermore, differences in hours of farm work between experimental and control households must be due to price and income effects on these unmeasured characteristics of working time.

[6] Saupe's paper and other studies of the rural negative income tax data have also looked at issues that may cause hours of farm work to change.

A third concern is that the empirical models reported give too much emphasis on diversity of response between Iowa and North Carolina households and not enough emphasis on building models applicable over the whole sample of households, or at least over some groups consisting of observations from both states. It was argued that there was too much diversity across states to pool observations. This lack of uniformity of response has quite undesirable implications when one considers a universal negative income tax.

A scholar has the obligation of finding a systematic response in seeming diversity. Furthermore, I think that the challenge is not too great. It may, however, require reformulation of the models to be estimated. Bryant reports on one such successful attempt with the data from the negative income tax experiment.

Modern econometric techniques provide methods for pooling observations even when some response coefficients differ across groups. Pooling all the relevant observations also increases the degrees of freedom and generally increases the variation in the variables. Both of these characteristics are important for those who expect to find statistically significant relationships. A search of the literature shows that at least 200 to 300 micro observations are generally required before important explanatory variables in a relationship can be expected to consistently have t-values that generate excitement. The research reported above has paid a price in the form of small t-values for the ways the models were built.

The initial round of analysis of the data for the farm households from the negative income tax experiment has provided fewer conclusive results than one would like. But perhaps behavioral changes were small, and we expected too much. Later analysis with more comprehensive models may uncover more results. The results of the initial analysis do suggest that any work disincentive effects are generally small for farm household members. Thus, a major welfare reform based upon some type of negative income tax continues to be a promising goal.

Welfare Implications of Extended U.S. Fisheries Jurisdiction
(Virgil J. Norton, University of Rhode Island, Chairperson)

Constraints to Welfare Gains under Extended Jurisdiction Fisheries Management

Daniel D. Huppert

The recent extension of the U.S. fishery conservation zone to 200 miles and the adoption of economic objectives for fisheries management in this zone make the consideration of welfare gains an important current issue. The economic objectives contained in the Fishery Conservation and Management Act of 1976 (FCMA) are especially noteworthy. It has been well established in both theory and practice that economic gains will not necessarily result from fishery management geared to the traditional biological objectives such as maximum sustainable physical yield (MSY). The maximization of social welfare requires the explicit consideration of economic values generated by fisheries, the private and social costs of exploiting and managing the fisheries, and the probable distribution of income resulting from fishery regulations. In addition, theoretical economic analyses must be tailored to statutory requirements and political necessities before economically sensible fisheries management will be achieved. To assure that this administrative and political process results in the realization of potential economic gains will be a long-term task for fisheries economists and administrators.

The received body of theory in fishery economics emphasizes the importance of free access to fisheries as a source of welfare loss. The theoretical argument has changed little since the publication of Gordon's seminal article in 1954. Gordon argues that a competitive industry exploiting a common property fish stock will grow until all potential net economic return (or rental value of the stock) is dissipated. Fishing vessels that are privately maximizing their own profits will fail to respond to the social costs of depleting the resource and, as a group, will deplete the fish stock until the average cost of production rises to equal the market price of the fish. If the rate of fishing were lower than the competitive equilibrium rate, the fish stock would be more abundant and the cost of production per ton of fish would be lower. The ideal economic solution to the common property (or "externality") problem requires that the investment of capital and labor in the fishery be prevented beyond the point where incremental costs are justified by marginal social returns. There are a variety of institutional arrangements that could facilitate the achievement of the economically efficient production pattern, including administrative allocation of fishing licenses, fixed price license sales, fishing license auctions, landings taxes, assignment of individual quotas to fishermen, and undoubtedly others (Christy).

The static economic efficiency theory has been extended to incorporate dynamic efficiency criteria by, for example, Brown and Clark. Also, numerous case studies have applied variations of Gordon's theory to real fishery situations and have uniformly found that efficient economic exploitation of fish stocks entails the maintenance of larger fish populations and smaller fishing fleets than would be achieved under free access competition (see, for example, Crutchfield and Zellner, Crutchfield and Pontecorvo, Gates and Norton, Huppert, or Bell). By maintaining smaller fishing fleets and larger average fish stock abundances, an efficient economic man-

Daniel D. Huppert is with the National Marine Fisheries Service, National Oceanic and Atmospheric Administration, La Jolla, California.

agement system would provide more real income to the nation than would either free competition or management for maximum physical yield.

Christy suggests that the total amount of economic yield lost through free access competition in the U.S. fisheries is on the order of $300 million annually. At 6% annual interest, the capitalized value of the lost economic yield is about $5 billion. This represents an impressive potential gain in real national income and should provide an incentive for greater efforts to achieve economic efficiency in fisheries.

Some Income Distribution Aspects

The body of traditional literature on fishery economics clearly emphasizes the inefficiency of free competition for fishery resources and prescribes economically efficient rates of exploitation. To a large extent, the policy prescriptions of received theory rely upon an implicit assumption that the group or groups subject to the welfare arguments are well defined. In actual fact, there are several stances that might be taken in defining the constituent group. Each definition carries with it a different set of conclusions for U.S. policy. Three possible accounting frameworks that come immediately to mind are (*a*) the group of existing participants in U.S. fisheries, i.e., the domestic fishermen; (*b*) the domestic populace as a whole, dominated by consumer interests; and (*c*) the world population. Clearly, the fishery management policies that would be adopted to benefit the existing domestic fishermen most would differ from the policies that most benefit the aggregate of domestic and foreign fishermen or that serve the population of the United States at the expense of foreign consumers and fishermen.

Although an interesting discussion could focus on the relative deservingness of foreign versus domestic interests, the FCMA is obviously intended to place U.S. citizens in a privileged position. However, maximizing domestic benefits from fishery resources in the Fishery Conservation Zone is not synonymous with developing a solely domestic fishery. Not only are some of the heavily exploited fishery resources presently utilized mainly by foreigners (such as Pacific hake and Alaska pollack) but it may well be that sunk investments in substantial vessel capacity coupled with lower wage rates make foreign exploitation an economically desirable alternative to development of domestic capacity.

Explicit economic cooperation is a growing possibility. Joint fishing arrangements between foreign interests and U.S. domestic companies are already beginning to appear. These arrangements take two forms: the foreign processing vessels plan to buy fresh fish from U.S. fishing vessels, and foreign companies invest directly in U.S. companies for the purpose of assuring a future supply of fish. In either case, the flow of fish from the U.S. zone to the foreign nation may proceed despite the declaration of exclusive fisheries jurisdiction by the United States. The United States can still benefit from the fishery harvests by harvesting and selling the fish, by participating in a joint venture to harvest and process the fish on U.S. soil before shipping to a foreign nation, or by simply charging a fair price for the foreign harvests.

Domestically, the welfare gain estimated by Christy could be distributed in a number of ways. If existing participants are freely given property rights to the annual yields of the domestic fish stocks and the exploitation of these stocks is rationalized through limited entry programs, the gain could accrue solely to the aggregate of fishermen. If, on the other hand, the marginal social value of the fish stocks is extracted from fishermen through taxes or license fees, the net economic value of fisheries could accrue through the public treasury to the U.S. populace as a whole. Innumerable combinations of fees and licensing arrangements could be devised to distribute any proportion of the potential economic value to both the fishermen specifically and to the public generally. In any case, the realization of the potential economic value is predicated on a reorganization of existing institutions. Such reorganization removes the long-observed right of all citizens to fish commercially and replaces it with a conditional permit to fish bestowed upon the chosen fishermen by the federal authorities. Regardless of how this transformation is engineered, some fishermen are bound to be excluded from traditional fisheries in order to allow the remaining participants (or the general public) to enjoy the fruits of economic efficiency. A measurable increase in net income to some existing and all future participants may not be socially desirable, however, if it is accomplished only at the cost of impoverishing some segment of the existing fishery or eliminating potential future

income of yet unborn fishermen. Thus, the existing economic structure may combine with official reluctance to deal with difficult distributional issues and prevent the development of institutional arrangements that allow net economic benefit to be enjoyed from the nation's fisheries.

Potential Barriers to Welfare Gains

Because the FCMA provides the most important new set of institutions in the domestic fishery arena, most of my comments will focus on it. Nevertheless, the new fishery management councils and the Secretary of Commerce's authority to promulgate new fishery management regulations must be viewed as an additional layer of federal jurisdiction imposed upon established state/local and international institutions. States retain fishery management authority within their boundaries (i.e., within 3 miles of shore), and highly migratory species of fish, primarily tunas, remain within the institutional framework of international fishery management agreements. Also, many of the important species of fish exploited by U.S. fisheries do not obey the artificial political boundaries of the Fishery Conservation Zone. On the West Coast, transboundary stocks include the several species of salmon in the Pacific Northwest, the northern anchovy stock, and several commercially and recreationally important pelagic fish stocks. In the New England region, the major demersal fish stocks range significantly into the Canadian fishery zone. Superficially, the FCMA appears to create the mythical "sole owner" envisioned by Scott and other economic theorists, but in reality the federal authority created by the Act is but one of two or more authorities now claiming some management rights to many of the fish stocks important to the U.S. fishing industry.

The lack of comprehensive, unified management authority and the resulting possibility for counterproductive jurisdictional disputes can be identified as a significant institutional factor constraining the potential achievement of economic efficiency in U.S. fisheries. Disputes between state and federal authorities are likely to be of relatively minor significance due to the preeminence of the federal authority (sec. 306, FCMA). This is not to say that differences of opinion will be rare but only that the ability of the Secretary of Commerce to overrule state management regulations within state waters should be sufficient to prevent any substantial economic losses through inadequate management control in fisheries occurring both within state waters and the Fishery Conservation Zone.

In the international arena, of course, there is no similar superior authority. Ideally, the independent nations participating in a given fishery would reach agreement upon optimal management measures and would subsequently share in the economic benefits of efficient exploitation. In most cases, such agreement would probably have to rest upon improvements in the welfare of each participating nation. Crutchfield notes that most major international fisheries in the North Atlantic and North Pacific involve sufficient waste that rational management could provide adequate welfare gains to a large number of participating nations. Nevertheless, the institutions for implementing international management authority, even with unanimous agreement about its desirability, are either nonexistent or poorly organized in important cases. Also, it is unfortunately true that some nations may choose to engage in strategic behavior designed to gain them greater shares of the world's resources in the long run, rather than to join international agreements that tend to reinforce existing shares as a compromise position.

Although some nations may find unilateral or multilateral agreements beneficial even without full participation by all nations involved in the fishery, economic theory suggests that such actions may be disadvantageous. According to Anderson, if one nation reduces fishing effort in order to approach a unilateral optimum fishing level, there is an automatic incentive for other nations to increase their rates of fishing. It is even possible that the resulting decrease in available fish to the original nation could be of sufficient size that in the new international equilibrium the nation loses economically (Anderson). Under such circumstances, international cooperation would appear to be an all-or-nothing proposition. On the other hand, most shared fisheries important to the United States may be sufficiently controllable unilaterally to allow the achievement of some welfare gains without full international cooperation.

Some specific provisions of the FCMA and current implementing regulations may also act to retard progress towards economic

efficiency. The FCMA specifically prohibits the Secretary of Commerce from collecting from domestic fishermen fees that exceed the administrative costs incurred in issuing permits to fish. This provision effectively bars any limited access program attempting to restrict fishing effort through imposition of user charges or attempting to extract some of the net economic yield from the fishing industry for support of scientific research, management costs, or general budget items. Without charging fees sufficiently high to extract rent or discourage excessive investments, a limited access program can still be implemented and can result in substantial economic efficiency benefits. But the distribution of the benefits is a rather nonnegotiable matter; the fishermen (or the owners of permits to fish, if not fishermen) will "get the swag." Depending on one's sense of distributive justice, this could be bad or good. But, as Christy observes, the general taxpayer will be footing the bill for research and management but not receiving any corresponding return from the public fishery resource, and the Office of Managenent and Budget may feel compelled to severely limit the funds for fisheries research and management.

The level of foreign fishing fees levied under the authority of section 204 of the FCMA is to be established by the Secretary of Commerce in consultation with the Secretary of State. The Act imposes no rigid limit on the fees charged to foreign interests, but the fees are to be reasonable and apply nondiscriminatorily to each nation. The fees adopted for the period starting 1 March 1977 include a permit fee of $1.00 per gross registered ton for each fishing vessel, $0.50 per gross registered ton for each processing vessel, and a flat $200 annual fee for each vessel assisting or aiding the fishing operation. Also, a poundage fee of 3.5% is levied against the exvessel value of the foreign harvests. As of 21 May 1977, nearly $10.3 million dollars had been collected from these fees—$785,087 in permit fees and $9.5 million in poundage fees. In adopting the fee schedule, the Department of Commerce decided not to use the fees as a management tool to restrict foreign fishing but did want to cover an appropriate part of the management costs related to foreign fishing. It was never made clear what the "appropriate part" of the costs were, but clearly the low poundage fee would not extract a significant portion of the total value of the foreign catch, estimated to be $271 million at 1977 prices.

The decision not to use the foreign fees as a management device or as a means to appropriate a significant part of the resource value has important ramifications. Under the constraint of minimal foreign fishing fees, the domestic optimization of fishery management may rely upon second-best measures, including an excessive emphasis on replacing foreign fleets with domestic fleets, even in those fisheries that are most efficiently prosecuted by foreign fleets. Also, some fisheries will continue to be dominated by foreign interests. In these, the combination of low fees and rationalized management could eventually result in a transfer of economic rents from the United States to foreign fishing firms. A theoretically sound fee structure would place a tax on harvests equal to marginal increase in fishing costs due to the reduction in fish stocks by harvesters (see Smith, p. 194, for example). While there may be compelling political and economic reasons for not charging such a tax to domestic fishermen, the extension of this policy to foreign interests will certainly reduce the welfare gains enjoyed by the U.S. citizens under extended jurisdiction fishery management.

Other possible constraints to the achievement of welfare gains arise from the regional orientation of the fishery councils and the makeup of the councils themselves. It seems highly probable that each Regional Fishery Management Council will tend to consider only regional income gains. Because the political and social, if not economic, importance of the regional fishing industry will loom larger than national concerns, a parochial view of management on the part of councils could easily lead to management plans aimed at improving the economic wealth of regional segments of the industry at the expense of the nation as a whole. Such a tendency could, for instance, be manifest in plans requiring tremendous inputs of research and administrative manpower, while requiring little or no restrictions on commercial fishing to improve efficiency and calling for no fees whatever to be paid by the beneficiaries of the plan.

Countering this tendency are the national objectives and standards of the FCMA. Specifically, the optimum yield of each fishery is to be defined such that the greatest overall benefit to the nation is served. Theoretically, such a yield is defined with a heavy weighting given to consumer interests, emphasizing larger sustainable supplies of fishery products and prices as low as possible under current

cost structures. Also, the national standards relating to efficiency and cost minimization, if vigorously enforced by the Secretary of Commerce, would constrain the ability of Regional Fishery Management Councils to act in a nationally nonbeneficial manner.

One additional observation on the likelihood of fishery management being focused on local, rather than national, interests is appropriate. By and large, the appointed membership of the councils is dominated by industry spokesmen and others having long-time connections with past fisheries management bodies. While this is only natural under the circumstances, the new economic objectives and initiatives called for under the FCMA may not come easily from such management bodies. Experienced fisheries scientists and administrative officials in the United States have generally been reluctant to tackle issues of income distribution and economic efficiency. To many, limited access is anathema on ideological grounds. Witness the "Alaska limit" purse seiner, the sail-powered clam dredge, the grossly overcapitalized Pacific Northwest salmon fisheries. Combine this with the pronounced tendency of labor unions to maintain employment above technologically necessary levels, and the general interest of established industry members to protect entrenched interests, and there may be substantial resistance to the adoption of measures that improve fishing efficiency and that sufficiently reduce or retard overcapitalization.

A final constraint to improved economic performance of fishery management is the woefully inadequate existing economic knowledge of recreational fisheries and the consequent lack of serviceable economic models and measurements addressing the trade-offs between recreational and commercial fisheries. On a theoretical plane, enjoyment of fishing as recreation has as much claim to the attention of economic analysis as the consumption of fish as a commercial product. As a practical matter, the marine recreational activities have a substantial economic value. It should be expected, therefore, that a significant source of national welfare gain would accrue from optimal treatment of recreational fisheries.

One reason for the dearth of economic studies on recreation is the difficulty encountered in applying traditional competitive market theory. The output in the recreational fishery is not satisfactorily valued at market prices. Economists have emphasized that recreationalists are not buying fish but are paying for an experience, one aspect of which is the capture and consumption of fish. A commonly espoused institution in recreational fishing is free access to the resource.

Lacking adequate price data, demand curves can be estimated by the travel cost method (see Brown, Singh, and Castle) or the direct interview method (see Meyer). The resulting estimates provide a means of valuing fishing trips but do not necessarily yield information pertaining to the marginal value of fish to anglers. Special efforts must be made to estimate marginal values so that recreational and commercial values can be converted to the same economic units.

Further confounding the ability of fishery managers to adequately balance recreational and commercial values is the fact that the optimal yield and optimum stock size may be radically different for a recreational fishery than for a commercial fishery. As noted by Radovich, recreational fishing may be best with fish stocks much closer to virgin levels than to the level required for maximum sustainable yield. To the extent that a high catch-per-angler day is a valuable aspect of recreation, any attempt to optimize a commercial fishery will be of detriment to recreation. Also, large "trophy" fish are more abundant in a large, older fish population. Finally, there is some evidence that recreational fish have a greater tendency to strike angler's baited hooks when fish populations are closer to maximum abundance.

On the assumption that management authorities will take quantified, commercial value as more important than unquantified, recreational values for fish, the lack of established, measured values of fish to the recreational sector could result in substantial misallocations of fishery resources, reducing the welfare gain achieved under extended jurisdiction fishery management. The responsibility for solving this problem rests squarely on the academic and government economists involved in fisheries. The evaluation of all fishery sectors is, after all, the job of the practicing economists.

Conclusions

The fact that several important constraints to welfare gains can be found in current institutions should not be received with overwhelming pessimism. Necessary, but not sufficient,

conditions for improved economic performance of U.S. fisheries are created by the passage of the Fishery Conservation and Management Act of 1976. Among these conditions are the establishment of federal authority over areas of sufficient breadth to allow unified management; creation of regional councils authorized to develop management plans with local industry cooperation as well as scientific advice; specific economic criteria for fishery management plans; and means to control foreign fishing harvests within the U.S. zone. Although there are some disturbing restrictions upon the use of economically desirable management tools (such as substantial fees or landings taxes on fishermen) and jurisdictional disputes could encourage economically inefficient fishery management plans, the success of the management effort to achieve economic welfare gains will depend more upon the actions and attitudes of the fishery councils and federal authorities than upon any rigid institutional constraints.

Constraints to Welfare Gains under Extended Jurisdiction Fisheries Management: Discussion

Lee G. Anderson

Huppert has presented a good discussion of the constraints to welfare gains under extended jurisdiction fisheries management. While I certainly do not have any serious qualms with his presentation, one definitional point should be made at the outset. As used in the paper, at least as I interpret it, welfare gains really mean potential welfare gains or, more properly, the attainment of economic efficiency. In fact, phrases like "constraining the potential achievement of economic efficiency" and "retard progress toward economic efficiency" are used interchangeably with others like "constraints on the achievement of welfare gains." The former are superior in the context of this discussion because not achieving economic efficiency does not preclude welfare gains to at least some groups. In my comments I use the more straightforward term—economic efficiency.

Huppert began by making the very basic, but still quite often neglected, point that an unregulated fishery can result in economic inefficiency as well as biological depletion. He then touches on the distribution issue and points out that there are three possible accounting frameworks. In my view, the fishing industry, including harvesters, processors, etc., are receiving the most attention, as opposed to the nation as a whole or the rest of the world.

In his comments on using a worldwide accounting framework, Huppert touches on the issue of joint fishing arrangements between foreign interests and domestic companies. Depending upon the exact regulations concerning joint ventures that are promulgated, there may be serious problems in the interpretation of surplus yield (i.e., the difference between optimal yield, as defined in the law, and domestic capacity), and this may require some modification in the law. The distribution of the gains will depend critically upon the final resolution of this issue.

Five potential barriers to economic efficiency are discussed. They are (*a*) overlapping authority (from the different states below and other nations above); (*b*) certain provisions of the act, especially restrictions on the use of taxes as a regulation tool; (*c*) the regional orientation of the councils; (*d*) the industry domination of the councils; and (*e*) the inadequate knowledge of recreational fishing, which may cause it to be neglected in decision analysis.

I definitely think provisions exist in the act that retard progress toward achieving economic efficiency, one of which may be more serious than the constraint on the use of taxes. The provision that bothers me is national standard 5, which states: "Conservation and management measures shall, where practicable, promote efficiency in the utilization of fishery resources; except that no such measure shall have economic allocation as its sole purpose" (U.S. Congress, PL 94-265, sec. 301(a)(5)). If the last part was not included, this would be a useful national standard. However, if the term "economic allocation" is to be interpreted in the sense of an "efficient allocation of resources," the last phrase essentially negates the first one. Using this definition, this standard says that we should strive for economic efficiency except that we should not strive for economic efficiency. If this interpretation is used, the fact that taxes cannot be used becomes relatively unimportant. Not being able to use an economically useful regulation tool does not really matter if an economically rational management program is precluded.

If the term "economic allocation" is to be interpreted as distribution, the prospects for

Lee G. Anderson is an associate professor of economics and marine studies, University of Delaware.

economically rational management are not so bleak. I was hoping that, when the regulations for implementing the FCMA were distributed, the confusion would be settled. Unfortunately the results are mixed. In that part of the guidelines that are final, the section that expands upon National Standard #5 states:

> Economic efficiency may be regarded as one of many factors to be considered in the development of a plan. Councils will be involved in decisions about the distribution of costs and benefits, provision of employment opportunities, changes in the rate and composition of regional economic development, environmental effects, etc. To follow efficiency principles exclusively may not provide the greatest overall benefits to the nation or necessarily reduce costs to the consumer. Accordingly, both the advantages and disadvantages of "efficiency" will have to be carefully weighted in the context of the objectives for the particular fishery involved (*Federal Register* 1977a, p. 34459).

I find this satisfying. First, it says that economic efficiency may not be the only goal. However, this is not the same as saying it cannot be the main or central goal, making economic efficiency at least a possible candidate for a management objective. Of course, there can be some adverse distributional or other sociopolitical effects from following a strict economic efficiency policy, and there are certainly times when trade-offs between economic efficiency and other social goals may be desirable up to a point. This is allowed for according to the above guideline.

Further on in the same section of the guidelines we read: "Where conservation and management measures are recommended for economic allocation and for other purposes, due consideration shall be made of the biological, ecological, and social consequences of such measures" (*Federal Register* 1977a, p. 34459). The definition of "economic allocation" is still not clear (although phrases in the first quote such as "distribution of benefits and costs" may mean that it refers to distribution rather than efficiency), but at least the guidelines are not as strong, in a negative sense, as the standard itself. All it says is that consideration shall be given to other effects.

The problem of interpretation is made more difficult by the section of the guidelines in the *Code of Federal Regulations* that deals with the specifics of writing management plans, which, by the way, are only preliminary at the time of this writing:

> Any plan containing a limited entry system shall also discuss why other management measures are inadequate for conservation and management of the fishery. Limited access is a management technique that is directed at economic as well as biological objectives. This technique is used to reduce the congestion and economic waste that often occurs from the "open access" condition of common property fisheries. Any system of limited access shall be for the purpose of conservation and management, and economic allocation shall not be its sole purpose (*Federal Register* 1977b, p. 36983).

Here, the reference to the economic wastes that occur with open access may mean that economic allocation should be interpreted as in "efficient allocation of resources." In any event, a plain interpretation of the section would be as follows: limited access is a tool to eliminate economic waste, but it cannot be used solely for that purpose. This is somewhat contradictory to the passage quoted earlier, and I hope that, when the final version of the regulations are promulgated, this confusion is resolved.

Moving on to the point about the lack of recreational data, the problem is really one of a lack of adequate social and economic information in general. A casual reading of law makes it obvious that fisheries are to be managed to achieve social and economic objectives and not, as has been done in the past, for strict biological survival of the stocks. Given the nature of international fishing commissions, achieving biological survival was perhaps the best that could be hoped for. Now, with a central control, we are hoping for more. However, we have no counterpart to the biological information that has been collected for decades to aid in selecting strategies to achieve social and economic objectives. The problem of a lack of information is complicated by inertia. Most fisheries managers are used to thinking in biological terms, and it will be understandably difficult for them to expand their frame of reference when there is little data on which to rely.

Constraints to Welfare Gains under Extended Jurisdiction Fisheries Management: Discussion

Richard Marasco

The Fisheries Conservation and Management Act of 1976 (FCMA) resulted in reclassification of a number of fish species that reside off U.S. coasts. Prior to existence of this Act, the United States could claim ownership to numerous species of fish only after capture. Resources of this type have been referred to as being "fugitive" (Ciriacy-Wantrup, p. 141). The FMCA has reduced these resources to common property of U.S. citizens.

The question that must be posed is, "Does the reclassification of fish off the coasts of the United States insure socially desirable usage?" The answer is no. As indicated by Huppert, the received body of theory in fishery economics emphasizes the importance of free access to fisheries as a source of welfare losses. Classification of fish resources located within the 200-mile zone as common property does, however, facilitate devising of regulatory systems that can be used to affect socially desirable usage.

It is in the examination of regulatory possibilities that constraints to welfare gains from fisheries management are brought into sharp focus. Fishery regulations may be classified into two categories, those affecting the size of fish caught and those affecting the total amount of fishing effort. Prohibition of fishing in nursery areas, seasonal closures, size limits, and gear limitations are examples of regulatory measures that can be used to control the size of fish caught. Regulations that influence fishing effort are area closures, gear restrictions, quotas, time closures, limitations on the number of boats, and various forms of taxes and licensing schemes.

Fishermen have historically opposed regulations that restrict effort. In situations where exploitation reduced the biological status of a fish stock to a depressed state, fishermen have supported regulatory measures that permit free access to the fishery such as gear and time restrictions. A question that might be asked is "Doesn't the state of Alaska's limited entry program provide an example of fishermen's support of effort limitations?" Elimination of non-Alaskan fishermen served as the catalyst that generated interest among Alaskan fishermen in entry limitations. Thus, support for the program did not stem from a concern over economic efficiency. Support instead was based on the desire to protect the economic position of a certain group of fishermen.

Fishermen's opposition to entry limitations coupled with industry's power within the current regional councils suggest that achievement of economic efficiency via entry limitations faces a difficult battle. Therefore, I share Huppert's concern over the makeup of the various regional fishery management councils. It is not clear that the current composition of the councils will facilate the adoption of positions that will lead to economically sound operation of the nation's fisheries.

The purpose of encouraging adoption of regulations that serve to foster sound operation of fisheries by the councils could be furthered by the development of more refined and realistic empirical bioeconomic models. The availability of data and the cost of data acquisition serve to hinder these efforts. Fish stocks exist in ecological systems where stock interrelationships and environmental conditions are extremely important. Salinity, temperature, prevailing currents, number, and feeding habits of other species of fish are known to be important environmental factors that influence stock growth rates. Collection of data that are required to determine the importance of various environmental factors on growth rates is costly but required if realistic models are to be developed.

Richard Marasco is an economist at the Northwest and Alaska Fisheries Center, Seattle, Washington.

Deficiencies also exist in the economic data base. In addition to the lack of knowledge associated with recreational use of fish identified by Huppert, numerous voids exist in the knowledge of the nature of food fish consumption. Only limited information is available on the degree of substitutability among species at the consumer level. It is generally believed that restaurant consumption accounts for in excess of 50% of all the food fish consumed in the United States. At present, hard data on the magnitude and determinants of restaurant consumption are nonexistent. Knowledge of foreign fish markets is also unsatisfactory. Sufficient information concerning the competitive atmosphere existing in the processing sector as well as capacity and costs are lacking. The current harvesting cost data base is erratic and in many cases out of date. Harvesting capacity in most fisheries is not known. Considerable fishing effort data exists; however, there are serious gaps. In general, the definition and measurement of fishing effort is a complex issue, and the most appropriate data elements vary between fisheries. While the above list of data deficiencies might be considered lengthy, it is not exhaustive. Data deficiencies when encountered retard the development of fishery management models. These inadequacies serve as constraints to the realization of welfare gains that could accrue from fisheries management.

An examination of constraints to welfare gains is incomplete if the issue of cost of instituting and enforcing regulatory measures is not mentioned. The magnitude of costs associated with implementation and enforcement depends upon the nature of the regulatory measures selected. Enforcement costs for programs requiring either aerial or ship surveillance will be high. Experience with fishery regulations off the Northeast Coast of the United States suggests the need for comprehensive and effective enforcement if regulatory measures are to succeed.

In conclusion, I find myself in agreement with the list of constraints to welfare gains provided by Huppert. I would, however, amend his list to include knowledge deficiencies associated with both biological and economic fishery systems and cost of instituting and enforcing regulatory programs.

Distributional Implications of the Extended Economic Zone: Some Policy and Research Issues in the Fishery

Daniel W. Bromley

> Welfare economics has a nasty tendency to trail off into philosophy and inaction if pursued far enough (Crutchfield, p. 385).

At a recent conference on the economics of extended fisheries jurisdiction, Bishop and I argued that distributional considerations had been largely ignored by economists as they sought to influence public policy. Among the reactions to that paper, the least surprising was that efficiency analysis is scientific and value free, while distributional matters are value laden, mercantilistic, and concern "love." Another reaction was that to pay undue attention to distributional concerns would freeze us into total incapacity in attempting to "rationalize the fishery." The historical justification for this emphasis on efficiency was that it was difficult enough convincing biologists and policy makers (often one and the same) of the relevance of economics and that therefore it was better to get "half a loaf" rather than nothing. Besides, everyone else is already a "specialist in distribution."

The premise of this paper is that there are important insights to be gained by a more careful specification of the traditional steady-state/yield-effort models and by viewing the economics of extended jurisdiction in a welfare theoretic framework. Length restrictions preclude a comprehensive treatment, yet it is possible to offer some analysis that is suggestive of directions for research. More importantly, I am hopeful that useful policy recommendations might also result.

In the following section I briefly introduce my view of distributional matters as they pertain to the fishery. Then, I present a simple model for assessing the distributional implications of extended jurisdiction in an international setting. Next, I discuss access to the enlarged "domestic" fishery with the primary motive of reminding economists of the elements hidden in that raw number "fishing effort." Finally, I discuss some research and policy implications.

Daniel W. Bromley is a professor, Department of Agricultural Economics, University of Wisconsin, Madison.

The author is grateful to Richard Bishop, Robert Haveman, and Peter Helmberger for assistance on an earlier draft. This work was funded (in part) by the University of Wisconsin Sea Grant College Program under a grant from the Office of Sea Grant, National Oceanic and Atmospheric Administration, U.S. Department of Commerce, and the state of Wisconsin.

Toward a Working Definition of "Distributional Implications"

Unfortunately, distributional issues get placed in the "love" category, and it is even more serious that distributional concerns are considered to be a mere hinderance to doing "something" in the fishery. That it is controversial and difficult to raise the matter of who gets what in the policy arena cannot be denied, but to dismiss its analytical importance for whatever reason is to indicate a serious lack of appreciation for its role in welfare theory. This brings me to the more serious aspects of the lack of appreciation for distribution. This blind spot exists because the economic models of the fishery are adaptations of firm optimization theory to society as a whole. Let me put it a little differently—distribution has been ignored because economists have been using the wrong conceptual framework.

Traditional fishery models consider fishermen not as independent decision-making units but as mere factors of production aggregated into something called "effort." Firms utilize factors of production according to well-established optimization criteria, adding and subtracting inputs as conditions external to the firm change. Here, distribution is beside the point since there are assumed to be many willing buyers and sellers of said factors. When distribution is discussed, it is in terms of factor payments and income shares.

The yield-effort models hide the fact that individual firms are discussed, which in turn also hire factors of production according to some optimization criteria. Thus, to use the yield-effort model to deal with aggregates of firms is to apply a microeconomic construct to derive policy prescriptions on a macroeconomic scale. We cannot use firm optimization theory to offer prescriptive advice in the large—that is what welfare economics is about.

Once the fishery problem is cast in a welfare theoretic framework, it is ineluctable that distribution is central to any policy recommendation. How else can one say that social state I is better than social state II? These are fishing families that are being retained or restricted out of the fishery, not mere pounds of fertilizer, acre-feet of water, or tons of bauxite. The appropriate maximand for public policy is aggregate social welfare. This is not known until the distributional implications are known (Bromley and Bishop, Graaff, Mishan).

The issue then is how might one begin to develop models of fishery policy that will give explicit recognition to distributional matters? The first obvious step would be to develop a more careful understanding of what is meant by distribution. Is it the Gini coefficient? Is it the percentage of the population that falls in various income (or wealth) quantiles? Or is it something else?

I prefer to consider distributional matters in the context of entitlements and exposure. Imagine a situation in which an upstream landowner has sold the mineral rights to a party wishing to strip mine for coal. There is also a downstream riparian owner of land upon whom excessive sedimentation would be deposited if the strip mining occurs. If government takes the side of the strip miner (entitlement), the downstream riparian will suffer losses (exposure); and if government takes the side of the downstream riparian (entitlement), the would-be miner loses (exposure). Consider another example. I wish to install a solar collector on my roof, but my neighbor to the south happens to have a penchant for tall trees. If government takes my side (entitlement), my neighbor is denied some freedom (exposure), while if the government takes the side of my neighbor I am inconvenienced. Yet another example is found in the famous case of sparking railroad engines; if government protects the railroads the wheat ranchers suffer, and if government protects the wheat ranchers the railroads suffer.

Thus, distribution is here concerned with entitlements to streams of utility and/or wealth over time—in a word, access. But it is also concerned with exposure to the entitlements of others over time—that is, lack of access. The state as an enforcer may help in the determination of entitlements and exposure, but the essence of distributional matters is which party is exposed to the actions of others? Entitlements in an economic system legitimize the imposition of costs on others. My ownership of a piece of land legitimizes the imposition of a cost on anyone who may wish to cross it. My entitlement to dump wastes into a stream legitimizes the imposition of costs on those who may wish the termination of that dumping. Their entitlement to be free of my dumping legitimizes the imposition of costs on me should I want to dump. The structure of entitlements and their enforcement by the state is the mechanism whereby certain costs become legitimized. If I am a fisherman who survives "the cut," my right of access legitimizes the imposition of costs on those who were not so lucky—the cost of being denied access to a way of life and a familiar source of income. This is the distributional component that is concealed in the numeraire "fishing effort."

There is another aspect of distribution—the international dimension. Here, access has the same meaning, and the entitlement legitimizes the imposition of costs on other countries rather than on other fishermen in the same country. In the subsequent section I briefly explore the international dimension of entitlements as they relate to distributional issues.

International Dimensions

(For two excellent treatments of the international fishery, see Anderson and Southey.)

Assume that an area of ocean has historically been fished by two nations (A and B) and that A now declares—unilaterally—part of it to be its sovereign territory; the area and its harvest gained by A is lost by B. In figure 1 we see two interdependent production possibility frontiers (*PLA* and *PLB*) representing the initial (presumably stable) situation. If either A or B alters its level of fish harvest in the commonly fished area, the production locus of the other will shift.

Once A has declared a portion of the area to be its exclusive territory, the two production loci shift to *PLA'* and *PLB'*. Assuming A does not fish in the areas where B also fishes, the interdependence ceases and *PLB'* represents

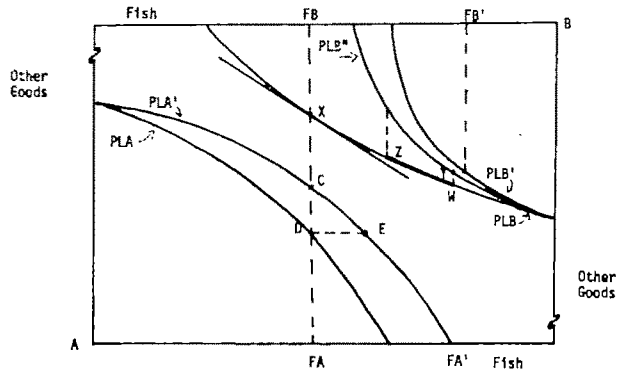

Figure 1

the actual locus of fish production and other goods for B without access to the area now controlled by A. If relative prices for B remain unchanged, its fish harvest would be reduced by the magnitude $FB - FB'$.

With B excluded, country A is now theoretically able to move from point D to point E; this might be thought of as the total allowable catch from the formerly jointly exploited fishery. If the initial open-access situation had represented one of overexploitation, PLA' can be thought of as representing a recovery of the fishery.

Considering first the impact on country B, the exclusion of access to the territory under study would prompt an investment in fishing technology and/or the searching for new grounds to make up for those expropriated by A. Hence, after some time the production locus of B might shift out to PLB''. There, the approximately similar price ratio would result in production of Y. If we assume that B is "settled" at point Y and then country A agrees to allow some harvesting of "foreign catch" in the extended zone, B's effective production locus shifts out to the line segment WZ, with the exact location of Z dependent upon the allowed harvest in the new jurisdiction claimed by A. Since this brings a disequilibrium in B between the marginal rate of product transformation and the ratio of relative prices, it is unclear as to what B will choose to do. If it considers this access as strictly temporary, it may choose not to respond to the offer by A. If it is considered to be long-run access, the line segment WZ becomes part of the production locus and B will respond accordingly.

Turning now to country A, there is the decision as to what constitutes optimum yield and the decision regarding how much will be harvested by A and what can then be offered as "foreign catch." The line segment CE on PLA' represents that locus of output possibilities where it is possible to gain in both outputs. It seems safe to exclude the line segment EFA', since this would entail a reduction in the output of other goods and services. Between C and E there are issues of the current trade position in fish and in other goods, as well as the degree of fishing capacity to harvest the newly claimed endowment. Should it turn out that A is unable to take full advantage of the new entitlement, and country B is not allowed to harvest any fish from the extended jurisdiction, it might seem that country A has been made only slightly better off, while B has been made markedly worse off, though more analysis would be necessary to be certain about this.

To simplify the analysis current and potential consumption, import and export magnitudes have been ignored. It is also possible to derive utility possibility frontiers for A and B from the various production loci. My interest in this type of analysis lies in its ability to depict intercountry relationships in a fishery when there is a unilateral change in entitlements. The recent confrontation between England and Iceland over fishing access is an interesting example of two countries with drastically different production possibility frontiers between fish and other goods. The tenacity with which Iceland resisted British fishing activity tells us something of the marginal rate of transformation of fish for other goods in Iceland.

Distribution in the Domestic Setting

"Since the allocation of permits is, in essence, a matter concerning the distribution of wealth, it will inevitably become controversial and difficult. 'Who *should* get licenses' is not an

issue on which economists have much to say. It is rather, a matter for negotiation among fishermen and administrators" (Christy, p. 150). This quote asserts that economists do not have much to say on who gets access to the fishery, yet we sometimes hear contempt for administrative or judicial decisions that reserve part of the fish harvest to the native Americans.

Another economist who has worked extensively in the fishery says:

> Extended jurisdiction in itself solves very little. Used improperly, it exclusively reserves to the U.S. the right to squander its valuable capital and labor through the imposition of quotas to insure that fish are "saved." The way to repair the market failure is through the transformation of common property resources into private property resources. I see no one worried about the conservation of chickens, pigs, cows, or turkeys (Bell, p. 24).

This curious statement highlights the distributional quandary among fisheries economists. On the one hand we are told that the economists have nothing to say about who gets access, then we often hear that returning part of the catch to the American Indians is a mistake. Finally, we are told that the fish need to be converted into private property. But whose property? Obviously not the Indians' if we listen to some; the highest bidder's if we listen to others. But we must be careful how we define the highest bid.

Assume that the domestic portion of allowable catch has been determined and that there are three (homogeneous) groups of fishermen seeking permission to fish. The usual answer is to sell licenses or certificates to fishermen, thus extracting some of the rent for the state and insuring that those who value fishing the most would get in. In table 1 I have depicted three groups of fishermen: "commercial" fishermen (CF), American Indians (AI), and "marginal" fishermen (MF). Assume that both CF and AI are serious "full-time" fishermen, although there are important differences between their two operations. CF consist of heavily capitalized fishermen with the latest technology who catch great quantities of fish but who incur considerable cost; assume a net present value of access to the fishery of 105. For AI, fishing is much more labor intensive, and while catch per unit of effort is lower than for CF, so are costs. Thus, I assume a net present value for access to the fishery of 100. As for MF, this group has neither the modern technology of CF nor the skill of AI; this group is rather nonchalant about fishing and is capable of a variety of other work. Assume that the net present value of access for this group is 60.

Table 1. Net Present Value for Three Groups of Fishermen

	CF	AI	MF
NPV_F	105	100	60
NPV_A	95	30	45
$NPV_F - NPV_A$	10	70	15

Note: Figures assume each group is alone in the fishery.

Consider the alternative occupations for the individuals in these three groups. For CF, boats could be sold, and these individuals might fare rather well in nonfishing occupations. For AI, we cannot assume that things would go so well; this group is not well suited to occupations other than the traditional one of fishing. Finally, as indicated, those in MF are moderately adept at finding alternative employment. The net present value of these groups in their best alternative is depicted in the second row of table 1. The final row in table 1 shows the difference in net present value for each group between fishing and their assumed best alternative—it is the opportunity cost to them, and to the nation, of being denied access to the fishery.

Assuming all of the fishermen in only one group are to gain access, which set of figures is relevant? The "commercial" group has the highest net present value in the fishery, but this group also has the best on-shore income potential. The "marginal" fishermen do not fare so well in terms of income generated in the fishery, though they do not experience a serious decline if denied access. But the Indians would be the one to suffer the greatest fall in income from being excluded from the fishery.

The difference between NPV_F and NPV_A might be considered an index of the willingness to pay of each group to have access. But, the great difference between this figure for CF and AI must be interpreted with care. If the Indians' "willingness to pay" (70) is an imputed value rather than the result of market transactions (as we might assume is the case for CF), then their ability to enter a bidding contest with CF (or even MF) may be seriously constrained. If this group does not have access to capital markets, it may be even more seriously disadvantaged by a competitive bid-

ding scheme for licenses. If we think of the figures in the table as the real net income of each group in the two possible occupations, and if only one group can have access, then present-valued income is enhanced if AI have access to the fishery and the other two groups do not. Here, aggregate net present-valued income is 235 compared with 180 for CF in the fishery and 185 for MF having access. Indeed, assuming that the interaction effects are zero and that it is possible for two groups to have access to the fishery, aggregate net present-valued income is highest in this example if CF are denied access ($NPV = 95$) while AI and MF are allowed in (100 + 60). Thus, the appropriate way to allocate limited access to the fishery is by a careful accounting of the alternative income earning potential of all petitioners and by a realistic assessment of their ability to bid for limited access.

Policy and Research Implications

Without condoning the territorial imperialism of the extended economic zone, I share with other economists the sense of optimism concerning the opportunity for improved fishery management. Yet I am worried that "Crutchfield's Complaint" (opening quote) may continue to find sympathy among economists. Fishery economics and policy is concerned with the study of alternative institutions pertaining to who may fish, what technology will be employed, when and how fishing may occur, and what will happen to the harvest. These are matters that cannot be dealt with in an economic framework other than welfare economics; intellectual honesty will allow no other approach. I am sorry if welfare economics is not as "well behaved" as conventional price theory or firm-optimization models. But there must be a more compelling reason to avoid appropriate economic models than the mere fact of intractability. It is indeed inconvenient for those who feel constrained to have quick advice for policy makers that welfare economics has a "nasty tendency to trail off into philosophy and inaction if pursued far enough." But is the correct response to thus ignore welfare theory and its distributional imperative?

The big gainers and losers of any management scheme are the fishermen themselves. One need only look at the livestock industry in the West, where access to public grazing lands is so crucial, to appreciate the devastating long-run economic loss of those who were not so fortunate as to gain access; efficiency issues pale in comparison with the distributional ones. Entitlements to a resource are the key to policy-relevant analysis. When a certain subset of those who currently have access sit on planning bodies designing management schemes—including gear type, vessel size, total annual catch—it does not take much intuition to begin to understand "whose ox is being gored."[1] When a large contingent of politically aware sport fisherman take on a few commercial fishermen, it is not difficult to imagine who will win. Surely economics has something to offer in this important policy issue.

I have tried to offer several suggestions for introducing distributional considerations into the analysis of both international and domestic fisheries policy. I have no illusions that it will be simple, but I reject the notion that we should press the economic management of fisheries "as far as possible on allocative or efficiency criteria before modification if absolutely necessary, by equitable or distributional criteria" (Scott, p. 410).

On the domestic front, a distributionally related management program would begin by paying careful attention to the real mobility (both monetarily and nonmonetarily) of all who would seek access. Economists have talked for too long of managing fisheries for the greatest economic benefit to the resource rather than for the economic benefit of the nation; this latter concept includes those involved in the fishery as well as those precluded from involvement. I am dismayed at the cavalier way in which some talk of denying access to the fishery. My friend, Jim Crutchfield, approvingly discusses the situation in the state of Washington by saying: "the drive for a limited entry program that severely restricts effort is coming from an industry group rather than the preachings of academic people" (p. 384). Yet where do we suppose industry groups get the imprimatur for making others worse off so that they (those in the fishery, organized, and probably more "successful") can be made better off? Could it be from "academic preachings" that refer to this redistributional approach only in terms of achieving efficiency in resource use?

[1] In Wisconsin's Lake Superior, fishery access is constrained by a $10,000 investment, $5,000 of annual (historical) catch, and at least 75 days of fishing per year.

Moreover, the move toward limited entry is often dismissed as being of minor harm—and far outweighed by the good resource allocation implications. "While it (limiting entry) may confer unearned windfalls initially, once those rights become established as transferable property their price thereafter will pretty well limit the rate of return to new entrants to a competitive level, and allocative benefits will be realized. There will be a desirable tendency for those permits to gravitate to those who can use them *efficiently and professionally*. The negative impact will occur only in a once and for all fashion" (Crutchfield, p. 385, emphasis added).

I suspect that the concern with giving part of the harvest to Indians is because we suspect that they are not "efficient and professional" and that they are probably disinclined to treat the rights of access as "transferable property" that would someday gravitate to those who are professional and efficient.

Yet distributional analysis is concerned precisely with who gets what. We cannot be so casual about the fact that the negative impacts are merely of the "once and for all variety"—access denied is precisely that, and while our value judgments about who should get access are immaterial, we do have an analytical interest in the process whereby some obtain access and some do not.

Economists should be able to build models of the differential level and incidence of transaction costs that are relevant to the sort of subtle (and often nonsubtle) bargaining about who gets what. We should be able to build models of international comparative advantage that would be helpful in understanding the opportunity cost to various nations of denying them access to our extended economic zone. We should be able to disaggregate "fishing effort" into its component parts so that we do not continually beguile ourselves into thinking that it is some homogeneous and standard input. We should be able to build fishery models that somehow recognize that there are individuals of a wide variety of skills and capital equipment in the fishery and with a wide disparity of economic opportunity outside of the fishery. We must remember that the optimal way to manage the fishery is as an integrated industry with all others. It is nonsense to manage fisheries for the maximum economic benefit to the resource. If we make the political decision not to exterminate any fish stocks, economic theory tells us to manage that small segment of our extractive resource base for the greatest possible benefit of all of us. As unhandy as it may turn out to be, this is what welfare economics is about.

Distributional Implications of the Extended Economic Zone: Some Policy and Research Issues in the Fishery: Discussion

Richard S. Johnston and Frederick J. Smith

We heartily applaud Bromley's paper. As expected, it is provocative. We agree with his premise that "there are important insights to be gained by a more careful specification of the traditional steady-state/yield-effort models and by viewing the economics of extended jurisdiction in a welfare theoretic framework." However, we are concerned with two particular aspects of the paper.

Bromley seems to go beyond the identification of distributional consequences of fishery policy and suggests certain fishery policies because of their distributional consequences. Economists generally employ theoretical constructs in order to predict the consequences (distributional or otherwise) of alternative policies. Theoretical constructs do not prescribe policy "for the greatest possible benefit of all of us." Economists must therefore doff their economists' hats when they enter the policy-making arena. Bromley does not tell us when he is wearing his economist's hat and when he is wearing his manager's hat (nor do Crutchfield or Bell, as quoted in Bromley's paper). We would prefer a clearer distinction between Bromley's use of welfare theory to provide policy prescriptions (normative) and Bromley's use of welfare theory in predicting consequences of policy decisions (positive).

Our second concern relates to the role of distribution in welfare theory. Bromley argues that efficiency (or maximum net economic rent) is only one socially relevant variable. We agree. He then introduces distributional considerations. Does this imply that distribution is another socially relevant variable, or is distribution another dimension of efficiency?

If distribution is another socially relevant variable, are there not many more that deserve consideration? The Fishery Conservation and Management Act of 1976 contains an extensive list of socially relevant variables. Our own experience suggests that fishery participants would rank efficiency fairly low on an extensive list of socially relevant variables.

If distribution is another dimension of efficiency (as implied in Bromley's discussion of "access"), what of the distributional dimensions of the other socially relevant variables? We suspect that the current controversy over allocation of fish (or fishing rights) is more closely related to who gets fish, flexibility, etc., than to who gets what share of the maximum net economic rent. In substituting the net economic rent criterion for the maximum sustainable yield criterion, economists have exposed themselves to the same criticisms leveled at proponents of the maximum sustainable yield criterion. Our model is still single valued and incomplete.

Fortunately, the new management regime created by the Fishery Management and Conservation Act of 1976 provides for public hearings where potential gainers and losers cannot only identify socially relevant variables but can express priorities for distribution.

Bromley emphasizes that fishing families are "not mere pounds of fertilizer, acre-feet of water, or tons of bauxite." We find it unfortunate that he dismisses, by implication, the rewards accruing to owners of fertilizer, water, and bauxite, who may also have families.

The international model presented by Bromley appears to have a variety of interesting applications. For example, it might be used to predict the reaction of Japan (i.e., country B) to the current management policies under the U.S. (country A) Fishery Conservation and Management Act of 1976. In contrast to Brom-

Richard S. Johnston and Frederick J. Smith are with the Department of Agricultural and Resource Economics, Oregon State University.

ley's example, fish (does "fish" in Bromley's model refer to fish stocks or fish production?) are not unilaterally expropriated by country A but are initially allocated between countries A and B roughly in accordance with the status quo. Also in contrast to Bromley's example, the new management regime does not shift production possibility curves. However, we would expect the production possibility curve of country A to shift outward in the direction of F as the perceived risk (and therefore cost) is reduced by the very existence of the Fishery Conservation and Management Act of 1976.

We face a dilemma in predicting the eventual allocation of fish between countries A and B. Bromley implies that the beginning allocation of fish, FB to country B and FA to country A, is less than optimum for country A and optimum for country B. The optimum for country B appears as a tangency point equating marginal costs to price ratios. Unilateral fishery policy by country A presumably allows it to achieve a similar tangency (or internal equilibrium). But doesn't that tangency represent maximum efficiency, the very single-dimension criterion that Bromley decries?

The eventual allocation of fish between countries A and B then depends upon the new country A production possibility curve location and the management criterion used in determining tangency. With the quota approach to allocation, country B's production possibility curve is discontinuous at the quota level—a situation requiring extreme country B measures to accomplish some internal equilibrium (such as joint ventures with country A fishing firms, aggressive buying of country A inventories, influence peddling, etc.).

Bromley's example in table 1 is a little confusing. Is $NPV_F - NPV_A$ a row vector of "rents"? If so, will not maximizing this rent to the resource come about through the bidding process by which the highest bid comes from group AI and the lowest from group CF? It seems that rents can be determined only after consideration of alternative income sources. The meaning of net present value is not clear. Does "net" mean "receipts less all costs?" If so, NPV_A is already accounted for in the NPV_F row and $NPV_F - NPB_A$ has no relevance.

In conclusion, we would have preferred a little more caution in the prescriptive use of welfare theory and a clearer interpretation of the role of distribution in welfare theory. We are still very much in sympathy with Bromley's desire to view "the economics of extended jurisdiction in a welfare theoretic framework." However, our illustrations and examples must be more cogent and consistent. We must not stop at distributional considerations; we must also give some attention to other socially relevant variables in fisheries policy research.

Distributional Implications of Extended Fisheries Jurisdiction: Some Research and Policy Issues: Discussion

Darrell L. Hueth and Virgil J. Norton

Bromley's paper draws attention to the importance of distributional considerations in fishery management decisions (as in Bromley and Bishop), and he suggests these implications be identified before such decisions are made. Bromley also attempts to demonstrate how distributional considerations can be used to evaluate policy questions arising from extended fisheries jurisdiction in international and domestic settings. While these points are important, he has not clarified these concepts sufficiently for them to be useful in identifying policy and research issues.

The general equilibrium analysis of international fisheries is confusing. It is difficult to understand the interdependent production possibility curves presented in his figure 1. The production possibility frontiers of countries A and B without extended jurisdiction are given by *PLA* and *PLB*, respectively. His presentation seems to indicate that complete specialization in fisheries by both countries would produce more fish than it is possible to produce (i.e., the width of the box). If it is intended that movements along a frontier (*PLA*, for instance) shift B's frontier, this would, in turn, shift A's frontier and, thus, *PLA* becomes meaningless except for point *D;* that is, if there is interdependency as he indicates, *PLA* and *PLB* cannot simultaneously hold.

This figure is basic to his entire international presentation, and therefore the appropriateness of conclusions drawn from the international section is questionable. We would, however, be interested to learn more about the metric and the type of analysis he implicitly introduces in his otherwise ordinal analysis by suggesting that "it might seem that country A has been made only *slightly* better off, while B has been made *markedly* worse off, though more analysis would be necessary to be *certain* about this" (emphasis added).

Bromley's analysis of distribution in the domestic setting begins with three groups of fishermen seeking permission to fish. He implicitly assumes there would be a limitation on total effort within each group (the value of the license or right to fish to any group without such limitations would be zero) and asks the question: to which of these three groups—commercial fishermen (CF), marginal fishermen (MF), or American Indian (AI)—should the licenses be granted?

He concludes that, even though the "net present value" of fishing (NPV_F) for AI is lower than for CF, calculation of the "relevant figure" implies allocation to this group. To arrive at this conclusion, he assumes that, while the NPV_F is lower for AI than for CF, the net present value of onshore employment NPV_A is far less for AI than CF. Hence, the difference in net present values $NPV_F - NPV_A$ is greater for AI than CF.

We have two concerns about Bromley's analysis. First, he has made important implicit distributional decisions regarding allocation within each group or, as is mentioned above, there would be no economic rent or willingness to pay for access to the resource. We are surprised that he allows this to remain as an implicit assumption since he later indicates, "I am dismayed at the cavalier way in which some [economists] talk of denying access to the fishery." Obviously, the approach in this section involves denying access to the fishery to someone in each group. Distributional questions within as well as among groups should receive attention.

Second, we question Bromley's calculation of willingness to pay for access to the fishery. He assumes a net present value of access of

Darrell L. Hueth is an associate professor and Virgil J. Norton is a professor of resource economics, University of Rhode Island.

University of Rhode Island Agricultural Experiment Station Paper No. 1757.

105 for one group (CF) and a net present value of their best alternative to be 95 (his table 1). Why, if CF can earn a present value of 95 onshore and 105 fishing, would they be willing to pay anymore than 10 for the right to fish? Only if CF were unaware of these onshore employment opportunities (which would then change their private opportunity cost) or if CF obtain utility from fishing (not mentioned by Bromley) would this seem to be the case. Traditional analysis suggests that opportunity values would be included as a cost in calculation of NPV_F. Therefore, what Bromley calculates as $NPV_F - NPV_A$ would, in fact, represent willingness to pay for access. Following this, the implication of Bromley's example is that AI would have the highest willingness to pay. Thus, Bromley seems to be suggesting that access be allocated to the highest bidder, a procedure he questioned earlier.

Moreover, since social rents to a resource are appropriately calculated by summing the net present value of total revenues minus total costs where total costs are the social opportunity costs, the allocation to AI also maximizes rents (or benefits) to the resources, which, Bromley argues, is "nonsense." In the domestic analysis, it appears to us that Bromley is simply arguing: allocate on the basis of economic efficiency, but calculate the benefits and costs properly.

On the subject of properly calculating benefits and costs, while Bromley's introductory comments regarding entitlement and exposure are interesting, he did not relate this discussion to his later analysis of distribution in the domestic setting. Also, in various examples given, he fails to consider the role of compensation in the alternative proposed solutions. Therefore, the section "Toward a Working Definition of 'Distributional Implication' " is not helpful in interpreting the remainder of his paper. Certainly, this section and the international and domestic analyses do not provide the conceptual approach we hoped would be present when he indicated that in past analyses by other economists "distribution has been ignored because economists have been using the wrong conceptual framework."

On a more general point, Bromley correctly points out, "The appropriate maximand for public policy is aggregate social welfare." We are concerned, however, about the implications of his next statement: "This is not known until the distributional implications are known." The function that maximizes aggregate social welfare is not and cannot be known. Hence, even with the distributional implications we can never say that any social state I is actually better than social state II. At best, from the new welfare economics we can define an increase in potential real income and then only under certain conditions (see Samuelson, p. 11).

Does this mean that economists must abandon the fisheries policy field to the biologists? Certainly not! As Bergson has stated, "Before committing himself, the public official will surely wish to know whether, according to any usual calculation, the measure in question would be economically advantageous or disadvantageous . . ." (p. 41).

To provide this necessarily incomplete information to decision makers, however, one must shift from the purely ordinal general equilibrium framework to an approach that provides a basis for cardinal measures, namely, the economic surplus framework. This approach has the additional conceptual advantage of allowing us to identify income distributional consequences of alternative policy decisions since it is explicitly developed from individual (human) behavior.

Estimates of yield-effort models could provide important input into welfare studies using this approach. Thus, in contrast to Bromley's suggestion that we break out of the traditional steady-state/yield-effort models, such models represent one input into an appropriate economic surplus framework that may allow for distributional comparisons.

There is enough theoretical and empirical evidence to indicate that public action in management of fisheries, like petroleum in the ground and radio frequencies, represents a potential social gain. We assume Bromley would accept this position. Thus, a basic research question is to identify the efficiency effects of alternative management techniques. Certainly, when possible, the distributional consequences of these alternatives should also be presented; but even when they cannot, estimates of potential gains will be useful information in the decision process.

If economists want to have an input into decisions, we may wish to take the advice of Scott (p. 414); that is, we should attempt to predict the most likely actions of the Regional Management Councils and initiate research in the areas that will provide an input into these actions. This approach may suggest that research is needed in the following areas: (*a*)

industry structure, conduct, and performance in order to determine whether potential gains from extended jurisdiction will be passed on to consumers or captured as producer surplus; (*b*) comparative cost and trade studies to determine the implication of eliminating foreign effort from the U.S. economic zone; (*c*) economic implications of alternative methods of controlling incidental catch in multispecies fisheries; and (*d*) economic issues involved in allocation of fish to commercial and sport fishing activities (Brown and Schuler have addressed some distributional implications of this issue).

These issues are currently being considered by the councils. Each of these issues carries important efficiency and distributional implications. Economic tools do not provide the basis for choosing among distributional alternatives. However, economists can identify and measure the magnitude of the efficiency and distributional effects. Recent advances in economic surplus methodology have substantially enhanced the economist's capability to determine and interpret these magnitudes (see, for instance, Just and Hueth, Schmalensee, and Willig). Applications of these measures to the fishery will represent essential information for the decision makers who must choose among the alternatives.

Measuring the Effects of Commodity Stabilization Programs on Supply Response and Social Welfare
(Richard G. Heifner, Economic Research Service, USDA, Chairperson)

What Do We Know About Agricultural Producers' Behavior under Price and Yield Instability?

Clifford Hildreth

Unstable prices and yields imply uncertain prices and yields. One could imagine a situation where controlled prices were announced well in advance but fluctuated according to perceived circumstances at the times of the announcements. Some agricultural programs have approximated the latter, but the main interest here is in supply response with price unknown at the time production and tentative marketing decisions are made.

In considering producer behavior in the United States, it is worth noting that 70% of cash sales are furnished by the 450,000 farms (16%) having sales of $40,000 or more. On the average, each operator in this group controls nearly a million dollars worth of farm assets. Thus, supply response is principally determined by a group of highly competitive, respectably sized businesses. Direct observation supports the theoretical conjecture that survival or growth in such businesses requires intelligent, industrious, and informed managers. So the mental image I have of the party whose decisions we want to understand is that of an alert, sophisticated person continually mingling physical and supervisory tasks with a wide assortment of calculations and gathering and sifting a variety of relevant information.

Difficulties in Achieving Firm Knowledge

Our knowledge of the decision-making processes of these farmers comes primarily from three sources: (*a*) experiences of people who work closely with farmers—feed dealers, implement dealers, extension workers, buyers, etc., including farmers themselves; (*b*) theoretical models of behavior; and (*c*) econometric studies.

Interdependencies between the sources are clear. Advances in each are made by drawing on the other two. For example, a good econometric model builder tries to represent plausibly important judgments of experienced people and to reproduce aspects of the more promising general theoretical models. The results then provide some evidence as to the validity of the judgments and the relevance of the theories. Many extension workers and agribusiness trainees study theory and consult econometric studies to interpret their experiences more coherently.

To make a specific appraisal of how much we know about producer behavior under uncertainty would indeed be a formidable task. It would involve testing the forecasts of experienced people and the best models we could construct as well as forecasts by people of good judgment with access to all sources. An important question would be the relevance of past experience and analysis to a situation changed by such factors as changing impacts of government programs, increased contracting, changing international trade policies and patterns, etc.

I have not the resources to make such an appraisal and am inclined to doubt that a large undertaking would be the best use of research resources now. I think that the forecasting record would be sufficiently mixed and tests of econometric models would reveal sufficient possibilities of sampling and specification

Clifford Hildreth is a professor of economics, University of Minnesota.

error that the pressing need we feel to improve our understanding would be reinforced. I, therefore, turn my attention to some possibilities for improvement. The possibilities are numerous, and some very perceptive people disagree on what is most promising. Let me label what follows as one person's opinions without implying that any of the opinions are new.

Further development and empirical exploration of expected utility models of producer behavior seem promising avenues at this stage. Studies like those of Officer and Halter; Lin, Dean and Moore; and Just tend to confirm our notions that farmers are predominately risk averters. One expects this to lead to somewhat lower output than if average prices and yields could be known and stable. However, this tendency must be partially offset by loss shifting provisions of tax laws and investment credits. To further test our current notions and to obtain more precise relations, extensions and modifications of such studies should be undertaken. Before making some specific suggestions, I note two relevant developments.

Related Developments

Financial gain is not the only incentive shaping human behavior. Social status, religious values, domestic tranquility, leisure, and aesthetic enjoyments might immediately be cited in the case of our producers. This has led to analysis of multiattribute utility models in which the expectation of a function of several variables is presumed to be maximized. Keeney and Raiffa have prepared a stimulating exposition of such models and experiences with them. Certainly, such models for agricultural producers should be formulated, analyzed, and tested.

However, my conjecture is that when this is done the narrower utility of monetary gain model will be a useful approximation in many instances related to year-to-year supply. My impressions from introspection and from recent interviews with a panel of Minnesota farmers (work partially supported by the Economic Research Service and not yet reported) is that nonfinancial considerations typically enter very importantly into the decision to farm and the decision of the kind of farm to organize. But, once these decisions are made, I suspect that financial considerations dominate most of the year-to-year production and marketing decisions so long as the basic organization of the farm is not reconsidered.

Of course, personal tastes will be indulged when the financial considerations are not large. A farmer who has fed Holsteins (there are dairy herd liquidations in his area) for several years remarked last spring, "I'll be glad when I can go back to beef steers; they're nicer to watch." However, these motivations are not apt to affect supply relations greatly. For me, the upshot is that it seems desirable to start developing multiattribute models for some aspects of producer behavior, but I would not like to see this interrupt further development of financial gain models in appropriate settings.

Another relevant line of thought worth noting is associated with topics like satisficing, adaptive economics, and bounded rationality (see the book edited by Day and Groves). Very loosely, a decision maker typically has a variety of goals. He formulates a more-or-less precise strategy that seems to offer the chance of substantially achieving these goals and proceeds.

As long as achievement is substantial, the strategy is likely to be retained. When sufficient disappointment accumulates, a search for a new strategy is undertaken. A complete ordering of outcomes is not always assumed. Traditional economic theory is too rigid and narrow in postulating a precise individual equilibrium that maximizes utility or expected utility.

Even in the above garbled version, the approach has considerable merit. I still see, however, considerable promise in the further development of expected utility theory in contexts in which the decision maker may be expected to closely comply with the axioms that permit an expected utility representation (see Fishburn for a reformulation and brief historical sketch).

Consider the following possibility. Global lifetime decision making (Savage's grand world) is perceived as proceeding according to some metamodel that might or might not be Bayesian. Within the metamodel the decision maker sometimes formulates (or acts as through he formulates) expected utility models of specific decision problems (Savage's small worlds).

One function of the metamodel is to indicate when smaller models are to be reconsidered. Reconsideration might include (*a*) states of

nature regarded as possible and the prior distribution of states; (*b*) the flow of information used to successively form new posterior distributions and the statistical models used to interpret new information; (*c*) the space of possible actions; (*d*) the relation specifying a consequence for each state-action combination; and (*e*) the decision maker's perception of his utility function.

A possible advantage of the expected utility framework for small problems is that the kinds of difficulties encountered may provide hints of promising reexaminations. Two cases are obvious. If states of nature that were not contemplated occur, the state space has to be broadened. If realized outcomes do not yield the anticipated satisfaction, the utility function is not well articulated.

Assuming neither of the above, realized utility may still not agree very well with expected utility. Once an action has been chosen, the decision maker has a subjective distribution of outcomes and a subjective distribution of possible realized utilities. For convenience, call these the final distributions. If realized utility is consistently low—say, it is consistently below the mean of the final distribution—this suggests difficulty in the expectation formation process. Better information may be needed; the statistical model through which information is interpreted should be tested; the decision maker may be using a very precise prior that does not respond to new information.

On the other hand, it could happen that realized and expected utility tend to agree reasonably well over time, but both are consistently low. Optimal plans just do not provide much chance for happy outcomes. In this case, the available actions would seem to be a logical place to start reconsidering. If modest reconsideration does not yield something helpful, actions like hiring a consultant or going out of business might be contemplated.

The above might be described as common sense in special jargon. If Bayesian models lend themselves to using common sense, this seems to the good. It is to be hoped that in specific contexts the kind of trouble-shooting described might lead to more specific remedies than unaided common sense. So my current reaction to the satisficing, bounded rationality development is that it appears interesting and worthwhile but not inconsistent with the continued useful development of familiar expected utility models in suitable contexts, including aspects of supply responses.

Improvements in Expected Utility of Wealth Models

Assuming there is a wide range of agricultural supply problems to which expected utility of gain or wealth models can be usefully applied, I have several suggestions for the continued development of such models.

It has been recognized from the outset that the choice that maximizes expected utility will lie on the efficient mean-variance frontier only in special cases. Quite a few investigators have, however, conjectured that analysis in terms of mean and variance might frequently yield approximately optimal decisions and have continued to use this approach. It seems to me that we need to broaden our approach, to test mean-variance analysis against alternatives, and to use it only when there is good reason to believe that it does furnish a suitable approximation.

Use of mean-variance has frequently been accompanied by polynomial utility functions. Polynomials have the distinct disadvantage that behavior of the function for large values of its argument is determined by the sign of the coefficient of the highest order term. Both alternatives are implausible. If the coefficient of the highest order term is positive, the polynomial is, and remains, convex for sufficiently large wealth. If the coefficient of the highest order term is negative, the function becomes downward sloping—less wealth is preferred.

One can claim that a particular polynomial is a good approximation to utility in the relevant range. The difficulty is that the relevant range depends on the particular alternative choices contemplated. Changing these involves changing the relevant range and having to reverify and possibly change the utility function.

Keeney and Raiffa report several increasing, concave functions that permit decreasing absolute risk aversion. Among those reported are

$$u(x) = \sum_{1}^{N} a_i e^{-b_i x},$$

$$u(x) = a + b \log(x + c),$$

$$u(x) = a + b \log(x + c - d|x|),$$

$$u(x) = a + b \log(x + c - d[(x^2 + f^2)^{\frac{1}{2}} - f]),$$

and

$$u(x) = a + bx^c.$$

I have occasionally used

$$u(x) = ax - be^{-cx},$$

which is simple and also has the properties usually sought.

We should, of course, continue to check the possibility that utility functions have convex regions. My current conjecture is that risk aversion probably dominates business decisions. An argument tending to support this conjecture is given in the appendix.

Particular decision problems are never encountered in a vacuum. While a decision maker deals with uncertainties associated with some aspects of his life, other uncertainties exist and are typically relevant to his current decisions. It seems reasonable that uncertainties in livestock enterprises should be relevant to a farmer's crop decisions. His holdings of securities are relevant to all his farm planning. I have called these background uncertainties the initial prospect (Hildreth 1974b, Hildreth and Tesfatsion). It turns out that the initial prospect does not have to be explicitly taken into account if it is known to be statistically independent of the ventures currently considered. Whether or not this is the case needs to be carefully considered in each application.

There are, of course, hosts of other problems that require early attention. Multiperiod models, effects of the tax structure, and the process of expectation formation are immediate instances. Finding things that need doing is not a current problem. As models of producer decisions become more complete and more firmly established, they will have implications for econometric models of market behavior and for models of public decisions. For example, a frequent assumption in econometric models is that expected price is a linear function of past prices with coefficients following some predisposed pattern.

In early July 1977, I found several beef feeders uniformly optimistic about next summer's prices. More adequate feed to halt herd liquidation was the principal reason. Expected inprovement in the general economy was next. I cannot help wondering how well the historical price sequence captures such considerations. With regard to public decision, a large part of the Keeney and Raiffa volume cited earlier is concerned with extending expected utility reasoning to this realm.

Appendix

Suppose Mr. A has the Friedman-Savage "typical" utility function shown in figure 1 while Mr. B has the concave function of figure 2. The latter is similar except for the linear segment over $[x_1, x_2]$.

Suppose A and B can place fair bets with arbitrary probabilities and appropriate stakes of size $x_2 - x_1$ or smaller. If A finds himself with wealth x_3, he can quickly achieve expected utility y_3 by placing a bet that will pay $x_2 - x_3$ if an event with probability $\frac{x_3 - x_1}{x_2 - x_1}$ occurs and will cost $x_3 - x_1$ if not. Thus, we expect to observe A at x_3 only momentarily.

Suppose A and B are both at x_4, and each is considering a venture that will gain $x_5 - x_4$ or lose $x_4 - x_3$. If p is the probability of success, then B's expected utility if he pursues the venture is $py_5 + (1 - p)y_3$, and he will pursue if and only if $p > \frac{y_4 - y_3}{y_5 - y_3}$.

If A reckons in terms of his utility of wealth function, his expected utility on taking the venture is $py_5 + (1 - p)w_3$, and he will pursue if and only if $p > \frac{y_4 - w_3}{y_5 - w_3} > \frac{y_4 - y_3}{y_5 - y_3}$. However, if A thinks one step ahead and recognizes that he will quickly take the previously noted fair bet if he does land at x_3, his contemplated expected utility under the venture is $py_5 + (1 - p)\frac{x_3 - x_1}{x_2 - x_1}y_2 + (1 - p)\frac{x_2 - x_3}{x_2 - x_1}y_1 = py_5 + (1 - p)y_3$, which is the same as the contemplated utility of B. Thus, starting from x_4, and assuming that A's potential bets depend on an event independent of the venture being considered, A and B accept exactly the same ventures. Their behavior is indistinguishable except that A may sometimes be detected making supplementary fair bets after observing the outcomes

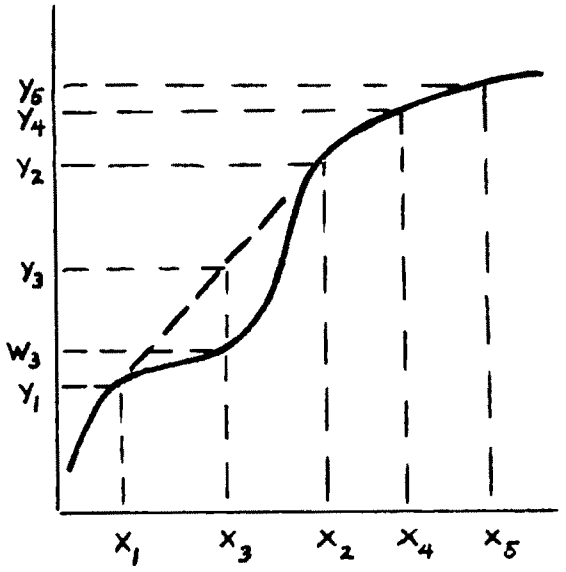

Figure 1

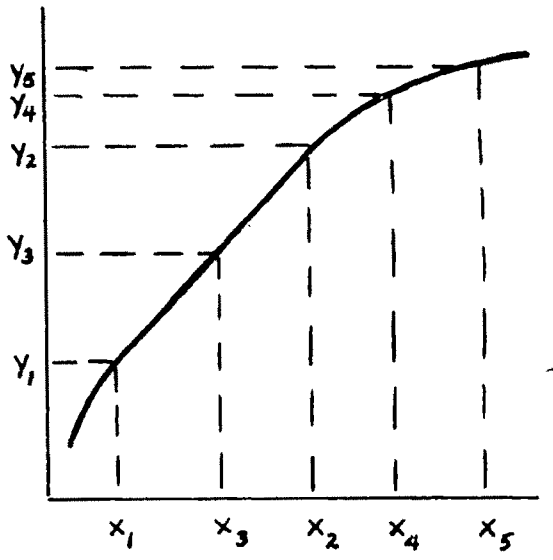

Figure 2

of his ventures. It is easily verified that this is true regardless of starting point.

In our economy there may not be fair bets of every desired size and odds. However, a very wide assortment of nearly fair prospects is surely available from Las Vegas, commodity futures, commodity options, stock options, foreign currency, and many less exotic business opportunities. If purchasing a commodity future is an unfair prospect, selling it can be unfair by at most transactions costs that are small.

Sophisticated producers who mainly account for fluctuations in supplies of farm commodities must typically be aware of some of these opportunities. In some cases the potential bets are not independent of contemplated ventures, as, for example, a wheat farmer whose venture is expansion and whose contemplated bets are wheat futures. Dependence can be better or worse than independence and needs careful exploration (this is stressed in Hildreth 1974a, Hildreth and Tesfatsion, and Just). If he desires, the wheat farmer can get an independent or nearly independent bet by using Congo currency. Also, A could, for practical purposes, convert a purchase of a commodity future into an $(x_2 - x_3)$ versus $(x_3 - x_1)$ bet by arranging to close his position as soon as he had either made $x_2 - x_3$ or lost $x_3 - x_1$.

Modified models that more completely reflect circumstances of particular kinds of entrepreneurial situations should be examined, but I believe these considerations establish a presumption that convexities lying between concave segments in a pure utility of wealth function may be taken to be substantially "filled in" when business ventures are contemplated.

Measuring Aggregate Supply Response under Instability

William Lin

In spite of the strong interests that agricultural economists have had in measuring aggregate supply response in the past, there are only a few studies that explicitly introduce the risk element into the models (e.g., Behrman, Just, Traill). Behrman quantifies both yield and price variabilities by using three-year moving average standard deviations about a simple moving average of yield and price. Just formulates a risk response model by assuming that decision makers would form their risk expectations by geometrically weighting past observations of risk similar to the way in which price and yield expectations are formed. The risk variable was taken to be the square of the difference between the actual explanatory variable (such as gross return) and the expected values. Each lag variable was then divided into observable and unobservable parts similar to the approach suggested by Klein. Assuming the disturbance term follows a normal distribution, an iterative procedure was undertaken to derive the maximum likelihood estimates of the regression coefficients, given values of the lag parameters and the internally generated risk observations. Results obtained from Just's multivariate adaptive expectations model often indicated risk to be significant in acreage response.

Traill uses a polynomial lag to measure onion acreage response at the national level. He utilizes an iterative procedure to first estimate the distributed lag effects of the past price variables, then formulates the risk observations by quantifying the absolute deviations of the actual and expected prices. Expected risk is then specified as a distributed lag function of past observations of risk. He found that a simple two-year moving average standard deviation of past actual prices performs at least equally as well as the iterative procedure.

The remainder of this paper proceeds as follows. First, a polynomial lag wheat acreage response model in Kansas is estimated. Second, estimated results, elasticities, and implications are discussed. Third, future research directions are sketched. Some specific methodological procedures are also suggested to deal with these research problems.

The Polynomial Lag Model

The use of geometric, Pascal, or polynomial lag in supply response studies is a matter of choice depending on the researchers' view of the relative importance of past values on expectations. A convenient feature of the geometric declining lag is that once the coefficient of expectation is determined the lagged response pattern follows smoothly (Nerlove 1958). The "price" that researchers pay to use geometric lag, however, is its restrictive lagged response pattern arising from the use of a constant coefficient of expectation. It is due to this restrictive assumption that I turn to the polynomial lag model (Almon). The polynomial lag is flexible enough to obtain a lagged response pattern similar to that implied by geometric lag.

In the past, risk response models typically were estimated for a small geographic area. Traill recently attempted to estimate an onion acreage response model at the national level for the first time but found the risk variable only moderately significant. At the national level, one encounters not only the aggregation problem suggested by Just but also the difficulty of including competing crops price variables in the acreage response equation. At the state or regional level (perhaps California is an exception), the price or profitability of the second best alternative crop can be effectively incorporated, and the aggregation problem becomes more manageable.

William Lin is an economist with the Economic Research Service, U.S. Department of Agriculture.

Perceptive comments and suggestions from Richard Heifner, Gerald Plato, Larry Deaton, John Baritelle, Peter Emerson, Dale Heien, and Fred Nelson are gratefully acknowledged. Needless to say, any errors remaining are the author's sole responsibility.

Preliminary empirical results of wheat acreage response in Kansas during 1950–75 are given in table 1. A second degree polynomial function is employed, since a higher degree polynomial appears to commit a larger specification error. Variables included in the equation are defined as follows: PW_{t-n} is the wheat price received by farmers in Kansas state, lagged by n years; *ESR* is the effective support rate; *EDPR* is the effective diversion payment rate; *AA* is the acreage allotment; PS_{t-1} is the price of sorghum, lagged by one year; T is the time trend (1950 = 1.0); *IC* is the index number of prices paid by farmers for production expense items, excluding livestock and poultry sectors; *SDR* is the three-year moving average standard deviation of past actual returns per acre; and t is the time period. Variables of PW_{t-n}, *ESR*, *EDPR*, PS_{t-1}, *IC*, and *SDR* are all deflated by the index of prices paid by farmers for family living and production expense items.

Following previous developments in incorporating governmental policy variables into supply response analysis (Houck et al., Just), I include "effective" support rate, "effective" diversion payment rate, and acreage allotment as three governmental policy variables. Price of sorghum lagged by one year is used as the expected price of sorghum. Time trend variable is included to capture the upward trend of wheat yields as well as the effects of wealth increases over time. To bring the input cost variable as relevant as possible to wheat production decisions, the livestock and poultry sectors were excluded from the index number of prices paid by farmers for production expense items. The ending lag

coefficient or weight is restricted to zero to avoid any unreasonably sharp discontinuity in the lagged response.

The estimated results are reasonably satisfactory. All coefficients have expected signs and reasonably large t-ratios, particularly when five years is chosen as the "best" length of lag. The choice of the best length of lag can be subject to a more rigorous test suggested by Harper. According to the minimum residual-variance criterion (Theil), a five-year lag appears to be the best length of lag, either including or excluding the risk variable, SDR, in the model. Inclusion of the risk variable only improves the explanatory power moderately, although some coefficients are moderately altered. Further exploration on the measures of risk variable is needed to reach firmer conclusions of the effects of risk on acreage response.

The short-run price elasticity of acreage response with respect to the lagged market price (PW_{t-1}) was computed as 0.37 at the sample mean—virtually the same as that reported earlier by Houck et al. (0.39) and close to 0.47 reported by Nerlove (1956) for the 1910–32 period. The long-run cumulative price elasticity for all N lagged periods was computed as 0.84, again, very similar to the 0.93 reported by Nerlove (1956). The empirical results also imply that a 1% decrease in instability, defined in terms of the three-year moving average standard deviation of gross returns, would lead to an increase of 0.06% in wheat planted acreage. Had the expected risk in 1975 been reduced from the actual $21.19 per acre to the historical trend of $4.00, some additional 622,000 acres of wheat would have been planted in Kansas.

The lagged response patterns for three, four, and five years lags were shown in figure 1, of which the five-year lag appears to be the most plausible. This lagged response surface is convex toward the origin, not totally different from the geometric lag response obtained by Nerlove (1956, 1958). In fact, Nerlove's previous finding suggests that the lagged responses beyond the past sixth year become negligible, a response pattern resembling that suggested by our results. Our lagged response pattern, however, represents a dramatic departure from the pattern obtained from Just's previous work in California, which implies that wheat farmers would take twenty years in San Joaquin Valley and thirty-five years in Sacramento Valley to complete one-half of the total lagged response using "model 3" results. As evidenced in figure 1, Nerlove (1956) reports a coefficient of expectation of 0.52 for the United States, compared with 0.035 in San Joaquin Valley and 0.02 in Sacramento Valley reported by Just.

Contrary to results reported earlier by Just in California, instability estimated for each point in time during 1950–75 suggests that wheat return was considerably stabilized for the period approaching 1970, compared with the early 1950s (Lin).

Future Research Directions

There are numerous research areas that need to be pursued further if the effects of the instability on supply are to be adequately measured. The remainder of this paper focuses on some of these research needs and possible procedures.

In spite of calls for normative risk response studies, the published aggregate risk response studies all follow the positive approach wherein the supply function is estimated directly using historical time series. Yet, the positive approach cannot effectively account for the effects of changes in the decision-making environment as is theoretically possible with the normative approach. The major obstacle to the normative approach, in my judgment, are problems associated with the estimation of an aggregate utility function for producers, capital rationing by lenders, and resource fixity.

To the extent that the aggregate utility function or the trade-off between mean and vari-

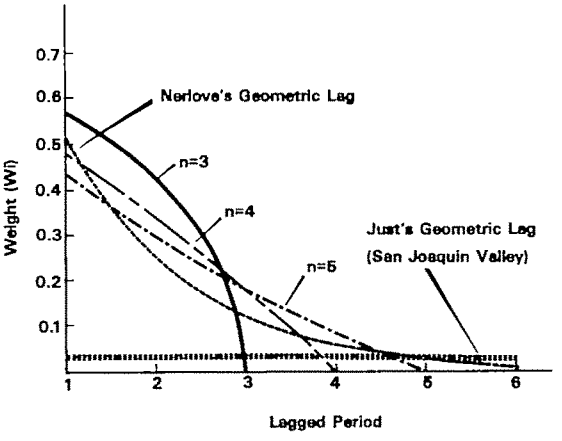

Figure 1. Polynomial lag response for Kansas wheat planted acreage

ance of return can be measured, then a regional E-V analysis would be an appealing approach to measure aggregate supply response under instability. Recent theoretical work by Keeney suggests that it is possible to derive such an aggregate utility function, provided interpersonal comparison of preference is allowed. Questions related to capital rationing by lenders can be pursued in several ways. Farmers' loan-borrowing capacities for farm operation can directly be added into the resource constraint vector. Alternatively, lenders' attitudes toward risk can be incorporated into the E-V analysis by imposing a "safety-first" constraint to the E-V frontier. Thirdly, lenders' utility functions, in addition to producers' utility functions, may be needed if the lenders possess some control on farmers' planted acreage decisions. With regard to resource fixity, there is a need to extend the static E-V analysis to a dynamic analysis so that the process of resource adjustment over time can be captured by the model.

Expectation models, such as adaptive expectation, are predicated on the premise that expected price is a function of past historical prices, "if more specific information is not available" (Nerlove 1956, p. 499). Yet casual observations remind us that producers may rely partly upon other market indicators, such as futures market price and outlook information, to form their price expectations. Recent empirical evidence suggested by Gardner that futures price, as an expected price, performs equally well as the lagged price in explaining crop acreage response further confirms our observations. This raises a question: How should we incorporate futures market or outlook information, in addition to historical prices, into the expectation model? One possibility is to convert the prior subjective probability distribution of historical prices, taken to be the weights of past prices in the estimated expected price equation, into the posterior probability distribution by integrating the expectation model with Bayesian decision theory.

An important application of risk response studies is to assess the distribution of welfare gains and losses from stabilization. Recently, Turnovsky has shown that when the assumptions of linear demand and supply equations and additive disturbances are dropped the allocation of welfare gains between consumers and producers tends to become indeterminate. Thus, specification of the demand and supply functions becomes an important issue in assessing stabilization policies.

To the extent possible, specification of functional form should be guided by economic theory. In the absence of a priori theoretical basis, existing few risk response studies have all relied upon the linear specification. Recent developments in the area of transformation of variables (Box and Cox), however, greatly widen the choice of functional forms and make it possible to determine the best form in a more rigorous and formal manner.

Economic uncertainty tends to induce farmers to favor diversification over specialization; the former generally is associated with small economic units, and the latter is commonly identified with large commercial farms. Early empirical studies suggested that stable prices encourage large-scale farming; however some agricultural economists begin to doubt whether the small family farms are able to survive in high-technology and high-risk phases of agricultural production. Is there any basic contradiction? To answer the above question, one would have to quantify the differential risk effects on farms of various scales of operation. Supply response under instability, if it can be broken down by farm size, certainly offers an important aspect of the risk effects on farms of various scales. Implications of instability on farm structure can further be drawn from this type of study.

Considerations in Designing Stabilization Schemes

J. R. Anderson, P. B. R. Hazell and P. L. Scandizzo

Stabilization schemes have, in the current national and international debates, come to mean almost exclusively price stabilization schemes. We shall largely share this preoccupation in our paper, but it is worth considering briefly the rationale of this focus.

Economic theory, while somewhat ambiguous on the topic, is far from supportive of the need for price stabilization schemes. Axiomatic treatments of the theory of well-behaved and decentralized economies under uncertainty (e.g., Arrow, Debreu, Hanoch) lead to the conclusion that Pareto-optimal equilibria can be reached without any need of government intervention. A key feature of these analyses is to define commodities by possible states of nature as well as by their physical characteristics, so that Pareto-optimal equilibria are defined for the economy for each state of nature. Uncertainty is then only undesirable if the economy fails to make automatic adjustment from one equilibrium to another, a possibility that can only arise through market failures in either the demand for contingent claims or the supply of real insurance contracts or because of imperfect information. Thus, uncertainty is only undesirable if accompanied by market failure, and the obvious remedy is to correct these market failures rather than to remove the uncertainty itself.

Samuelson, in a rather different approach, argues that an economy in a Pareto equilibrium devoid of uncertainty cannot attain greater welfare simply through the introduction of uncertainty (unless, of course, the majority of individuals are perverse risk lovers). The conclusion in this case is that stabilization must always be desirable and that the first-best policy is to remove the source of uncertainty. Since price instability is usually the result of more fundamental sources of uncertainty, such as production risks, price stabilization is unlikely to be a first-best policy,

In overlooking these results from theory, government and international bodies are clearly responding more to what might be called the pragmatic policy approach. Proponents of this view argue that in the real world, uncertainty causes markets to fail almost everywhere. United Nations Conference on Trade and Development (UNCTAD) in various documents argues, for example, that uncertainty disrupts the orderly behavior of economic agents in a competitive economy, introducing difficulties and errors in investment and production decisions, stimulating inflation and business cycles, and increasing the risk of bankruptcies and debt default (see, e.g., UNCTAD). Arguments for developing countries are also furthered by their usual specialization in a few primary commodities for which export prices are uncertain. Uncertainty then also has a direct and highly disruptive effect on export earnings and hence on economic stability and growth and, in conjunction with low foreign currency reserves, conspires to reduce a country's ability to borrow abroad and to increase its risk of international debt default.

The policy pragmatic approach concludes that stabilization is always a good thing and the relevant question is what to stabilize and how. Price stabilization is a viable policy not because it is necessarily (if ever) a first-best policy but rather because it is one of the few forms of market intervention available to a government or international agency. However, alternative stabilization policies are often available depending on the policy goals, for example, international compensatory finance schemes, buffer funds, or producers' income insurance schemes, so that the current preoccupation with price stabilization must have yet a further underlying rationale. One rationale is suggested by the existing literature

Opinions expressed in this paper are the sole responsibility of the authors.

on applied welfare economics, which, while increasingly indeterminate, does tend to show that producers as a group are, on average, the main beneficiaries of price stabilization (see Turnovsky for a recent review). Possibly, those concerned with the development of predominantly agricultural economies are hopeful of capturing these welfare gains from the international markets.

However, policy makers should not be too easily seduced by the apparent gains and feasibility of price stabilization schemes. There remain important questions about the distribution of gains and losses from stabilization schemes that have yet to be resolved. These concern not only the trade-offs between consuming and producing interests, both within and between countries (a favorite topic of economic analysts), but even the distribution of the gains and losses within these groups themselves. Lipton, for example, argues that price stabilization of major food commodities tends to stabilize rural wages and real incomes for poor rural families dependent, or partly dependent, on wage earnings; but, given the usual sorts of magnitudes for demand elasticities, it will tend to destabilize the revenue of farmers with a marketed surplus. He concludes that price stabilization may have desirable intrarural income distributional effects in countries with a high proportion of subsistence farmers but have less desirable effects in countries with more advanced agricultural sectors.

When production variability is the source of price uncertainty, the consequence of stabilizing prices for revenue stability depends crucially on the price elasticity of demand; revenues are also stabilized when the absolute value of the demand elasticity is 0.5 or less but are destabilized otherwise (Tomek, p. 77).[1] Policy makers in countries producing commodities for export in more elastic markets than this might well want to consider the inherent trade-offs between price stabilization and the stability of producers' incomes and national export earnings. If the latter are of primary interest, simple price stabilization may well be an inappropriate goal.

While many unresolved considerations exist in determining the appropriateness of price stabilization measures, we turn now to a discussion of considerations to be taken into account in the design of such schemes. We focus on commodities that can be stored and assume price stabilization is to be achieved through a buffer stock agency (BSA). Our discussion will undoubtedly be incomplete in touching on all the key considerations, and we plead guilty to emphasizing those considerations of most interest to us, as well as those that we consider to have been neglected in the past.

A highly pertinent question in the design of any price stabilization scheme is the price, or range of prices, at which market prices are to be stabilized. There are two tricky issues here. In the first place, longer run market efficiency will only be sustained in a decentralized economy if prices are still allowed to retain their role in providing signals to producers and consumers in allocating their resources. While a prime purpose of a stabilization scheme is to remove unnecessary noise in the price signal, the BSA must still set, and indeed adjust, its prices to reflect structural changes in the economy. Given the many sources of price uncertainty in the real world (production risks, business cycles, demand fluctuations, etc.) and frequent structural changes in technology and demands, the BSA is faced with an analytical problem that is likely to be beyond the ken of even the most able econometrician. A second issue concerns the size of the stocks the BSA can carry. Given existing costs of storage and money, any BSA will face a real nonzero probability of running out of stocks in some years. For a given storage capacity, this possibility increases as the desired range of price variability is narrowed through BSA operations, so that the choice of a price band cannot be made independently of the allocated resources of the BSA.

But the problem of price setting does not end there. Any institution that has a major price-setting role will rapidly find itself confronted by pressures from special interest groups. When demand for the commodity in question is inelastic, producers undoubtedly see the value in coercing the BSA to raise its average selling price, even at the expense of accumulating surplus stocks. At the international level, producing countries may see the establishment of world buffer stock schemes as a forum for improving their average terms of trade. For example, the UNCTAD proposal for an Integrated Commodities Program claims, as one of its stated objectives, the "Establishment and maintenance of commod-

[1] Tomek reports his results in terms of the price flexibility coefficient F. Our interpretation assumes that $1/F$ is the demand elasticity, which is only strictly true in the absence of cross price elasticities.

ity prices at levels which, in real terms, are equitable to consumers and remunerative to producers, taking full account of the rate of world inflation, the need to provide incentives for adequate investment in commodity production, the depletion of non-renewable resources and the need to keep the prices of natural commodities competitive with those of their synthetic substitutes" (p. 3). While such objectives may well be justified,[2] it is clear that the establishment of BSA's requires a serious resolution of their political and economic roles and responsibilities and especially of the interests they are to serve.

Yet a further consideration in determining the desired price level has been raised by Hazell and Scandizzo. They argue that, if producers facing risky production allocate resources on the basis of anticipated prices and yields that are formed independently of each other, competitive markets can be inefficient. Social welfare can then be improved by establishing a BSA that has sole purchasing power with producers and that pays producers a lower price than the one it sells at to consumers. The optimal size of the price wedge can be determined as a function of the elasticity of demand and the coefficient of variation of yields.

Although it has generally been ignored in both theoretical and empirical work, another key consideration in designing BSA's is that producers modify their supply behavior in response to the stability induced by a BSA. The usual reasoning here is that producers are averse to risk and that, if a price is stabilized, they tend to produce more of the formerly risky commodity. Indeed, such risk-averse behavior has seemingly been captured in empirical models of risk-responsive supply of agricultural commodities—most notably by Just. Moreover, our own work employing his methodology has confirmed such risk-responsive supply behavior in enterprises as diverse as grain and vegetable production in northern Mexico and jute production in South Asia. Such effects appear pronounced and statistically significant. Thus, they are also bound to be economically significant in the design of a BSA, since any producers' gains induced by stability may soon be competed away through their own responsiveness to the new environment.

Proponents of BSA's often seem to assume away the existence of private stockholdings in commodity markets. Yet these may be quite substantial and, prior to the introduction of a government BSA, may play an important role in bringing some stability to market prices. It is clearly important to know how private stockholders will respond to a government BSA. If, as is likely, they reduce their stocks, the BSA will require additional capacity to offset the destabilizing effects of reduced private stocks. Of course, if private stockholders previously acted in a speculative and destabilizing way, the introduction of a BSA may be accompanied by a bonus gain in stabilization as speculative behavior is reduced.

A final consideration is that of risk pooling. Two potential sources of risk pooling exist: across commodities and across regions or countries. The essential principle here is that the size and cost of a BSA can be reduced without any loss in its price stabilization role by exploiting risk-pooling opportunities. The gains are obvious in the case of geographic risk pooling. If producers of the same commodity in different regions or countries face less than perfectly correlated (+1) production risks, offsetting output fluctuations will lower the necessary size of the stocks required to achieve a given level of price stability. Geographic risk pooling provides a good argument for establishing BSA's at the multinational level.

Risk pooling over commodities can serve a similar role if they are close demand substitutes and if their yield risks are not perfectly correlated. Commodities that are not good demand substitutes offer little advantage to a BSA, but they can be a good basis for risk pooling in buffer fund schemes, such as proposed by UNCTAD.

[2] Prebisch and Emmanuel have demonstrated that developing countries are disadvantaged in competitive international trade—the so-called "unequal exchange" theory. This view is also popular with Marxists, though their rationale is based on the labor theory of value (Mandel).

Theoretical and Empirical Possibilities for Determining the Distribution of Welfare Gains from Stabilization

Richard E. Just

The general question of price stabilization is one of those problems in economics where the complexity of the issue is far beyond the theoretical and technical capabilities we now possess for analyzing it. Consequently, analytical studies of stabilization policy have been reduced to examination of only one or a few important aspects of the problem (at a time) while disregarding others. As a result, much of the theoretical work on price stabilization has been overlooked by empiricists and those involved directly in the policy-making process.

However, these theoretical studies, simplistic as they may be, can often illuminate some disastrous pitfalls in empirical research. Perhaps the results of a single theoretical paper can invalidate or cast great doubt on the conclusions of a host of expensive empirical studies. In point of fact, this paper discusses several noteworthy examples. In such cases, a bit of analytical work in advance or some better communication between theoreticians and empiricists could avoid a great deal of both effort and expense.

This paper contributes to this latter end; that is, I would like to briefly assess the theoretical literature dealing with commodity price stabilization, summarize the major results, point to their implications for empirical research, and then discuss the extent to which these findings have been considered in empirical research.

Nonlinearities

Consider, first, the implications of the theoretical literature on price stabilization relating to nonlinearity. Papers by Turnovsky (1974b) and Just et al. (1978) are of particular interest in this respect. Using special cases of assumptions similar to those used under linearity by Massell, Turnovsky has pioneered a methodology for examining the role of nonlinearity in determining the gains and distribution of gains from price stabilization. Further paralleling the work under linearity by Hueth and Schmitz, the Just et al. paper extends Turnovsky's methodology into a framework of international trade.

The framework of these papers is quite restrictive in that instability can only be assumed to arise from one sector at a time. Nevertheless, the results of the work carry considerable implications for empirical research. Contrary to the earlier work under linearity, Turnovsky concludes for a closed economy that "the desirability of price stabilization for either producers or consumers *does not depend upon the source of the price instability*, but only upon the shapes of the deterministic components of the demand and supply curves" (1974b, p. 24). Similar results developed by Just et al. (1978) with respect to importing and exporting countries also demonstrate that shapes of supply and demand curves are critical in determining qualitative effects of stabilization.

Just et al. (1977) further demonstrate that an excessive degree of nonlinearity is not necessary to obtain a reversal in who gains and who loses over the case of linearity. Specifically, they show, for the range of elasticity estimates forthcoming from most econometric studies of grain supply and demand, that a switch in specification from linearity to log-linearity with commonly accepted elasticities can be sufficient for such a reversal depending on the source of instability.

What are the implications of these results for empirical and simulation studies of stabilization? The theory implies that any empirical study that does not adequately investigate

Richard E. Just is an associate professor of agricultural and resource economics, University of California, Berkeley.
Giannini Foundation Paper No. 469.

functional forms may, in fact, be determining results through arbitrary specifications and assumptions. In point of fact, "approximation in the range of relevancy" is not sufficient as in most econometric problems (e.g., price forecasting), since standard welfare measures depend on the shape and position of supply and demand curves outside the range of normal price variation.

To what extent have these considerations been made in empirical stabilization studies? Nonlinearity, of course, is a problem that has plagued econometricians for years. The usual empirical or simulation approach, which has been continued in stabilization studies, has been to simply specify a linear or log-linear form. As examples (although these studies are not to be criticized more than others), I cite Cochrane and Danin; Johnson and Sumner; Sharples, Walker, and Slaughter; and Zwart and Meilke. Hence, simplistic as the theoretical studies may be, they lead to great reservations concerning use of this empirical work in applied welfare analysis; that is, since the theory suggests that reversals can take place as one switches between the two popular specifications, one cannot be sure of even the qualitative results of such empirical studies. The true degree of nonlinearity may be greater or less than that suggested by log-linearity. These conclusions are supported by the empirical work of Reutlinger who, in using crude piecewise-linear demand curves, concludes that "the storage impact on gains and losses by consumers and producers is particularly sensitive to the assumed shape of the demand function" (p. 8).

The Form of Disturbances

Another matter of specification that theoretical studies have shown to be important is the way in which random disturbances enter the problem. The early work, e.g., Massell and Hueth and Schmitz, was based on additive disturbances in supply and demand. Turnovsky (1976) has since argued, however, that multiplicative disturbances in demand are much more plausible than additive ones, and other authors such as Hazell and Scandizzo have also adopted multiplicative random disturbances in supply. Although these two alternative stochastic assumptions are admittedly simple, the theoretical literature has been able to argue on the basis of the results that "the [welfare] distributional conclusions are highly sensitive to the form of stochastic disturbance assumed" (Turnovsky 1976, p. 134). For example, one can compare the Just et al. (1978) results with those of Hueth and Schmitz with linearity.

Again, as with respect to nonlinearity, we must conclude that an empirical study that specifies the form of disturbance a priori may be influencing not only the quantitative but also the qualitative nature of the results obtained. As Turnovsky concludes, "unless the policy maker has reliable information on this question, any stabilization policy may have undesirable effects on the group it is intended to assist" (1976, p. 145). So, even though very simplistic cases are considered in the theoretical literature, the cases cannot be dismissed a priori and, hence, the negative results (if not the positive) have major implications for empirical research.

To what extent have these considerations been made in empirical studies of stabilization? Unfortunately, very little if at all. Representative studies such as those mentioned above all seem to arbitrarily assume either additive or multiplicative disturbances usually depending on whether linearity or log-linearity is assumed. Again, as with nonlinearity, it must be concluded that little confidence can be placed in empirical and simulation studies until the form of random disturbances is adequately investigated.

Risk Response

Consider further the implications of risk response for price stabilization policies. As price stability is attained, risk can be greatly reduced. But as risk is reduced, risk-responsive farmers may increase supply (Just 1975b) and, as a result, expected profits will increase by more than the standard Massell and Turnovsky risk assumptions would indicate. Also, buffer stocks could accumulate indefinitely at stabilized prices that would otherwise be reasonable (Just 1975b). Similar arguments can be made with respect to risk-responsive consumers as evidenced by the work of Lutz and Newbery.

Again, the theoretical results tend to be negative and imply that estimates of gains from stabilization may be seriously biased downward (under risk aversion) and that any efforts to determine an optimal stabilization

policy (e.g., normal price) may be thwarted when risk response is not considered.

Examination of the empirical stabilization literature reveals that risk response has been considered only rarely even though risk consideration in applied econometrics is becoming quite common. The traditional stabilization studies that have used econometric estimates of supply and demand have almost universally ignored risk response. Hazell and Scandizzo, however, have been able to treat risk response by using a mean-variance programming approach for agricultural supply. Although their model is more restrictive in behavioral assumptions than other econometric studies of stabilization, their results are consistent with those of the theoretical studies cited above and raise further doubts about other empirical work. In fact, they conclude that "the potential welfare gains to be had from optimal intervention policies are surprisingly large, in fact far greater than might be anticipated" (p. 18) in the case where risk response is considered.

Trade Controls and Institutional Considerations

Some other factors that, no doubt, play a considerable role in international grain marketing relate to trade controls and institutional structure. In this respect the papers by Bieri and Schmitz and by Just et al. (1977) are interesting since they imply that trade restrictions and institutional structure can significantly affect the outcome of stabilization policy. For example, Bieri and Schmitz show that, when the source of instability is external, the importing country prefers price stability when trade is restricted by tariffs but not when trade is restricted by marketing boards. These results are contrary to those under competition developed by Hueth and Schmitz and, thus, suggest that institutional structure plays a decided role in determining even the qualitative effects of price stabilization.

The paper by Just et al. (1977) considers the effects of such controls as variable trade levies on price stability and specifically investigates the way in which variable trade levies have apparently been used in the Common Market to export instability and thus maintain stable domestic prices. The results suggest that such a policy in importing countries causes the role of nonlinearities in the exporting countries to become even more crucial in determining the welfare effects of stabilization than without trade levies, while nonlinearities in the importing countries are no longer important.

Again, although each of these papers uses a rather simple theoretical framework, the implications of the results must be considered in empirical problems where market power and trade restrictions may play a role. For example, in problems like wheat price stabilization where large U.S. grain trading companies and institutions such as the Canadian Wheat Board dominate international trade, one must seriously question the extent to which gains from stabilization might be affected by market power among traders.

In examining the empirical stabilization literature, one finds that these considerations have not been made (again, for example, the representative empirical studies above may be cited). Thus, given that institutional and trade factors can strongly influence the qualitative welfare effects of stabilization even in a simple model, one must seriously question the studies that ignore these factors in attempting to find quantitative estimates of welfare impacts.

Private versus Public Storage

Another area in which empirical work has apparently been weak relates to the role of private storage. For example, the empirical work of Cochrane and Danin, Reutlinger, and Sharples, Walker, and Slaughter has recently been criticized by Helmberger and Weaver because it ignores the stabilizing effect of private storage as well as the reaction of private storage supply to the imposition of a public storage program. As Helmberger and Weaver show, the distribution of welfare gains from price stabilization may be much different when these reactions are adequately considered.

Since Helmberger and Weaver have dealt with this point at some length, it suffices to say that there has been a disturbing lack of private storage considerations in empirical studies of price stabilization. In particular, given the empirical research that verifies private storage supply response (e.g., Lutz), one must view most empirical work thus far with some degree of skepticism.

Choice of Stabilization Policy Controls

Another issue for which the theoretical literature has made some interesting suggestions relates to the use of alternative stabilization

policy controls. For example, empirical work has generally considered only arbitrarily selected rules for buffer stock transactions based on price bands, quantity bands, etc. Theoretical investigation, however, has indicated that economic efficiency leads to some buffer stock transactions even at near normal prices and that a strict price bound should not be enforced in periods of either extreme shortage or extreme surplus (Just 1975a). Rather, a variable stock policy based on current prices should be used to attain an efficient trade-off between welfare costs associated with price variability and storage costs associated with buffer stock variability. While these results are derived in a simplistic framework, the more recent empirical work of Cochrane and Danin and of Zwart and Meilke has indeed found that such policies are preferable to storage policies of more traditional forms (although, again, several important aspects of the problem are not considered in their work).

Moreover, one must consider the possibility that controls other than buffer stocks provide a more economically efficient means of attaining stable prices. For example, Turnovsky (1977) shows that publicly announced forecasts can have a price-stabilizing impact. Thus, for example, federal funds may be better spent on improving U.S. Department of Agriculture forecasts than on operating a buffer stock. Other prospects are provided by insurance and by futures market operation and regulation. Yet, another possibility involves the use of variable trade controls in the same sense as considered by Just et al. (1977). By imposing variable trade levies, it is possible, at least in principle, for a small country to completely stabilize internal prices at normal levels without incurring storage costs. This may be the cheapest form of price stabilization for (small) developing countries; yet related empirical studies (e.g., Reutlinger) have not considered this alternative. The possibilities for exporting instability from the United States with this mechanism are more limited, however, because extremely low prices may be obtained for U.S. exports in years of excess production and, furthermore, trade retaliation may be induced.

The Surplus Concept Used for Measuring Welfare Impacts

Finally, the use of producer and consumer surplus has been heavily criticized over the years and, while I do not adopt the philosophy that "consumer surplus is questionable, therefore we should not do anything," I believe we should seek better understanding and more competent application of the surplus concept in use. For example, the standard assumption of perfectly elastic input supplies is surely not justified in agriculture, so what does producer surplus associated with grain supply mean? How should surplus measures be aggregated over time to correctly estimate long-term effects of stabilization? How should comparisons of producer surplus associated with risk-responsive supply curves be interpreted? Should different interpretations be attached depending on whether risk response is due to technical efficiencies or producer preferences? These are questions that require clear answers before competent empirical analysis can be performed. The answers are not beyond our grasp. Indeed, several of these questions have been addressed in recent unpublished work by Hueth, Just, and Schmitz; and more answers promise to be forthcoming shortly.

Conclusions

I will conclude with some comments about the perspective with which theoretical and empirical studies should be viewed in the context of applied policy analysis. As this paper has attempted to show, theoretical investigations can be useful in illuminating the potential consequences of some particular aspects of a problem. Since one is usually not able to rule out the same phenomenon in a more general, real world situation, the results can be useful even when the theoretical work is based on considerable simplifications and abstractions. Hence, models intended for theoretical investigation need not be forced into the complexities of "real world" assumptions in order to serve their purpose but must simply include the essential but tractable aspects of a particular problem.

Empirical studies, on the other hand, are usually efforts to derive some quantitative estimates relating to the impact of present or proposed policies and as such are by design an effort to deal with a real world situation. In this context one must have great concern for the aspects of the problem that plausibly have an important influence on results. Theoretical study in a variety of abstract situations is a useful and relatively inexpensive way of determining some important aspects that should

be considered in designing an empirical study. Thus, theoretical work should not always be viewed as an attempt to answer important policy questions but must also be recognized as a means of identifying important needs in empirical research.

With this approach in mind, I have attempted to discuss some of the more important implications that the theoretical literature on price stabilization holds for empirical research. I view the topics specifically addressed here as particularly important because I feel that we now possess sufficient econometric and empirical skills to explicitly consider the associated problems. There are, of course, a number of other aspects of the problem that should also be considered but that were of less importance for this paper due either to the nonconsequential nature of the results or the lack of adequate theoretical results thus far. For example, Turnovsky (1974a) argues that lags in decision making and serial correlation in disturbances should also be considered, but his theoretical results do not differ qualitatively from others, nor does empirical consideration cause great difficulties.

Some less tractable problems, which may also be important in formulating stabilization policy, include the effects of speculation and the interactions with other economic sectors in a general equilibrium context. For example, Peck argues that the existence of a futures market has important consequences for price stability, which should not be ignored in developing price stabilization policy. From another viewpoint, Caves argues that flexible exchange rates should be adopted when macrolevel instability is due to foreign sources. To the extent that exchange rates affect grain trade and price stability, the interaction of exchange rate stability with commodity price stability must be considered in developing price stabilization policy.

Even more disturbing complications arise when one considers the optimal interaction of production and storage policy in a general equilibrium context of international trade: For example, Feder, Just, and Schmitz show (contrary to both the partial equilibrium case and the general equilibrium case without storage possibilities) that an exporting country should respond to greater price instability by increasing production and reducing storage. These results suggest that production policy should depend critically on the storage policy that is adopted and that the gains from buffer stock stabilization may be strongly influenced by whether or not production policies are adequately coordinated with storage policies. A sufficiently general empirical approach to investigate these kinds of propositions, however, appears as of now to be somewhat beyond our grasp.

Toward a Philosophical Basis for Community Development
(Donald M. Sorensen, Colorado State University, Chairperson)

The Creation of "Truth" by Social Scientists and Planners: Assumptions, Decisions, and the Negotiation of Reality

Jerry A. Moles

Hermann Hesse (p. 42) once wrote a short story in which God sent a flood putting an end to a bloody World War. The last European was struggling in the flood waters when an ark appeared under the command of an aged patriarch named Noah and the unfortunate man was hauled on board. The crew of the ark was composed of persons from every ethnic group on earth. During the voyage each was called upon to demonstrate his or her skill. Finally, the time for the European to perform came, and he informed his arkmates that he was skilled in the use of his intellect in solving the ". . . great problems on which the happiness of mankind depends."

Noah was impressed, " 'The skill that brings happiness is certainly more important than any other. Just tell us what you know about the happiness of mankind. We shall all be grateful.' "

Up until then the European had been haughty and self-assured. Now he seemed at a loss.

" 'It's not my fault,' he said hesitantly, 'but you still don't understand. I didn't say I knew the secret of happiness. I only said that my intellect is working on certain problems the solution of which would promote the happiness of mankind. Such work takes a long time, neither you nor I will live to see the end of it. The problems are knotty and many generations will continue to ponder them.'

"The audience listened with mounting perplexity and distrust. What was the man saying? Even Noah averted his eyes and frowned.

"The Hindu smiled at the Chinese. When the others could think of nothing to say, the Chinese spoke up. 'Dear brothers,' he said most affably, 'this white cousin is a joker. He is trying to tell us that his mind is working on something which our great-grandchildren's great-grandchildren may or may not live to see. I suggest that we applaud him as a joker. He says things that none of us can quite understand, but we all suspect that if we did fully understand them they would make us laugh and laugh and laugh.' "

Social scientists are in ways like the European. We are interested in human happiness; we speak of the quality of life, personal satisfaction, sense of security, and freedom from need. We use our intellects to assist others in reaching these objectives. We expect to spend much of our lives in the quest of ways to increase happiness while knowing that we may be unsuccessful. As a consequence we run the risk of being called the joker. Our explanations, methods, and research techniques often do not provide adequate answers to many problems of pressing human concern. As Greer notes, "We have at best crude approximations of measurements for such variables as anomie . . . sentiment, attitude, and the like. Yet we have theories that hypothesize invariant associations of these among themselves and with other aspects of behavior. We imagine the 'felicific calculus' with units of happiness, but in practice we use crude questions for a crude concept" (p. 129).

We run the risk of being called the joker when we ignore many of the limitations that

---

Jerry A. Moles is an assistant professor in the Department of Anthropology, University of California, Davis.

The author has benefited from discussions with Paul W. Barkley, John W. Bennett, Sandra M. Gifford, R. J. Hildreth, L. M. Hartman, O. Norman Simpkins, and Donald M. Sorensen concerning some of the topics discussed in this paper.

exist in scientific inquiry and in the sharing of research results with policy makers, planners, and administrators who make decisions affecting our lives and the lives of others. I would like to discuss some of the limitations inherent in the scientific approach to the study of human behavior and suggest ways in which we can compensate for these shortcomings.

Science and in specific the social sciences constitutes one of the many subcultures in western culture. For our purposes culture may be defined as human knowledge. This is similar to the idea proposed by Boulding (1956) in which he conceptualized culture as images of ourselves and our surroundings. Science is a body of knowledge and one of the many methods that can be used to gain an understanding of the world. It is a powerful tool when applied with skill and insight, but science, like any other approach to understanding, has its limitations. I explore some of the ideas that have been developed concerning the nature of knowledge and relate them to social science inquiry and the uses of social science in the solution of human problems.

Knowledge is reality. What we know, our percepts and concepts, beliefs, values, skills, awareness of ourselves and others, and awareness of our environment constitute our reality. What we know is what we are. I know what I am by knowing my relationships with all other persons and things, past and present. I know there are many things I do not know, and this too is a part of my reality. Even the things I do not know are interpreted on the basis of the things that I do know. I know there are other realities. I know that I will learn about the realities of other people, but I can only interpret them on the basis of my reality, on the basis of my knowledge, because that is all that I have. I cannot share your experience, but we can experience things at the same time and place. You can experience me and I can experience you. I can tell you about my experiences, but my telling you of my experiences does not allow you to experience them. You can only interpret my experiences on the basis of your own experiences. As both Hume and Russell have shown, knowledge is ultimately derived from individual human experience.

Knowledge is "truth." While we may only be sure of our own death, there are other things which we accept as true. We ignore the philosophical complexities, receive information from interactions with the environment, and place our faith in this information. Of course, we know things that are false from our point of view, but the knowing that they are false is for us a "truth." We may erroneously accept a falsehood as being true but, until we discover that it is false, it remains true for us. In this sense some philosophers claim there is no false information, there is just information.

Knowledge is an adaptive "tool" and is more highly developed by homo sapien sapiens than by any other species. It is used to guide behavior and to interpret the behavior of others. Our ways of knowing permit social intercourse and communication. We use information to focus our attention on some aspects of the environment while ignoring other aspects. We fear the unpredictable, we fear chaos, and we continually create new knowledge to interpret and assign meaning to the present and to anticipate the future (Garfinkle, Goodenough, Mehan and Wood). Novak in his discussion of knowledge as culture notes, "Experience rushes in upon us in such floods that we must break it down, select from it, abstract, shape and relate. . . . A culture is constituted by the meaning it imposes on human experience . . . even the most solid and powerful social institutions, though they may imprison us, impoverish us, or kill us, are fundamentally mythical structures designed to hold chaos and formlessness at bay . . . culture begins and ends in the void" (p. 23).

Knowledge is also adaptive in the sense that new knowledge is created in the attempt to solve problems. We apply our energies to problems and develop new ways of viewing certain aspects of the environment. As a result, increased specialization is possible. As Simpkins notes, there is an increase of information with the development of occupational specialization. In the past when farmers served as their own blacksmiths, veterinarians, bankers, etc., there was a limit to the amount of knowledge that could be developed and brought to bear on any single problem. As people left farming and specialized in these areas, new knowledge was created and important breakthroughs occurred. A part of the creation of new knowledge includes the development of ways in which to search for knowledge. Scientific methodology has been one result of the search for new information.

Knowledge tends to be created at a conservative rate. Wallace points out that two major problems must be solved by all people. We must replicate uniformity and organize di-

versity. We replicate uniformity in order to make our behavior intelligible to others and to interpret their behavior, to use the skills and knowledge that have proven successful in the past to meet the needs of the present, and to reduce the need to continually learn de novo from new experiences or, said another way, to reduce the high cost of new information. We organize diversity so that we can interpret new situations, know how to handle new conditions, and learn from mistakes. Consequently, we try to limit the rate of change in knowledge to a level that we can control. It is often to our advantage to maintain the status quo if we are in a satisfactory position. In some cases when we are not in a satisfactory position, we do not attempt to change because the circumstances in which we exist are at least predictable if not comfortable. We are often amazed in development programs when farmers refuse to adopt a new crop that we believe would be advantageous. If they have had no experience with the new crop and cannot anticipate their return, they may well reject the offer. The cost of the new information is too high in that they must risk their livelihood to determine the yield of the new alternative.

Knowledge systems tend to be conservative in another way. Levi-Strauss pointed out in his study of mythology that knowledge systems tend to be circular and closed. It is possible to start at any point in a set of myths that describe and explain some phenomena and eventually work back to the starting point. Any set of knowledge, including science or any discipline, can be viewed as a type of mythology in that it is a set of interrelated abstractions used to account for certain kinds of phenomena. Generally, each of us accepts our view of the world as adequate at the moment for describing and explaining our world. Those things that we cannot describe and explain are often labeled as unimportant and not worthy of the efforts required to learn about them. If circumstances were otherwise, we would make the effort. While it is true that we continually search for new information in attempts to solve problems and learn from experience and that there is always a degree of novelty in behavior, learning is always based upon knowledge previously accumulated. Furthermore, we often ignore information that cannot be related to what we presently know because we have not learned to identify it, and consequently it falls outside of our range of awareness. We do not break the circle of understanding but rather continually expand it maintaining the integrity of its boundaries. We are victims of our past and cannot disassociate ourselves from experience.

In science we close the circle by calling what we are unable to account for the unknown and control the mysteries of the universe in this manner. In a sense, the concept of the unknown is a category related to the environment even though it is a residual one. We often say that the purpose of science is to make the unknown known and take comfort in this view; however, the unknown we speak of is delimited by present knowledge and the realm of discourse selected. In statistics, the explanatory circle is closed by calling unexplained variance a measurement error, but it is difficult to explain why it is an error or how to correct such an error. As noted earlier, we seem to have a special abhorrence of mystery and the unknown; we do not like not to know and as a consequence are very inventive in our attempts to close our conceptual circles. By keeping these circles closed, however, we reject potentially useful information.

Knowledge and thereby reality and "truth" are human creations. Knowledge is derived from experience and is created as we attempt to solve problems. Even though we have learned concepts that were developed in the distant past, they are only meaningful when applied to the present in which they are learned and related to information gained from experience. Furthermore, as Wagner suggests, when existing categories are applied, things in the present are made equivalent to things in the past and consequently this act of categorization is creative. After all, we have never been in this present before nor will we return. When new categories are created to interpret the environment, things that have never existed are invented. When we conceive of things that have never existed and make them occur, we have created reality. In science, we create the reality we report upon. The reality we "discover" is in part determined by the conceptual approach selected and the operational definitions or measurement techniques created to represent theoretical concepts and in part by the phenomena selected for study. For example, in quantum physics it is possible to view light either as waves or as particles, depending upon the measurement technique used and the research question at hand. We create variability by placing discrete entities into a single category

and looking at two or more of them using one or more additional categories as variables.

We create reality each time we select among alternatives. Regrettably we have but one life to live in this plane of existence, and the present is the eternity in which we all must live. When we select one television program over another or over mowing the lawn, we have created our reality. Moreover, in the social sciences we create additional realities to "explain" the realities we select and create. Economic theory holds that we select among alternatives in a "rational" manner and that the things selected have more "value" than the things not selected. We assume a value can be placed on the alternative selected and imply that a lower value is placed on alternatives not selected. The concept of opportunity cost was created to "explain" the selective creation of reality. Furthermore, the concept closes a rather obvious conceptual circle.

Part of our reality is created privately, and we do not attempt to share it with others. Other aspects of reality are negotiated with others and determined through consensus or at least an agreement not to disagree anymore. We will never know the perceptions and conceptions of another person. If I could see through your eyes, what I normally see as white might appear to be green. If you could see through my eyes, what you might see as white might appear to be purple. Nonetheless, we have both agreed to call the green and the purple white so we will concur that your shirt is white. Such consensus is usually referred to as intersubjective agreement. What we call the "objective" approach in science is based upon a number of negotiations that have transpired over the years in conversations, journals, and books. We have accepted certain standards for scientific endeavors or have agreed that further discussion is not productive. "Objectivity" is just another set of intersubjective agreements.

Some people have greater skill in negotiating reality and "truth," they may have greater power, or they may have considerable influence and consequently have a strong hand in the determination of reality based upon intersubjective agreement. Nietzsche once wrote, "*the real philosophers are commanders and legislators.* They say, 'It *shall* be thus!' They determine the 'whither' and the 'to what end' of mankind—having the preliminary work of all the workers in philosophy, the overpower of the past, at their disposal. But they grope with creative hands toward the future—everything that is and was becomes their means, their instrument, their hammer. Their 'knowing' is *creating*" (p. 135). I would add that many others play similar roles including businessmen, scientists, teachers, governmental administrators, etc.

We are often unaware of our creation and negotiation of "truth" and reality. We accept what we have learned and use it creatively without question. We accept social order including interpersonal interaction and economic transaction as "natural." Yet as Berger and Luckmann point out, "Social order is not part of the 'nature of things,' and it cannot be derived from the 'laws of nature.' Social order exists *only* as a product of human activity. . . . Both in its genesis . . . and its existence in any instant of time (social order exists only insofar as human activity continues to produce it) it is a human product" (p. 52).

We now return to an issue raised earlier, the limitations of science in the study of human behavior and in communicating research results with other people. I first focus attention upon the scientific study of behavior. Any social science approach is used like all other knowledge systems to reduce the complexity of the environment. Human behavior is a continuous stream that occurs day after day, and we cannot hope to deal with all of its variety and richness. As a result, we only deal with limited aspects of human activity. When specific areas of inquiry are selected, it becomes obvious that an increased number of categories are required to account for the variability encountered. After all, science advances with increased specification. As specification increases, it becomes more difficult for any researcher to remain aware of much of the behavior of the people under study. Consequently, any research report that meets contemporary scientific standards usually tells very little about a wide range of activities that may influence the specific behavior under investigation. For example, Schultz notes that some growth models in economics have treated institutions as givens or as a part of the "state of nature," while others have treated institutions as independent of economic change.

Economists have studied the management of capital, labor, and technology on farms while ignoring the social structure that supports agriculture. Anthropologists have studied the social structure of rural communities while

ignoring the economic aspects. It is clear, however, that we cannot account for economic behavior by the study of economics alone and we cannot account for social structure by the study of social structure alone. Even if economists, anthropologists, sociologists, etc., worked together, we would never be able to adequately describe and explain the behavior of farmers or anyone else. We view brief instances of their lives, but they live their lives on a full-time basis. While one objective of science is to generalize, increased specification reduces the ability to do so because of our limited capacity to control information. Also, the number of specifications are limitless; they are created by scientists and are limited only by the creativity of their minds. We are caught in a double bind. To have confidence in our results we must increase specifications, but in the process we lose sight of the subject of inquiry, people living in a particular time and place.

Social scientists have tended to follow the scientific paradigms created by the physical scientists. Becker notes that this narrow positivist approach that seeks to analyze separate and distinct aspects of behavior was bound to fail. Because of the limited realm of inquiry in physics and the degree of control a physicist can exert over the phenomena, the positivistic approach is plausible; however, as Ritchie notes, the approach has encountered serious difficulties in biology. Given the complexity in human behavior, these difficulties are compounded in social inquiry. Boulding comments that at the level of understanding human behavior "it may be doubted whether we have as yet even the rudiments of theoretical systems" (1968, p. 9). Wittgenstein may have been correct at least for the foreseeable future when he suggested "that even after all possible scientific questions have been answered, our problems of existence have not even been touched upon" (p. 6.52).

Despite the limitations in science, we remain in the business of the creation of social "fact." It can be argued that social science works and I agree. We create "truths" in which we can have a degree of faith. Social science works best, however, when the "truths" discovered are passed to nonscientists who have the power to construct social realities. Let me explain. We create approaches based upon theory, method, and the phenomena studied. As would be expected, a close congruency is created between disciplines and the environment. In recent history as the practitioners of the disciplines, especially the economists, became more proficient, the information created was used in government and business. What began as academic discourse became a working culture used to guide decisions in important sectors of society, thereby increasing the congruency between scientific approaches and the social and economic environment. Consequently, the descriptive and explanatory powers of social science increased. The view that science works best when the categories created become part of the knowledge used by persons in positions of power is supported by experiences in developing nations. Our descriptive and explanatory growth models work much less well in the third world.

I now turn attention to some of the limitations present in communicating results with policy makers, planners, etc. All social scientists specialize in one narrow aspect of behavior, and the advice we give is based upon a rather narrow range of data. Policy makers and decision makers, however, demand generalizations; they want to create programs for all farmers, all workers, etc., and expect social scientists to provide valid information concerning a broad population. These decision makers may have had very different experiences than have scientists, may have created different realities, and may be unaware of the fragile base of social science. Furthermore, they want information immediately so they can get on with the job. Consequently, we have little time to negotiate a reality concerning the limitations of what we know and its relationship to the program envisioned. There is a jump in levels of abstraction from the specific data developed by scientists to the generalities used by planners, and the relationship between the specific and the general is often tenuous. Nonetheless, the "truth" we create is used and reinterpreted many times. Policy makers pass the information on to program administrators who, in turn, pass it along to the population for whom the program was developed. What started as specific information based upon scientific inquiry becomes a social reality and, in some cases, it is difficult for the scientist who created the information to recognize the results of his handicraft.

Scientists are often unaware of their blind spots when they do give advice to policy makers. As Barkley notes, "Too often, the economist has been asked a quick and pragmat-

ic question and has responded with a quick and pragmatic answer. How do you eliminate poverty? By giving people more money. . . . How do you improve incomes in agriculture? By supporting the price of grains. These questions have been given quick and explicit answers but those providing answers have not taken time to learn of possible side effects the answers might bring" (p. 15). The same is true in other disciplines. Frequently, scientists are not aware or ignore the limits to their knowledge. As noted earlier, all knowledge systems tend to be circular and closed and we tend to ignore other viewpoints. While space limitations prevent a discussion of the topic, it should be mentioned that the information we create may be more useful to one group than to another and can possibly give advantages to some at the expense of others. When we assume that knowledge is adaptive, we should always consider to whom it is adaptive.

Knowledge produced through scientific inquiry has another limitation when used in program development. Our descriptions and explanations are based upon a narrow range of information, and in generalizing to other circumstances, we should always mention that our statements hold *ceteris paribus*. When we deal with responses to known phenomena or similar conditions, we have some idea of the unknown variables implicit in *ceteris paribus*. On the other hand, when we are asked what the impact of some program will be that has never been tried, we have little information on which to base a prediction. Science deserts us at this point as does every other knowledge system. Most of us have not been trained as program planners; rather we were trained as scientists, and our knowledge of the operations of programs may be limited. It is wise at times to say that we do not know.

Where does all of this leave us? We must accept the limitations of the scientific approach to the study of human behavior and attempt to make policy makers, planners, etc., aware of these limitations. We should remain mindful of the role we have had in the past in the creation of social reality and in this light accept the responsibility for the consequences of our statements. Given the limitations of science, I support less centralized planning and permit local people to keep their resources at home, set their own priorities, and assume responsibility for their lives in as far as possible. Schumacher notes that the administrators in any large organization are in a difficult position. They carry the responsibility for everything that happens without having the information nor the time available to make adequate decisions. On the other hand, we live in a complex and interrelated world, and some central planning is necessary. An important task for the future is to determine the levels at which programs can be most effectively carried out and the information that will be required to assist in the process.

Despite the limitations inherent in the use of scientific methods in social inquiry, I believe that it remains the single best way to find out what is going on in the world. We must be very careful to determine what kinds of questions can be answered and what kinds cannot be answered through the use of scientific procedures. There are areas in which we can work with some effectiveness. First, we can evaluate programs and study the creation of social reality by policy makers, planners, etc. Do programs really produce the consequences they were intended to produce? What are the unintended side effects of programs? Who benefits and who is disadvantaged by policy decisions? We have skills that can be put to use in answering these and similar questions at local, regional, and national levels. We may never be able to answer the question of what will work, but we can determine if things are not working as intended. Second, social scientists can monitor other social processes that may not be directly related to policy decisions but that may pose a threat to one or more segments of the society. Environmental degradation, social costs of technology, inequality of opportunity, health care, etc.—the list is endless and these things require constant scrutiny. John W. Bennett once suggested to me that the social sciences would be well served if more of us behaved as investigative reporters. The monitoring process I have suggested is related to such an investigative task.

In order to evaluate programs and monitor social processes, we must work toward more inclusive paradigms or approaches such as the one proposed by Simpkins based on the concept of scale. A great deal of effort needs to be directed toward the development of a more unified theory of human behavior in which the diverse aspects of behavior studied by the various disciplines can be organized in a way that can be related to specific populations. It may be that such a unified approach is impossible. Certainly we are never going to be able to deal with human creativity and the diversity of be-

havior that it produces. Nonetheless, such a search will be useful if it only reminds us of our limitations from time to time. Such reminders are needed because, as noted earlier, all systems of knowledge tend toward circularity and closure.

Finally, even if we only evaluate programs and monitor social processes, we will continue to create social "facts" and be involved in the construction of social reality. When we embark upon any research endeavor, we must remain aware of the possible consequence of our actions. We make difficult decisions and there are no clear guidelines to follow. Becker suggests that we give some thought to the ethical and moral issues involved in social inquiry. We claim that we are not biased but, on closer inspection, the claim that there is an absence of bias is in fact a bias. I believe such a claim is an attempt to avoid the responsibility for our findings and statements. There are no value free or neutral paradigms. Furthermore, we cannot cling to our present approaches by simply claiming that they constitute the best viewpoint currently available. While they may offer us some security and provide a consistent framework for exploring the world, they are used at some cost to ourselves and to the people whose lives are changed because of the realities we have helped create. We must become involved in determining the costs of our descriptions and explanations. As we become more aware of our limitations and our role in the creation of social reality, I believe that moral and ethical questions will weigh more heavily upon us.

I have one last thought to share. Scientific disciplines are limited because they are systems of human knowledge. On the other hand, since we create them, scientific disciplines are unlimited; they can be so much more than what they are.

Economics as Science and as Culture

L. M. Hartman

> Our meddling intellect misshapes the beauteous forms of things: We murder to dissect (Wordsworth, p. 57).

Two aspects of contemporary society motivate this paper. First, is the recognition of a growing awareness that our society is in a period of major social-cultural change, and second is the recognition of science as the major institutionalized and organized basis of knowledge within society (Bell). The implication is that science can either impede or facilitate the change. The proposition that economics is both science and culture recognizes that economics as a discipline embodies society's traditional sense of historical purpose and values but that it does so in the name of science. Culture is used conceptually to designate society's common sense of purpose and meaning (Bell). We conceive of a cultural tradition as the embodiment of society's historical, experiential knowledge (Cassirer). The paper develops around the proposition that experiential knowledge is the basis of human meaning and purpose and is prior to, and takes precedence over, scientific knowledge as a ground for action and choice (Cassirer).

The thrust of the paper is to clarify the distinction between cultural and scientific knowledge and, thus, the role of science, to give some historical background on how economics developed as both, and to develop some implications from this analysis regarding the future. This discussion necessitates considering science and the social sciences generally. Agricultural economics is an applied social science, and the implications will be expressed in terms of that discipline. One conclusion is that agricultural economics as now practiced is both bad science and uninformed culture.

L. M. Hartman is a professor of economics, Colorado State University.

Culture, Science and History

The basic proposition regarding the priority of experiential knowledge is derived from an understanding of human beings open to meaning and purpose and who act in accordance with the meanings and purposes they embrace. Culture develops, or is created, out of the historical experience of a society and, thus, it is appropriate to speak of a cultural tradition. Modern society was formed by several traditions extending to the beginning of historical time. The Greek and the Judeo-Christian traditions were integral to the formative process.

The proposition that knowledge growing out of experience takes precedence over scientific knowledge for action-choice situations requires elaboration on several points. The most crucial to the argument of the paper is the explicit recognition that the process of learning through experience results in knowledge and that this type of knowledge can be communicated and shared, i.e., can become public (Cassirer). This publicness is the basis of cultural tradition. The triumph of science has created the illusion that scientific knowledge is the only valid type of knowledge. Also, there is the recognition that action-choice situations are by their nature evaluative, involving qualitative aspects of different alternatives. Science by its distinctive form of knowledge precludes any decisive understanding of the quality dimension. Economic analysis of the choice process assumes the ends as given or assumes value priorities that originally came out of a community of shared values. Most importantly for the individual, knowledge developed through experience is decisive as formative of the consciousness and is developed only when responsibility is taken for the evaluative basis of choices. This understanding is implicit in our own western cultural tradition emphasizing freedom and autonomy.

To conceive of culture as knowledge is to view it as evolving and developing through

time, i.e., there is progressive movement towards greater understanding. Historical experience is the basis for exploring, formulating, and testing aspects of human potential. A tradition represents its cultural forms in terms of language, religion, art, literature, science, and technology as different aspects of experience and potential for creative expression (Cassirer). Prior to the modern period, a religious tradition dominated western society. The modern period has been one of transition from religion to science as a world view dominating the central institutional system. The disjunction occurring on the contemporary scene, in what some authors call the postmodern period, is the recognition by a significant minority that society has lost some qualitative dimensions to experience. The scientific community has failed to respond to the cultural conflict that has been generated. This failure to respond stems in large part, in terms of the charge of this paper, from the inadequacies of the world view of science. This world view permeates the approach to economics.

Science as a tradition is embedded in the scientific community. That community is the "carrier" of the tradition. It is institutionalized primarily within the university system with process for admittance into the community, viz., evidenced mastery of theory and methodology within the disciplines of the tradition. Transformation of that tradition must, therefore, evolve from that community in accord with common meanings associated with it.

We may pose the question—why is science crucial to the process of change and historical development? The answer—because embedded in the tradition of science are prescriptions concerning legitimate methodologies for growth of knowledge and selection of legitimate problems. The historical faith of science is in the ultimacy of a certain kind of natural order and the effectiveness of the scientific method to discover that order. Human progress is conceived in terms of the growth of knowledge and the power of that knowledge in the realization of human purpose. The original intent of science is to delve beyond appearances to the objective facts, to arrive at a new classification of phenomena, from that of common sense, where order would be discovered in consciously established relationships. As Hayek summarized, "the history of science is a progressive emancipation from our innate classification of external stimuli" (p. 20). The polar classification of perceptual understanding into the categories of subjective and objective that evolved out of that aim left the individual in a private world of his own. All qualitative dimensions of human experience were precluded from scientific understanding; thus, values and human purpose were left to the private world of the individual. Therein lies the problems of science as an inadequate cultural tradition. Experience within science has achieved a state of maturity to reassess its traditional grounds.

Economics as a Historical Discipline

According to Weber (1958, 1947), Tawney, and others, leadership in the establishment of early modern values, social purpose, and the institutional system emerged from Protestant Christianity, the dominant cultural tradition of the early modern period. The values of individualism, freedom and democracy, the pursuit of material goods as a religious calling, and the calling as the individual's place in society to contribute to overall good were a part of the tradition of the Protestant Christian community. The process of transformation taking place in the modern period was a process of secularizing that tradition, i.e., a transvaluation into the terminology and world view of philosophy and science.

Economics was originally conceived as a branch of moral philosophy. As such, the concepts of economic freedom, self-interest, utilitarianism, and the rationality of achieving economic ends were stated as a position primarily explicated in terms of the social good. As a position, that formulation was merely one view among others. It was consistent with the action orientation of the emerging middle class. Thus, economics was concerned with the establishment of the conceptual basis of a moral order in accord with the world view of science and with the emerging social purpose of the entrepreneurial class. Within the view of the historical process being considered in this paper, the openness to meaning and purpose became progressively shaped around the economic goal and the world view of science. The moral problem, as a problem of choice among possibilities and potentials, became a scientific one regarding the nature of man. Ethical options became scientific postulates. One end among other ends

became the end, and science as expressed in economics became a dogmatic formulation of the values and purposes of the established system. In terms of culture, the economic end and the rationality associated with that end became the dominating sense of meaning. In Polanyi's terminology, the activity of providing for material well-being became disembedded or separated off as a distinct sphere of activity. Economists presume too much if they think they shaped that world; they presume too little if they take no responsibility for the future.

Economics as Science and as Culture

As suggested above, science is the dominant orienting perspective in the western cultural tradition. Economics is the major discipline within science that formulated society's action rationality. In other terminology economics is an action paradigm or cultural paradigm, a conceptual model for problem and policy formation. In the concrete action setting of institutions and of interacting individuals, rationality or consciousness is shaped by self-interest and utilitarian ends as embodied within the system. The family and educational and religious institutions have become integrated into that social sense of purpose and meaning and have largely lost their own autonomy. The discipline of economics has incorporated this sense of meaning into the assumptions of its theory. The theory explains how self-interest oriented towards economic ends operates within the varied institutional settings of our society. The assumptions represent a moral order legitimized by the society within the constraints of a vestigial Christian morality. Up until the present, the economist would have done his job well if through his theoretical analysis he showed better ways to achieve utilitarian ends. However, when the economist asserts his assumptions as scientific postulates, he is saying, with all the authority of science, "these are the ends you should be pursuing, and this is the sense of rationality that you have, whether you know it or not." In that sense economics is bad science, and science is bad culture.

The problem with economics as a science is that it is impossible to test its assumptions within the system. Historical experience created the cultural-institutional system from which the economist abstracted his assumptions; therefore, testing back involves an incorrect circularity. Development economists have the opportunity to test these assumptions within the context of other cultures. An evident shift in the development literature recognizes the cultural differences but presumes that western society is still the ultimate model. No concerted effort reexamines the theory and its implication for our own society with the serious intent of questioning our own cultural integrity. The key cultural-institutional differences result from the fact that in nonwestern societies economic activity is not differentiated from other activities. They are integrated within family, community, and religious meanings so that there is no activity that is economic as such. The development economist has seen this as something to be overcome. The economist attempts to integrate family, community, and religious activities into economic rationality, presuming that self-interest, utilitarian rationality is the truth concerning man's nature.

As a cultural tradition science and economics are centered in the university, which educates, or rather trains, a major segment of society who become leaders in business and government. The university faculties are associated with business and government through research contracts and as consultants and policy advisors. With the loss of geographic community and diminishing influence of the Christian community as an effective moral force, government becomes the major moral force supported by the scientific community as interpreters and legitimizers. The upshot of this combination is the extension of government and centralized organizations into all spheres of national life, and all of this being facilitated by university scientists (Sorensen and Hartman). The agricultural economist, for example, promotes through his research and policy recommendations the extension of this "good" life into the last bastions of individualism in this country, the rural communities. The effects of this centralization of traditional functional prerogatives are alienation and loss of individual responsibility.

An Alternative Conception of Science and Economics

As pointed out above, one of the crucial aspects of the scientific world view was to dichotomize perceptual understanding into the

categories of subjectivity and objectivity. Subjectivity was relegated to the private world of the individual, whereas objectivity connoted reality. That conception has pervaded all of the social sciences and particularly economics. The economist takes values and preferences as given. The utilitarian view, as a part of the natural man conception of science, is based on the idea that man's sense of purpose is to achieve a subjective emotional system state where all desires have been satisfied. In that perspective the subjective is desire governed by the rational mind. Values in this view are values attached to aesthetic goods, not values in the traditional sense associated with moral responsibility and freedom. The view to be developed here is a radical departure from the dichotomy and polarity of subjective-objective classifications.

The scientist-economist is like a man in an illustration used by Kierkegaard, from which I will quote:

> The objective truth as such is by no means adequate to determine that whoever utters it is sane; on the contrary, it may even betray the fact that he is mad, although what he says may be entirely true, and especially objectively true. I shall here permit myself to tell a story, which without any sort of adaptation on my part comes directly from an asylum. A patient in such an institution seeks to escape, and actually succeeds in effecting his purpose by leaping out of a window, and prepares to start on the road to freedom, when the thought strikes him. . . . When you come to town you will be recognized, and you will at once be brought back here again; hence you need to prepare yourself fully to convince everyone by the objective truth of what you say, that all is in order as far as your sanity is concerned. As he walks along and thinks about this, he sees a ball lying on the ground, picks it up, and puts it in the tail pocket of his coat. Every step he takes the ball strikes him, politely speaking, on his hinder parts, and everytime it strikes him he says:"Bang, the earth is round." He comes to the city, and at once called on one of this friends; he wants to convince him that he is not crazy, and therefore walked back and forth, saying continually: "Bang, the earth is round!" (p. 174).

The proposition that experiential knowledge is central to human meaning and purpose is contrary to the notion that truth is only contained within the objectivity of western science. The plain fact of the matter is that objectivity is defined by a subjectively developed sense of meaning and that we become entrapped by our own creation. Science is a method for discovering order by a process of abstraction and theorizing. Theory is a created conceptual ordering of the phenomena in such a way that the theory can be tested back against the phenomena from which it was abstracted. Objectivity is the congruence of the theory with only certain aspects of the phenomena. With respect to the human sciences, the abstractive process reduces human beings to only selected aspects of total humanness. Each discipline is developed on the basis of some selected aspect, some partial view. It is only in action and experience that the total man is involved, and if we suppose that consciousness can become aware of itself, i.e., one can be self-conscious, then consciousness is the phenomenon of whole man. But a science of consciousness is contradictory because science is by its methodology reductive, and to reduce consciousness is to lose the integrating wholeness. The conclusion to be drawn is that scientific theories provide only partial knowledge that can be integrated only within experience.

It follows that the view of science as a source of knowledge for human meaning or consciousness is illusionary. Does that mean man is left only with the black box of an isolated subjective? I think not. The concept of experiential knowledge implies understanding and order and the possibility of testing value rationality in experience. Likewise, the conception of a social order based on freedom and democratic process, as a part of our own western tradition, implies a mutual agreement through communication and, also, the possibility of universal values that become known and understood through common experience.

The world view of science that propagates the notion that the only way to know is to know objectively through reductive theory, observation, and quantification is merely misleading under casual circumstances. That view is vicious when it is institutionalized within the cultural center of the establishment and, thus, controls action possibilities. It has the power to control through manipulation and to discourage the open communication processes that are essential for establishing a qualitative dimension to the social order. In other words, scientific objectivity leaves out value considerations. Values are only experienced as a part of the life process. "Yes," the economist replies, "we know that because it is part of our utilitarian conception of man." But the values we are talking about are not values associated with aesthetic goods, more correctly known as preferences, but values associated with the

creativity, freedom, and responsibility of the individual. The development of this sense of consciousness or rationality comes from the individual affirming himself as an individual with the capacity to make moral choices. Experience verifies that the responding (responsible) individual is also capable of affirming a caring relationship with others (Fromm).

No doubt most people, through their own experience, experience themselves as being utilitarian, rational, self-interested individuals. This brings me to the crux of the argument: experience is an interpretation, from a frame of reference, of feelings that develop out of an action situation. If the formative experience for the individual grows out of an action situation structured by rules and a cultural sense of meaning that affirm self-interest, utilitarian values, the individual will interpret his own feelings on that basis and that sense of meaning will become his sense of self-consciousness. This is the side of economics as culture; it assumes what is culturally and institutionally defined at the action level. Contemporary society has reached this impasse. Structurally we have lost the experiential setting of community where the values of caring might be experienced and affirmed spontaneously, and culturally society is dominated by a scientific, objective sense of meaning that can affirm only self-interest, utilitarian values. Cultural diversity allows those on the periphery of the mainstream to experience the potential within themselves to determine their own sense of meaning, i.e., to experience the potentials of positive freedom.

Our experience in community development work, within our own community of family and friends and in communication with others, provides empirical, qualitative data substantiating the view that human beings have the potential for developing a sense of moral responsibility in caring, trusting interactive relationships under appropriate conditions. This is the decisive test that utilitarian, self-interest rationality is not an innate sense of consciousness. That experience indicates a different kind of social order emerging than that of competitive self-interest regulated by a legal order, which economics and public choice theory formulate. I see the need for the integration of both types of order. An illustration from a student paper may suggest some aspects of that integration. The student had worked in a local restaurant and had developed a friendship with the owner-manager, who shared with the student his sense of intentionality in terms of managing his business. His intentionality was based on a genuine caring concern for others. He saw serving food in an appropriate atmosphere to be an opportunity to express his own sense of value. His help were hired on the basis of their sharing those values and, according to the student's account, this man ran a flourishing business. The student recounted in his paper his own sense of experience, e.g., work was no burden, tips were generous, etc., when he was feeling a genuine sense of responding to the patrons. The example may seem trivial. It is not meant to be. It is presented with all the seriousness of the position being developed.

One straightforward conclusion emerges from both the experience with community development work and from the theory, and it is that change only occurs sporadically, as in the above example, unless facilitated by informed and self-conscious leadership. The university community lives in a world of ideas and action oriented towards teaching, researching, and extending based on those ideas. My conclusion is that such activity is misdirected because of the nature of those ideas. The university must break out of its historically established world of ideas. Society generally is involved in activities directed by the institutions and traditions of the past. The consolidation of the university world in a more intimately empirical way with outside communities in a mutual search for a new sense of meaning is the dynamic we are proposing. For the agricultural economists, this means a different sense of problem formulation.

Implication for Agricultural Economics Research

What is discussed in this paper is not simply as a basis for a research program. It is not intended for that purpose. Its main purpose is to open a dialogue. The paper develops an argument for a value position from propositions that formulate a social theoretical framework that is defensible and testable. The thrust of the theoretical proposition challenges the basic assumption of economic theory. Within the conception of economics as culture, the assumptions are identified as evolving out of a historical consciousness shaped by a specific type of scientific world view and a socially determined goal of economic development,

more generally understood as a goal of mastery over nature. The contemporary sociocultural change is in the direction of other aspects of human potential for creative expressions. The implication for agricultural economics research is to develop the capacity to respond to that change process.

The change process has many facets. Within agriculture it may arise as a yearning for farming as a way of life, rather than just as a business and a part of the system. Within geographic communities, a reaction to the forces of outside control is developing. This reaction is in the form of a movement towards local control and more self-sufficiency. In the city and among the young we can observe a movement back to nature and natural processes, making technology a servant rather than a master. All of these facets have a common value, a search for a way of life by the individual that integrates economic activity as a creative part of a total life situation and allows more control and more opportunities for creative expression.

One paramount process in the search for new meaning and for the development of individual potential is the interactive communication process of sharing feelings and experience. Out of this process evolves a new sense of social order called community, as opposed to the order of an institutional system. This sense of community can exist among friends, within a family, within a university department, and within a geographic area. It can be dynamic and open and facilitative of individual freedom. The phenomenon of community may be understood as a form of creative expression, and creative expression may be understood as the process by which the individual achieves self-identity and develops an integrated self-consciousness. These statements about community can only be asserted; their meaning and truth can be experienced only by involvement and response. Agricultural economists could become involved and respond to that process, both within the university setting and in the setting of rural people. Out of that involvement would come a new sense of responsibility.

As long as the agricultural economist sees his purpose within the context of the scientific, technoeconomic cultural and institutional system, there is only one way to go, and that is to extend that system of meaning and purpose into all aspects of life. Current attempts to expand the economic theory rationale to public and family decision processes are an example. As a value orientation, that approach affirms the system as more important than the individual. Serving people is a different purpose than serving the system. To think that human beings can only act on the basis of self-interest and utilitarian ends is bad science. To think that that tradition is somehow sacred is to be uninformed.

A "Scale" Approach to Community Development

O. Norman Simpkins

The literature on community development contains a plethora of definitions. For example, Biddle and Biddle list seventeen different definitions, some of which seem to contradict others. Community development is also frequently treated as virtually synonymous with such terms as modernization, urbanization, industrialization, etc. As to theories of development, each social science discipline has tended to go its own way with the result that there is no overall theory, only partial theories. Anthropologists tend to stress anthropological variables (Goodenough); economists stress economic variables (Rostow); political scientists, political variables (Apter); sociologists, sociological variables (Loomis); and psychologists focus on psychological variables (McClelland).

With all this variety, there does seem to be a common theme running through most of the current definitions of community development even though expressed in differing terminologies. This theme is that development implies a change in the community, region, or society toward betterment of the lives of the inhabitants of the community, region, or society. This change for the better is sometimes seen as a process and sometimes as a goal or end achievement. Also, the contexts in which most definitions are used focus on planned development or change, though they do not deny the possibility of unplanned development. What is needed is a definition of development that avoids as many of these limitations as possible. The following definition, I suggest, does this: community development is that process whereby a community, region, or society increases its scale.

Definition of Scale

The concept of scale has been in economics from the very beginning of its emergence as a scientific discipline. Economists usually limit its use to single organizations when they refer to economies and diseconomies of scale. The concept of scale used here follows the usage of two South African anthropologists, Wilson and Wilson. In studying the changes occurring in the tribal societies of Central Africa as a result of the impact of western civilization, the Wilsons developed an operational theory of social change utilizing the concept of scale which they define as follows: "By the scale of a society we mean the number of people in relation and the intensity of those relations. . . . In comparing the scale of societies therefore, we compare the relative size of groups with relations of similar intensity" (p. 25). This is a refinement of the concept of scale used by Hobhouse under whom both the Wilsons studied. Hobhouse, in turn, apparently based his usage of scale on the economic concept. Sorokin also developed similar views but did not use the term scale.

As the number of people in a community or society increases and the intensity of interactions with each other increases, their scale increases. As scale increases the rate of change or development increases. In other words, two communities having the same population size are equal in scale. However, if the intensity of interaction in one community is greater than the intensity in the other community, the community having the greater intensity of interaction is the larger in scale. The Wilsons assume that the intensity of relations, i.e., the total degree of dependence, is the same in all societies but that it may be more or less spread out.

The difficulty with the above conception is that the term intensity is extremely difficult to define and measure satisfactorily. The Wilsons get around this problem by developing and utilizing a number of behavioral indices for measuring intensity. These are (*a*) economic cooperation both within and without the group; (*b*) communication of fact in speech and writing both within and without the group;

O. Norman Simpkins is the chairman of the department of anthropology and sociology, Marshall University.

(*c*) emotional (i.e., artistic) expression communicated within and without the group; (*d*) the value set on contemporary cooperation and continuity within and without the group; (*e*) the relative degree of unity and continuity asserted within and without the group; (*f*) the degree in which a sense of unity and continuity is expressed within the group; and (*g*) the degree of social pressure exerted on and by outsiders.

From these seven behavioral indices the Wilsons go on to develop eight correlates of scale by which increases and decreases in scale can be measured empirically. From analysis of their discussion of the social changes occurring in Central Africa and from conversations with Monica Wilson, I have identified eight more. These sixteen correlates fall into four broad categories of human behavior as follows: those relating to the ecological level or to control over the material environment; those relating to the sociological level or to autonomy among people; those relating to the cultural level or to variety of ideas, symbols, values, etc.; and those relating to the psychological level or to autonomy of self (see table 1).

Correlates of Scale

The four sectors or levels of table 1 are arranged so that the more concrete correlates are at the bottom of the diagram, the more abstract ones are at the top, the ones pertaining to the individual are on the left, and the ones pertaining to groups are on the right of the diagram. The Roman numeral identifying each sector is in the order of increasing difficulty of measurement. Those correlates designated by the same capital letter relate to the sector in which they are placed as well as to the other sectors as follows: A's relate to sector I, B's relate to sector II, C's relate to sector III, and D's relate to sector IV.

Explanation of each of the sectors and correlates follows. Ecological level (control over the material environment), level I: As communities or societies increase in scale, they increase their control over the material environment and vice versa. Measures of this control are (A) energy development: Throughout history as communities have discovered or developed new forms of energy, they have been able to improve their level of living whether it has been the domestication of large animals, discovery of wind power, steam power, electricity, or nuclear energy. Thus, they are able to do more with less human energy and also increase their probabilities of survival and growth. One of the first applications of new forms of energy is usually toward the transportation system that is partially effective in increasing scale. (B) Occupational specialization: The larger the number of occupational specializations in a community or available to it, the greater are the chances that problems encountered will be solved, thus enhancing the probability of increase in scale and of survival. (C) Technological development: The development or discovery of new techniques enables a community or society to in-

Table 1. Expanded Correlates of Scale

III. Cultural Level (Variety of Ideas, Symbols, Values, Etc.)
- A. Communication of facts
- B. Identification with others, both past, present, and future
- C. Intellectual variety
- D. Artistic variety

IV. Psychological Level (Autonomy of Self)
- A. Technical skills
- B. Interpersonal competence (empathy)
- C. Symbolizing ability (intelligence)
- D. Self-awareness (self-concept, self-identity)

II. Sociological Level (Autonomy Among People)
- A. Economic cooperation (trade)
- B. Social mobility
- C. Impersonality
- D. Social pressure (influence)

I. Ecological Level (Control Over the Material Environment)
- A. Energy development
- B. Occupational specialization
- C. Technological development
- D. Scientific methodology (nonmagicality)

crease its scale and thus increase its survival probabilities. (D) Scientific methodology (nonmagicality): As a community or society utilizes scientific methodology rather than magical techniques, its control over its material environment increases and the use of magic tends to decline.

Sociological level (autonomy among people), level II: The correlates relating to this sector have to do with interpersonal interactions of the population of a community or society. As the following correlates increase, individuals and groups have more choices available, thus autonomy and scale increase. (A) Economic cooperation (trade): Economic cooperation enables a community or society to utilize resources not available locally, thus increasing scale. Along with trade goes communication of ideas, values, etc. (B) Social mobility: Increase in social mobility increases scale and increases freedom of choice. A community or society that limits mobility of its members limits its scale since the talents of those so limited are less available to the entire society. (C) Impersonality: As the ability of the members of a society to operate in impersonal situations, i.e., in terms of roles, increases, the scale of the society increases, thus increasing autonomy of individuals. Individuals able to operate only in personal situations are limited in scale, and this in turn limits the scale of the community or society. (D) Social pressure (influence): As the extent of social pressure or influence people exert on each other increases, the scale of the community or society increases. Social pressure makes organizations possible for otherwise concerted action would not exist.

Cultural level (variety of ideas, symbols, values, concepts, etc.), level III: The key to the correlates of this sector is variety. The greater the variety available in a community or society, the greater the possibility that use will be made of them and hence the greater the scale. (A) Communication of facts: The greater the communication of facts, i.e., reliable information, the larger the scale of the community, since more people have available more information on which to base decisions and acts. (B) Identification with others, both past, present, and future: The wider the range of identification with others as being essentially like oneself in one or more essential characteristics, the more communication and interaction is facilitated and hence the larger the scale of the society or community. (C) Intellectual variety: The greater the number of different views, frame of reference, *weltanschauungs,* etc., in existence in a community or society, the greater the choice in the development of a relevant world view and hence the larger the scale. (D) Artistic variety: The greater the variety of artistic expression in a society, the wider the range of choices in the outward expression of inward emotions and feelings and the larger the scale.

Psychological level (autonomy of self), level IV: The correlates in this sector refer to those areas of individual behavior and understanding that lead to increase in scale as they increase. (A) Technical skills: The more technical skills individuals possess, the larger their scale and the more resources the community has available. (B) Interpersonal competence (empathy): The key characteristic of interpersonal competence or empathy is the ability to see and understand situations from the other person's point of view. (C) Symbolizing ability (intelligence): This correlates refers to the ability to create symbolic abstractions as well as use them. (D) Self-awareness (self-concept, self-identity): Awareness of one's self as to who one is and what one's relation to others are is the key to the development of a self-actualizing or autonomous personality. The same applies to a group or community.

The set of sixteen correlates of scale briefly described above constitute an integrated system of concepts relating to all areas of human behavior. (Because of space limitations, illustrative examples of each correlate have been omitted.) Each correlate is so defined as to be positively correlated with each other and with the scale of the individual, community, or society. As the value of one correlate increases or decreases, the values of the other correlates tend to vary accordingly, not in a mechanical fashion but in an interdependent one.

In any real life community or society the values of the correlates will not be even at any one time. Some elements of the community or society will be larger in scale than others. This condition of unevenness of scale results in disequilibrium, opposition, strain, and conflict (Wilson and Wilson). Differences of scale will exist among different communities. Discrepancies of scale may also occur in which one might find a large-scale individual in a small-scale community or vice versa.

Within a given society the increase in scale of one community may cause a decrease in scale of other communities as a result of

changes in terminology, economic conditions, decisions of authorities, or other events. In the same way increases in scale of the larger society as a consequence of changes in one or more of the correlates of scale may result in a decrease in scale or even elimination of one or more local communities. For example, the dieselization of the railroads after World War II, which increased the scale of the United States, resulted in the decrease in scale of some railroad towns (Cottrell).

Use of the Correlates in Guiding Community Development

The concept of scale presented here does not provide a how-to-do-it manual for the community developer or change agent. It does not provide a community with information about what to do in any direct sense. It does provide a kind of paradigm for evaluating the probable consequences, many of which are latent rather than manifest, of whatever may be proposed whether the proposal be made by the developer, authorities, or the citizens themselves. Most current attempts at development tend to focus on the introduction of some new technology on the assumption that other desirable changes will in time ensue. The concept of scale enables developers to know more about where to look for those consequences and whether the results are likely to be positive or negative as far as development is concerned.

It opens the way for other than technological changes to be considered in a more balanced fashion. Use of this paradigm will help to prevent social or cultural blindspots from handicapping planned projects. It also makes it possible to have a more adequate basis for making decisions about trade-offs since no community ever has enough capital and resources to do everything it wants to do at any one time. It also enables a community to make a better estimate of the cost it may have to pay for certain developments.

This concept of scale enables developers to think on different levels of abstraction, avoid oversimplification, and avoid two-valued thinking. It helps in looking at a development program in holistic terms rather than only in analytical modes of thought. It is a continual reminder that "everything is connected to everything else."

Since community development has from its beginning stressed mass education of citizens as a major part of the development process and many practitioners of community development still do, the concept of scale as presented here fits well into this approach. It forms a workable framework for the development of educational curricula and programs. It is not very difficult to communicate the basic idea of scale to the members of the community, which then results in an additional impetus to the developmental process once a program has begun. All in all it provides a set of checks and balances that helps to avoid the hazards of a community "putting all its eggs in one basket."

Discussion

Paul W. Barkley

The three papers dealing with community development are the result of several years of affiliation among the scholars who presented them. I have been on the fringes of this affiliation, and this group of papers does not represent the best work of the group. Perhaps the group's best work comes only in intimate communication and does not transfer easily to the printed page.

The group is concerned with *community* in its grandest sense. Sometimes this concern focuses on development, sometimes on interpersonal relations, and sometimes on more pedestrian themes such as individual community facilities. Unfortunately, in this airing, only the Simpkins paper is involved with community. Hartman and Moles became mired in considerations of science and its relationship to culture and to truth. While these topics are of vital concern, they serve only to detract from the stated purpose of this session.

The Hartman paper is a misplaced *tour de force*, but it is not without precedent in the subdiscipline of agricultural economics. From time to time a number of agricultural economists have been frustrated by what they have been doing and how they have been construing reality. They bemoan irrelevance and admonish their followers to be more careful in selecting problems, stating assumptions, manipulating data, and inferring from small samples to large populations. These admonitions are healthy and sometimes lead to magnificent pieces of work. The best examples include Salter, Kelso, and Castle. These works make no pretense about focus; they are directed at the entire profession. The Hartman paper, too, is directed at the profession but for some reason harbors a minor pretension about community development. In my opinion, the pretension (or the foil) could as well have been dairy marketing or land tenure.

Hartman is stating some serious problems. Economists, especially applied economists, are indeed wont to confuse assumptions with postulates; they do live in a world guided by incomplete specification; they do have limited and self-serving objectives; and their thinking is dominated by objectivity while subjectivity is relegated to philosophers, theologians, politicians, and the very young. These points are well taken. The problem of culture, however, is not. There may be a western culture existing in opposition to an eastern culture or a third world culture. The western culture is large and diverse. It has so many dimensions that it cannot become an adequate framework for a discussion of the frailties and limitations of science or scientists. A discussion of a subculture centered in the academy would have been preferable.

It is no doubt true that the academy has become very narrow in its goal orientation. Those of us on the inside have responded to pressure to secure outside funding—funding that is often tied to very selective objectives and leads to research results that can be turned into large private gain. The opportunity to be creative is still present, but it carries high risks when compared with the bread and butter research that is open to nearly all of us. We have created a system that can be very profitable even while it pursues a relatively honest grade of science. It is to be condemned because its scientific endeavors are not as intense nor as innovative as they might be.

But what has this to do with community development? Are practitioners of development any more liable to commit these sins than those pursuing other branches of agricultural economics? I think not. If anything, they are less able to because their clienteles do not usually have the money to buy favor nor to purchase narrow research. Moreover, most (if not all) community problems are public problems, and solutions to them come in the form of nonappropriable public goods. Researchers in this arena may be involved in bad science, but it stems from their lack of knowledge of science or from their lack of inventiveness. It does not come from the frailties of the system or the selfish drive for personal gain.

I turn now to Hartman's comments on

Paul W. Barkley is a professor of agricultural economics at Washington State University.

community. One must differentiate between a community as a place and a community as a sense of involvement or human interaction. Hartman discusses the latter, although one gets the impression that a place is implied and that place is, moreover, a rural place such as one might find in the Plains, in the South, or in the West. To develop this community, one must improve interpersonal relationships and develop a sense of intimacy and reciprocal responsibility.

No one will doubt this. The question is: what can economists do to improve the capacity of those in a community to adopt a more selfless attitude toward their fellow men? This is not an easy thing to do because the assumption of acquisitiveness says we must grow to succeed; the assumption of empathy says we need not grow to succeed. Veblen, Galbraith, and Boulding have ventured into this land. Veblen wonders how tastes and values were formed, but he does not make these issues a part of the conceptual framework he uses to describe man. Galbraith takes up the cudgel but cannot do much more than describe the difference between man as a private person and man as a public person. Boulding comes the closest. He states continually that benevolence is a consumer good and that one can increase his own level of satisfaction by helping others. Boulding stops here and becomes a muse for later-generation economists. How does one give empirical content to these ideas? Here may be a starting place for economists to exercise their particular skill and to draw on their traditional concepts and tools.

Action programs are quite another thing. I am not confident that economists or anyone else from the academies will be more than modestly successful in making people adopt the quiet and personal dispositions of compassionate interdependence, mutual respect, and harmony. I doubt that those involved in domestic community development work can afford the time or financial resources needed to bring even one community along the road to development in Hartman's terms. It is a good idea, but the cards are stacked against it.

Moles takes a more positive stance toward science than Hartman does but is still critical of the practice of science in a monastic setting. Moles' science is evolutionary. It is based on perception and refutation. It requires investigators to abstract and simplify in order to find common threads that connect realities. The realities are negotiated when partial knowledge requires acceptance of one view rather than several. The world was flat to the denizen of medieval Europe because no other notion was necessary regarding the shape of the earth.

Moles has an interesting construct in his closed circle of knowledge. The job of science is to expand the dimensions of the circle, but the circle must remain intact. It it is broken, a whole series of new truths and perceptions may be needed to reestablish its integrity. The discovery of the Van Allen belt required the reinvestigation of aspects of the solar system.

Although Moles says nothing about communities, there is a lesson to be learned from the conjunction of his work with Hartman's. Hartman tries to maintain a circle of relationships within his community; Moles needs a circle of knowledge in scientific enterprises. When the Moles circle is broken, the whole system shudders and threatens to collapse. One suspects that when Hartman's community is threatened—either by a new member or a new idea—it comes close to collapse too. Moles suggests that knowledge is not stable. I believe community to be unstable also.

The Moles paper has one other remarkable attribute. Toward its end, it asks about the appropriate size of administrative units. At what size can administrators exert "effective" control? Herein lies one of the most important problems in community development: who should be in charge? A vast literature has developed to define the geographic limits of American federalism. This literature comes from a notable group of scholars inside and outside of agricultural economics. Most assume rationality and individual freedom of choice. Their work breaks down in transferring from individuals to groups. Herein lies Moles' problem. He wants a system that is responsive yet able to make use of technological change and take advantage of economies of scale. The combination is frustrating and leads to tremendous duplication, waste, and an overlapping of jurisdictional units. Moles correctly implies that this is part of the reality we create.

The Simpkins paper is directed at this audience, and it relates to the stated theme of this session. Simpkins is an anthropologist, so he has a considerable claim on the topic of community and communities. Unfortunately, anthropologists and economists use the language in slightly different ways. Simpkins picks up on an idea closely akin to the economists' idea

of scale. Apparently, it is familiar to most anthropologists, but the usage is somewhat different from the economists' concept of scale.

For Simpkins, there is a connection between sixteen attributes of a community and that community's scale. Moreover, these attributes have internal and external dimensions. Scale increases when internal specialization and trade takes place. Scale also increases when specialization and trade vis-à-vis some external area increases. One is inclined to think that the attributes have very different weights and that some may be complementary while others are supplementary or even competitive. Simpkins notes that attributes have differential degrees of difficulty associated with their measurements.

The Simpkins scheme is disappointing in that it implies that the scale of a community increases whenever there is an increase in any of his sixteen variables. All scale relationships are, then, in stage I or stage II of a production function. I am not this hopeful. Communities, even very small ones, are filled with distrust, spite, envy, greed, lust, and the lesser forms of evil—rivalry, jealousy, and indignation. Any of these can put the development of the community into stage III. Where do these fit in the Simpkins model? Moreover, how are we to make the model operational, and what will it tell us once it is? Will the model be a guide to local, state, or federal policy? Simpkins is on to something, but I need specifications, and I need clear glass rather than rose-shaded lenses when I begin to work with his model.

In sum, this session on community development has provided a forum at which several first-rate scholars could vent their collective wrath on the establishment and on the conduct of science. The topics need to be addressed. But the topic of community development needs to be addressed too. There are thousands of communities in the United States. Some are in isolated, rural areas, and some exist in the middle of more metropolitan areas. These communities suffer an unbelievable number of social and economic maladies. To date, neither the New Frontier nor the War on Poverty nor the Great Society has been able to help to a significant degree. The scientific community has some responsibility for the communities' present condition, and it should take some pains to alleviate the unwanted side effects of the progress it has created. This is not best done by berating the system. It is best done by doing good science and asking publicly employed persons to become risk takers in purveying the new-found knowledge. We need someone to learn about the relationship between capital fixtures and people. We need someone to learn about coping with scarcity, choice, and change. We also need someone to inquire into commonalities and differences; convergence and divergence within, between, and among communities.

Certainly we need Hartman to keep us honest, and we need Moles to give us perspective on the appropriate role of science. We need Simpkins to provide new twists to old researches. Most of all we should hope that this same group will continue to deliberate their problems and eventually provide us with a more pragmatic discussion of a very puzzling set of problems.

Irrigated Agriculture under Stress
(Charles V. Moore, Economic Research Service, USDA, University of California, Davis, Chairperson)

Pressures Created by a Severe Drought on Water Institutions

Ronald B. Robie

California has a complex and diverse water resources management system. Within the state there are about 195 major surface reservoirs with a capacity of 48,100 cubic hectometers (39 million acre-feet). The state is underlain by an extensive aquifer system that has a usable ground water storage capacity of 176,400 cubic hectometers (143 million acre-feet). Ground water pumpage has averaged over the recent past about 18,500 cubic hectometers (15 million acre-feet) per year, or about 40% of the state's total applied water use.

A myriad of water districts and agencies have evolved to tap these vast water resources. In addition to the reservoirs and conveyance facilities of the State Water Project and Federal Central Valley Project, California has hundreds of regional and local water storage and distribution systems. Among them, California's water purveyors provide the water for the state's agricultural and municipal and industrial needs. In 1975, the total statewide agricultural and municipal and industrial applied water usage was approximately 47,600 cubic hectometers (38.6 million acre-feet). About 85% of this figure represents applied agricultural water. Of this agricultural water, approximately 62% was supplied by local agencies and individuals, 34% by federal projects, and 4% by the State Water Project.

Most of the major waterworks systems now operating in California have come on line since California's last real drought during the 1928–34 period. Because that seven-year dry period was the worst on record, it served as a base against which the safe yields of projects were established. The contribution made by California's water systems has been great during the drought, and the ability to cope has been quite amazing considering the growth of population and irrigated acreage since the drought that occurred 40 years ago. During 1940–77 California's population jumped from 6.9 million to 21.8 million—a three-fold increase. In that same time period (up to the drought), irrigated agricultural acreage more than doubled—from 4.5 million to 9.3 million.

Why is California enduring a drought? There is simply less water running off this year than at any time in California's history. The record dry period has been surpassed. To illustrate the condition California is facing, table 1 shows the average annual runoff for the four major rivers in the Sacramento Basin for three different time periods. The 1975–76 water year (1 October 1975 through 30 September 1976) was the third driest in history. However, it was followed by the 1976–77 water year, which, when it ends on 30 September 1977, will have turned out to be the driest year on record. For planning purposes, the probability of such a dry year based on historical experience would be extremely low or, for all practical purposes, rated at zero.

Because of California's extensive system of state, federal, and local projects, the drought problems suffered during 1975–76, though serious, were fairly isolated. During the second drought year, however, the tentacles reached out to include the entire state in their grasp, affecting agriculture, industry, the economy, the environment, and the general public.

California had many water problems before this drought—quantity/quality interrelationships, lack of control of ground water, instream use conflicting with other water uses,

Ronald Robie is the director of the California Department of Water Resources, Sacramento.

Table 1. Average Annual Runoff, Four Major Rivers in the Sacramento Basin

Period (in Water Years)	Cubic Hectometers	Million Acre-Feet
50-year average (1921–70)	21,070	17.08
Historical dry period (1929–34)	12,063	9.78
Current dry period (1976–77)	8,017	6.5[a]

Note: The four rivers are the Upper Sacramento, Feather, Yuba, and American rivers.
[a] 1976: 8.2 million acre-feet; 1977: 4.7 million acre-feet (preliminary).

to name a few—and the drought exacerbated them. The complexity of drought problems and solutions has sometimes been hard for the public to grasp. There has been much public pressure for easy answers when, in fact, there are none. Water management and the operation of today's water supply and delivery systems is not an exact science, and there are shortcomings in both our knowledge and operating procedures. For example, the data base relied on for forecasting runoff from the mountains does not include years comparable with this one. We are without experience that could tell us what to expect under today's conditions. Extrapolations from past experiences have proved surprisingly useful, and model studies are of assistance, but they do not provide all of the answers.

In spite of the difficulties posed in water projects' operations due to information gaps, we are learning important things such as the way water use patterns change during a drought. Although traditional wisdom has dictated that drought periods are times when water users must take shortages, the demand for water is actually greater in a dry year. Farmers and urban residents tend to use water earlier in the year to make up for lower than normal soil moisture and because of higher spring temperatures. In 1977 more than 50,770 cubic hectometers (41 million acre-feet) would have been used for urban and agricultural uses compared with a normal year of 37 to 38 million acre-feet.

The California Department of Water Resources (DWR) and other agencies are undertaking programs to fill in some of the blanks in our data. One program of special interest is a data collection effort being undertaken by DWR economists. The objective is to define better the production functions of California agriculture, particularly as they relate to water. From this data, it should be possible to construct loss functions as related to water quality and quantity. The Department's economists have developed and utilized a statewide input-output (I-O) model to evaluate the economic impact of the drought. They are continuing to improve the model and to develop regional I-O models. The public demanded quick and comprehensive analyses of potential drought economic effects.

I do not mean to dwell on the information we have yet to learn. The drought has enabled us to gain practical knowledge about a number of drought management assumptions, strategies, and mechanisms. We have learned much about water conservation and about how people respond, how large reductions can be, how to enforce compliance, and how to establish goals. However, the concept of water conservation runs against the grain of many water utility managers, who generally see their roles as meeting needs, not reducing demands. Yet this is a very important part of good water management. Utility managers are now called upon to emphasize approaches that have not traditionally been considered as within the scope of the manager's role.

We are finding that in a drought urban residents conserve water voluntarily without mandatory rationing if they perceive a legitimate need. Where the situation is critical, mandatory rationing with fines for excessive use may be necessary to impress on the public the seriousness of the situation. Experience in the present drought shows that, with an urgent and perceived need, greater than 50% cutbacks in municipal use can be achieved. Industries can cut back, but not nearly as much as urban residents. Some industries could save more than they do but have not in order to hedge against more stringent regulations next year. At a recent drought conference, several industries indicated they could reduce water use but did not in order to retain some cushion in the event of future governmental restrictions. The California Department of Water Resources has contracted a survey of 6,000 specialized firms within California to determine their reactions to various water shortages. Preliminary results indicate that, with a

25% water reduction, only 20% of the firms would decrease production and that none would shut down, quit, or relocate.

Farmers also can get by on less water but again not to the same degree as urban users. Essentially, the same acreage is being irrigated in California this year with 15% less water. When adequate water is not available, farmers tend to put off salt leaching, use better water control, maintain perennial crops, and switch to lower water use crops. In other words, in times of shortage, agriculture can take deficiencies and still maintain reasonable production levels. The question is for how long?

There are many areas where increased on-farm efficiency can result in energy savings, reduction in water quality degradation, and increased flexibility in overall water management. The Department is exploring incentives for additional agricultural water conservation actions by farmers, urging long-range programs that will lead to more efficient use of irrigation water for agricultural, industrial, and domestic purposes, for example, drip and sprinkler irrigation where possible and increased promotion of irrigation management services provided by both the governmental and private sectors. The Department also believes that there should be additional federal funding to the Agricultural Stabilization and Conservation Services' Agricultural Conservation Program for cost sharing to cover purchase of irrigation equipment and other irrigation-related costs where this will result in water savings.

As indicated, urban water conservation has been very successful, so successful in fact that a national controversy was triggered when one San Francisco Bay Area official began urging that people stop saving water because water conservation was surpassing expectation, lessening revenues to the water utilities and prompting a traditional institutional response. The incident gained wide media attention and caused widespread public reaction.

State officials pointed out that, rather than cutting back on conservation measures, which would in effect be using more of next year's water reserve in an effort to balance utility finances, it makes more sense to explore alternatives, such as (*a*) adjusting rates in order to ensure necessary operating revenues during the drought but returning to existing levels once normal water supplies again become available; (*b*) using lifeline rates to work out inequities to the poor, the elderly, or others who are disadvantaged; and (*c*) using rates that heavily penalize excessive or unnecessary use of water during the drought emergency.

Another water management mechanism that has proven successful in spite of normal institutional constraints is the concept of water exchange. The Department of Water Resources has encouraged and developed water exchange contracts to voluntarily reallocate water from areas with sufficient supplies to water short areas. To date, the Department's efforts have been met with a fine spirit of cooperation. Exchange agreements have been accomplished to transfer more than 430 cubic hectometers of water (355,000 acre-feet) to areas of need. (In allocating the exchange water, the state included a requirement that no exchange water be allocated to lands not irrigated last year.) Prior to the drought, who would have been so bold as to suggest that water from the State Water Project that had been allocated and contractually committed for delivery to southern California would be voluntarily reallocated and by a rather complex physical and legal process delivered to a northern California county, which was not a State Water Project contractor nor within its service area? Nevertheless, it has happened.

Not all of the exchange water has gone to municipalities. In fact, the lion's share, 370 cubic hectometers (approximately 300,000 acre-feet), has been reallocated from the highly industrialized and urbanized area of Los Angeles to the irrigated agriculture areas of the lower San Joaquin Valley. Some economists might argue that this seems inconsistent with economic theory, particularly in times of water shortage. However, it is sound if there is sufficient slack in the water demand schedule such that little is sacrificed by urban users in the way of productivity, profit, or even convenience compared with the very substantial gains (or the losses averted) by the irrigation farmers in the San Joaquin Valley.

Perhaps most surprising is the evidence of such high payment capacity as demonstrated by the willingness of agriculture to pay the very high costs of exchange water.[1] However, this

[1] Take, for example, the 1977 canal-side costs of one State Water Project contractor. If the agency could have been delivered all the water requested, their average cost would have been between $10 to $15 per acre-foot (entitlement water plus surplus water). However, this year they paid about $43 per acre-foot, an increase of about $30 per acre-foot or $100 per irrigated acre. Several districts in the service area have asked the state to spread their 1977 charges over a period of several years, and the DWR is considering this request.

willingness to pay is only for the short run and is the farmer's response to minimize losses or to possibly avoid bankruptcy in a drought year and would not represent a long-term ability to pay for the water.

About two years ago, the California Department of Water Resources started a study to determine the feasibility of purchasing agricultural water entitlements applied to high-water-using crops and/or surplus crops for redistribution to high priority uses. Similarly, under emergency drought legislation enacted this year (PL 95-18), the U.S. Congress authorized the U.S. Bureau of Reclamation to act as a nonprofit broker in water transactions. However, this was not successful in California. Open bidding and brokerage of water supplies carries some basic institutional problems that have understandably made sellers wary and the legal implications have not been fully explored. The State Water Resources Control Board authorized hearings for water right transfers under its jurisdiction, but many water rights are not subject to Board control (riparian, pre-1914 appropriative, and ground water). Exchanges of these waters are at the peril of the parties and subject to legal challenge. The State Water Project's successful transfer was facilitated by the existing institutional mechanism—State Water Project contracts for the most part.

Another problem is that we have limited physical capacity to transfer water to areas of shortage. While there are interconnections within regions, connections between regions are few. We do not have a water grid comparable with the energy grid. (Most water exchanged went to state water contractors who were already interconnected.)

Some drought problems are the result of psychological factors. Although most water projects were planned to serve through both wet and dry years (with shortages during dry years), the planners failed to foresee the psychological effect of the economic and other adverse impacts of taking shortages. The state has had forty years without serious drought conditions. People forget. A "rose-colored glasses syndrome" sets in, and people refuse to believe that a drought exists and that it may continue. Although by early 1976 it was clear that precipitation in the 1975–76 water year was going to be low, most areas continued using water at near normal levels. There are few institutional mechanisms to control unwise use. The State Water Project did curtail some deliveries with an eye on the dry year ahead, but much criticism was received for doing so, particularly from agricultural customers in the San Joaquin Valley.

As the drought progressed into 1977, the situation was particularly difficult for state water contractors in the San Joaquin Valley because the state's water contracts call for a dry year reduction to agricultural contractors of 50% before municipal and industrial contractors take any cutbacks. Then, cutbacks proceed equally. For example, if municipal and industrial users are cut back 10%, agricultural contractors are cut back a total of 60%. When these cutbacks occurred in 1977, the impact was further aggravated by the fact that water users in the State Water Project service area had become accustomed to, and relied upon, the relatively inexpensive surplus water deliveries. They had planned on the use of surplus water during dry periods to help pay off initial investments that had been made in the previous ten years developing land for agricultural use.

In 1977, San Joaquin Valley contractors increased their reliance on wells, as did most other Valley water users. More than 3,000 new wells were drilled, and the overdraft is about 4,317 cubic hectometers (3.5 million acre-feet), as compared with 1,850 cubic hectometers (1.5 million acre-feet) in a normal year. There have been severe financial problems for some of the contractors because of the costs of obtaining temporary additional supplies from ground water on top of paying for the fixed costs of surface supply facilities.[2]

As an example of the impact of the drought on State Water Project agricultural contractors in the San Joaquin Valley, considering 1975 conditions as 100%, districts within one service area that rely solely on state water irrigated 95% of the acreage with 86% of the water in 1976. Similarly, in 1977 the values are 79% of the acreage with 63% of the water. This indicates an improvement in application efficiency in both years, but more significant is the probable stressing of some crops with consequent yield reductions in 1977.

Districts having additional water available are able to maintain nearly normal operations. Considering the total acreage irrigated by all

[2] In one district alone, for example, at least $1.4 million has been spent in order to increase ground water yield, in addition to pumping and other operating costs.

available water in the districts having additional supplies, their acreage totaled 100% in 1975, 101% in 1976, and 89% in 1977.

Irrigated agriculture, as any water-dependent industry, is reluctant to takes shortages. On the whole, California farmers are willing to take all the water that they can obtain now, even with the knowledge that potentially there could be no supplies available in the next year. The California farmer is a traditional risk taker, and many seem willing to maximize revenues in 1977 at a risk of having losses equal to fixed costs in 1978. We must develop more precise and predictable mechanisms for operating water projects and imposing shortage formulas, taking into consideration the need to carry over supplies to the next year.

On a long-term basis, we must reexamine the shortage formulas in water service contracts. It has always been assumed that municipalities could not take shortages and that agriculture could. However, the drought has shown that both can take shortages. In fact, municipalities have a greater potential for conservation.

Several other institutional problems associated with droughts are, briefly, (*a*) drought as a disaster: Most government financial assistance programs are geared to disasters such as floods or earthquakes, where there is one quick blast of destruction. Compensation, when it comes, arrives well after the fact. Fortunately, there have been signs that the federal government is becoming more aware of the gradual and anticipatory nature of drought disasters. Two examples of this are the Farmers Home Administration's new regulations that make emergency drought loans available to farmers for "prospective losses" and legislation that, if enacted, will grant similar loan authority to the Small Business Administration. (*b*) Emergency powers: Just what powers are available to various levels of government in an emergency? Who has the power to declare when rationing is needed? At what levels should certain decisions be made?

(*c*) Effectiveness of existing state water rights and water quality laws: The drought has particularly underscored the problems with the ground water laws, which permit unlimited new wells and provide no administrative mechanisms whatever to deal with ground water pumping. This year, Governor Brown established a commission to review California water rights law and to consider any needed changes in the water rights system. (*d*) Long-range forecasting: Long-range weather forecasting is still at an experimental stage and is not yet sufficiently proven to be a basis for critical operating decisions. Studies by the DWR, however, show that some skill appears to exist in seasonal weather forecasting. Extensive additional research is needed to improve these techniques and to establish their accuracy. Reliable forecasting techniques would be the single most important improvement in drought operations.

Although we have learned a good deal during this drought, school is not yet out. Even if 1978 is not a dry year, the drought will not be over. What if next year is below normal? Prudence dictates that we be conservative in future plans and not assume that the drought is over. In updating the plan of operations for the State Water Project, the DWR is assuming that water conditions of 1976–77 will prevail through 1978. The Department also is developing contingency plans to help local communities deal with the drought in the event that the coming winter is again dry. These will involve tearing down institutional barriers. The months ahead will be critical ones.

I particularly hope that when the drought is over we do not forget the lessons we have learned. The drought has created problems for society as a whole, but it is these societal problems that offer a rare opportunity for the economist, the engineer, the lawyer, and others to identify and document strategic data and responses while the drought persists. Finally, it enables the development of new procedures for the future.

Defining Upper Limits to Groundwater Development in the Arid West

O. R. Burt, R. G. Cummings, and J. W. McFarland

As western states attempt to respond to national needs for increased production of fossil fuels, the scarcity of water in this area looms as a major potential impediment. This is particularly true in the Rocky Mountain region, wherein coal production is expected to increase by more than 500% (Federal Energy Administration). With few exceptions, surface water supplies in this area are totally developed. Currently, efforts by state and regional planners to deal with the resulting dilemma—pressing needs for rapid industrial development and water scarcity—involve one or both of the following: reallocation of water from agricultural to municipal/industrial uses, and/or development and exploitation of groundwater stocks (*Albuquerque Tribune* 1976b, c; Cummings and Gisser).

In considering the possibility of rapid groundwater development in the western states, one has ample cause for concern given this area's experiences with groundwater development over the past twenty years. The pattern of such developments has been almost consistently one of overdevelopment. The scale of development has been out of proportion to the groundwater stock and natural recharge. The result has been rapid mining and thus depletion of the stock. This pattern is seen in many areas overlying the Ogallala aquifer, particularly in the High Plains area with subareas facing the depletion of groundwater stocks within three years (*Albuquerque Tribune* 1976a). Depletion of groundwater stocks in southern Arizona has been the raison d'etre for the Central Arizona Project (Kelso, Martin, and Mack); depleted stocks have become an increasingly serious problem in western Kansas.[1]

The basic notion developed in this paper is that problems of the sort exemplified above might be avoided, or perhaps diminished, if at the outset groundwater development plans were considered in the context of the optimal steady-state level for groundwater stocks and rates of natural recharge. The "optimal steady-state stock" (denoted x^*) is the level of groundwater storage at which mining optimally ceases and withdrawals of groundwater are limited to natural recharge (w). If, prior to groundwater development activities, planners know x^* and w for a given aquifer, the following kinds of policy-related questions can be addressed.

Given alternative levels of development (permissible annual withdrawal rates), for how many years can these withdrawal rates be maintained? Or, given initial storage x_0 and the steady-state storage level x^*, the difference $x_0 - x^*$ can be mined (withdrawals in excess of recharge); for a given annual rate of mining (m), the number of years that m can be maintained is given by

$$T(m) = (x_0 - x^*)/m.$$

The annual rate of groundwater withdrawals (u) consists of mining and recharge, i.e., $u = m + w$. Each rate of mining analyzed above implies a number of years $T(m)$ for which that level can be maintained. For each m, what is the impact on local communities of use rates u over $T(m)$ years, and what are the impacts of water-use levels (which fall from u to w) at the end of $T(m)$ years? With prior knowledge that a use rate can only be maintained for $T(m)$ years, what sorts of legal-institutional arrangements might compensate for the eventual (inevitable) fall in economic activity at $T(m)$ when use rates decline from u to w? What might be the ramifications of establishing a system of water rights that expire, in a staggered fashion, through time?

O. R. Burt is a professor of economics and agricultural economics, Montana State University, R. G. Cummings is a professor of economics, University of New Mexico, and J. W. McFarland is an associate professor of quantitative and management sciences, University of Houston.

Financial support for this work from the Los Alamos Scientific Laboratory is gratefully acknowledged.

[1] The overdevelopment of groundwater resources is certainly not a problem peculiar to the United States: Similar problems in Northwest Mexico are described in Cummings.

The questions given above are, of course, not comprehensive but are intended to be simply suggestive of the potential contribution to the process of water planning that estimates for x^* can make at the initial stages of groundwater development.

In the next section, the general methodology for determining such steady-state levels in natural resource systems is developed, and data from a case study of groundwater use in the Estancia Valley (New Mexico) are used to exemplify the usefulness of the approach (Cummings and Gisser). Concluding remarks are given in the last section.

Determining Steady-State Groundwater Stocks

The Conceptual Model

The basic structure of solutions for the optimal rate of extraction from natural resource systems has been the topic of a wide range of studies (see Burt and Cummings' bibliography) and can be heuristically described as follows. Given an initial resource stock, periodic extraction is carried to the point where the value of the last unit extracted "today" equals the marginal, or incremental, value of a unit of the resource in storage. The value of a unit in storage is measured by such things as increased costs "pushed forward" to all future periods and the value that the increment in storage can generate in future periods. With all future values discounted to the present, solutions for this class of problems normally involve high initial rates of extraction, with future extraction rates declining through time, eventually converging to the "flow" component of the resource system (natural recharge in the case of groundwater; convergence is to zero in the case of "exhaustible" resources).[2] The level of resource stocks that is obtained when periodic extraction rates equal the flow component of the resource system then remains constant into perpetuity. The resource system is said to be in a "steady state," and this resource stock that remains unchanged through time is called the steady-state stock. Thus, the solution to the dynamic optimization problem concerning the exploitation of a natural resource stock yields the steady-state stock and the time at which the system optimally enters the steady state.[3]

Solutions for dynamic optimization problems may become complex and costly and may be impossible to obtain with the amount of regional detail required by planners. This is particularly true in early stages of groundwater development where hydrological and agroeconomic data may be extremely limited. It is generally the case in early stages of groundwater development planning that the dearth of hydrological-agroeconomic data make efforts to apply "sophisticated" dynamic techniques a questionable exercise. Limited and weak data may be viewed as useful for only more cursory types of analyses. As shown in Burt and Cummings, however, it is possible to calculate the dynamic optimization problem's steady-state stock without going through the dynamic optimization process.

For a system characterized by a resource stock x and a single control variable u, define u as total periodic groundwater use (total pumping) and x as the groundwater stock. If $\phi(u, x)$ is net losses of groundwater stocks per period, changes in groundwater stocks obey the difference equation: $x_{t+1} = x_t - \phi(u_t, x_t)$. Let $G(u, x)$ measure periodic net incomes from groundwater use (e.g., net agricultural incomes from irrigation). As u increases, G increases. Higher levels of x imply higher values for G for reasons described above, e.g., as x increases, water tables are higher, pumping costs are lower, and net agricultural incomes increase.

The general structure for the steady state given by Burt and Cummings involves the simultaneous solution of the following equations (in what follows, G_u is used to denote $\partial G(u, x)/\partial u$, $G_x = \partial G(u, x)/\partial x$, etc.):

$$G_u = \frac{\phi_u G_x}{(r + \phi_x)} \tag{1}$$

and

$$\phi(u, x) = 0, \tag{2}$$

where r is the discount rate. If w measures periodic net recharge to the aquifer and net recharge is independent of stocks, net decline in the groundwater stock is given by $\phi = u - w$, and equation (2) reduces to the simple result

[2] It is important to recognize that natural recharge is not independent of surface water development decisions, and there is often an opportunity to deliberately enhance recharge such that, for the same total flow of water consumption, a greater proportion comes from groundwater (see Burt). The severe drought being experienced in the West dramatizes the virtues of relatively greater dependence on groundwater.

[3] Technically, in many cases the steady state is approached asymptotically, in which case time, as used above, is infinity.

$$u = w. \tag{3}$$

To derive the steady-state groundwater stock x^* from equations (1) and (3), one needs only estimates of $G(u, x)$, i.e., how u and x determine incomes, periodic recharge w, and discount rate r.

A simple extrapolation of pumping costs in a relatively high storage situation to a severely depleted one can be extremely misleading and even result in a negative value for x^* in the solution of equations (1) and (3). Two economic forces tend to make the marginal value of stocks increase rapidly as stocks are approaching exhaustion. First, wells will go dry in an irregular pattern because the water-bearing strata will not be of uniform thickness throughout the basin. Second, drawdown at the individual wells during peak demand periods will result in water shortages during the critical periods of the season, especially from the larger bore wells.

The first phenomenon means that the groundwater stocks' function as a distribution system increases rapidly as stocks accumulate from the zero level, while the second implies that the intraseasonal storage function of groundwater greatly improves as stocks increase from zero. Both of these economic considerations would tend to make G_x increase rapidly as x goes to zero and thus force an equilibrium solution to equations (1) and (3) involving $x^* > 0$.

An Application

To allow perspective as to the potential relevance of steady-state stock levels, a somewhat hypothetical characterization of groundwater use in the Estancia Valley (some 40 miles east of Albuquerque, New Mexico) is used as an example inasmuch as a recent study of that area by Cummings and Gisser provides data required to estimate $G(u, x)$.

Groundwater stocks in this essentially closed basin are currently some 2 million acre-feet,[4] with net annual recharge of 20,000 acre-feet. An estimate for net agricultural incomes based on budget studies of irrigated farms is given in Cummings and Gisser. This work permits calculation of the function G in tubular form. Using parametric linear programming techniques, these data are used to estimate a continuous form for G by least squares fitting of a polynomial:[5]

$$\begin{aligned} G(u, v, x) = {} & 2{,}512 + 13.3u - 0.1u^2 \\ & + 587.1v - 198.4v^2 + 0.73(uv) + 76.6x \\ & - 0.16x^2 + 57(ux) + 0.72(vx) - 45(u^2x). \end{aligned} \tag{4}$$

In equation (4), u is the rate of groundwater use (in acre-feet per year), x is groundwater storage (in millions of acre-feet), and v is amortized annual capital costs (million dollars). Capital is included in G to reflect the possibility of substituting capital for water as groundwater storage declines. Ideally, capital would enter the problem as a stock. So long as groundwater stocks change slowly, and amortized capital costs in turn change slowly enough that the implied capital stock can be depreciated at an economic rate consistent with the assumptions underlying the production function, the "flow" nature of v may be palatable.

The net decline in groundwater stocks in the Estancia Valley case is simply a function of annual withdrawals or, with annual recharge (w) of 20,000 acre-feet,

$$\phi(u) = u - 20{,}000. \tag{5}$$

Consider the following hypothetical problem. Suppose that existing irrigation in this Valley is from surface waters. As a result of energy developments in the Valley, or in other parts of the state, planners are considering the development of the Valley's aquifer as an alternative source of water for irrigation. Given the hydrological characteristics of the Valley and its aquifer, what level of development "should" be allowed?

Current storage of groundwater and annual recharge are known: $x_0 = 2$ million acre-feet and $w = 20{,}000$ acre-feet. The optimal steady-state stock—the level of groundwater storage at which annual withdrawals are optimally limited to recharge—is calculated using the equations (1) and (2), augmented by an

[4] This is water of class I quality (0 to 1,000 parts per million dissolved solids); for simplicity, stocks of lower quality water are ignored.

[5] In terms of fitting equation (4) to data from Cummings and Gisser, a least-squares fit of a general quadratic in the three variables was somewhat deficient. Third degree interactions were introduced into the polynominal, and only one term was of much consequence, namely, linear storage times use rate squared (u^2x). Although statistical measures are not very relevant in this type of curve fitting, the t-ratio on this interaction term was 9.4, and the adjusted R-squared went from 0.968 to 0.981 with the addition of this variable into the quadratic. Clearly, the level of capital interacts with groundwater stocks in a sufficiently complex way that a simple cross-product term is inadequate. To reflect the "uneven bottom" problem of the aquifer, the model is structured such that land available for irrigation decreases by 10%, 25%, and 40% as stocks fall from 2 million acre-feet to 1.58, 1, and 0.58 million acre-feet, respectively.

equation to account for the variable v, viz., $G_v = 0$. Values for x^* and v^* for various discount rates between 0 and 10% are given in table 1. These hypothetical planners now know x_0 and x^*, the difference between which defines the upper limit on groundwater mining. Thus, with $r = 5\%$, $x_0 - x^* = (2 - 0.295)$ million acre-feet, and annual groundwater use is limited to natural recharge after 1.705 million acre-feet has been mined.

What then are the ramifications of alternative levels of development in this Valley, where "levels of development" are represented by annual rates of water use? Suppose that one arbitrarily chooses for analysis the rates 83,000, 66,000, 56,000 (approximately the current rate of use in the Valley), 52,000 and 25,000 acre-feet per year. Approximations for the associated annual levels of net farm income, regional income, and the length of time that these income levels could be maintained before groundwater stocks fall to x^* can be found in table 2 for discount rates of $r = 0$ and $r = 5\%$.[6]

With the data in table 2, the following line of argument is available to the planner. Given a zero discount rate, and allowing for 83,000 acre-feet of water use per year, annual net farm and regional incomes will be on the order of $4.65 million and $14.88 million, respectively. But after five years, these income levels will fall to those associated with use rates set at natural recharge; i.e., annual net farm and regional incomes will fall to $1.1 million and $3.6 million, respectively. With $r = 5\%$, the higher income levels are maintained for twenty years. With levels of development associated with annual use rates of 56,000 acre-feet, net farm and regional incomes of $3.14 million and $10.05 million, respectively, are maintained for eight to thirty years with r between 0 and 5%.

Knowledge as to the optimum steady-state stock level thus places in perspective the magnitude and potential timing of changes in levels of economic activity inevitably associated with declining groundwater stocks, given alternative levels of groundwater development.

Table 1. Steady-State Groundwater Stocks and Optimal Levels for Amortized Annual Capital Costs for Selected Discount Rates

Discount Rate (r) (%)	Steady-State Groundwater Stocks (x^*) (Million Acre-Feet)	Optimal Levels for Amortized Annual Capital Costs (v^*) (Million $)
10.0	0.197	1.535
7.5	0.232	1.545
5.0	0.295	1.561
0	1.546	1.887

Note: Using G defined in equation (4), x^* and v^* are derived by solving the following system of equations: $G_v = 0$, $G_u = G_x\,(1/r)$, $\phi(u) = u - 20{,}000 = 0$.

[6] Net farm income estimates are based on net farm income per acre-foot of water use given in Cummings and Gisser (table 5 and C.5). These measures are not comparable with corresponding measures that one would derive from $G(u, v, x)$ in equation (5), inasmuch as Cummings and Gisser treat x as a constant. Regional incomes are derived by applying a regional multiplier of 3.2 to net farm incomes.

Concluding Remarks

Decisions as to the upper limits on groundwater development in any particular area are based upon the interplay of socioeconomic, legal, and political forces. With increasing water scarcity in the West, increasing attention will undoubtedly be given to the structure of legal and institutional arrangements that govern water use in general and groundwater use in particular, and the resulting processes of development and change will surely require more and better data.

An effort is made here to suggest and exemplify computational techniques that provide protagonists in this process of change with information that may be critical for evaluating alternative strategies for groundwater development. The lines of argument developed here parallel the general philosophy that underlies adaptive control processes developed in recent years. The notion of an adaptive control process centers on the information "feedback" that can occur over time with operational experience. Thus, in the case of groundwater development, one begins with limited hydrologic information that is often based on general information as to geological formations. Elementary hydrologic information is obtained only as drilling and pumping take place.

It follows that early estimates for groundwater storage must be viewed as tentative and subject to a process of modification as additional data become available. Such processes imply the need for relatively simple and flexible computational techniques, and a response to this need is the raison d'etre of the argument developed here.

Table 2. Net Farm and Regional Incomes for Alternative Annual Rates of Water Use and Associated Years Before the Steady State

	Annual Rate of Water Use (Acre-Feet)				
	83,000	66,000	56,000	42,000	25,000
Net farm and regional incomes (million $)					
Net farm income	4.65	3.72	3.14	2.33	1.40
Regional income	14.88	11.9	10.05	7.46	4.48
Years before the steady state with discount rate (r) of					
0%	5	7	8	11.9	18
5%	20	26	30	41	68

Water Quality Management and Irrigated Agriculture: Potential Conflicts in the Colorado River Basin

John E. Keith

The enforcement of the Federal Water Pollution Control Act Amendment of 1972 (PL 92-500) has been primarily directed at "point sources" of pollution, that is, those polluters whose effluent is easily isolated and identified such as municipalities and industrial plants. Violators have been fined varying amounts depending upon the frequency, extent, and type of violation. The long-run goal of the legislation is, however, to eliminate all man-caused effluent, to reach a zero discharge level of effluents for all activities. If or when these standards are applied to irrigated agriculture, several problems may appear, both in the attempt to enforce effluent standards and in the effect that enforcement may have on agriculture in general and irrigated agriculture in particular. Some of these problems are suggested in a general context; a detailed discussion of some of the possible impacts of water quality controls in the Colorado River Basin is then undertaken, with particular references to a zero discharge requirement.

General Problems

One overriding question that has not been addressed by PL 92-500 or similar legislation is whether or not water quality standards are desirable on any basis other than emotional. Clearly, for many activities and cases, the social optimum will include some level of pollution. Elimination of all externalities will undoubtedly result in lower production and higher prices for all these activities than would occur at a social optimum (Kneese and Schultze).[1]

There is doubt about the applicability of the standards to diffuse sources. The permit criteria specify point sources only. The act as passed required that if a point source (i.e., canal outflow, ditch, etc.) can be defined, or if the return flow is from more than 3,000 contiguous acres, the permit requirement applies. The latter portion of the act was voided in 1975, so that the permit requirement applies only to the point source criterion. Most irrigated agriculture involves diffuse sources of pollution in that no one polluter's effluent can be distinguished from other polluters. Given a zero discharge requirement, there are only a few enforcement options available: to monitor each farm's outflow of irrigation water, to require each farm to treat outflow, or to require the water distributing agency to monitor or treat outflows. These enforcement options for the most part ignore potential pollution of ground water reservoirs, and in some cases it is these aquifers that significantly affect water quality in downstream surface water, as the aquifer is drained by natural springs or seeps. Further, all of the options for enforcement are expensive to the enforcing agency, to the polluter, and in the long run to the consumer.

There are some provisions in PL 92-500 that may also affect changes in the structure of American agriculture. If diffuse sources fall under that act, the costs of meeting effluent standards appear to be a particularly large burden for smaller farms. The incentives exist to force small farms to either sell, consolidate farms, or reduce the size of the farms below the size to which pollution controls apply. The "family farm" may well become a garden plot for part-time farming operators.

Beyond the enforcement problem, the crucial issues about the application of water quality controls to agriculture are those of the economic efficiency and equity of imposing the standards on the agricultural sector. Will the

John E. Keith is a research assistant professor in the Department of Agricultural Economics, Utah State University.

[1] Kneese and Schultze treat the zero discharge portion of the bill as a relatively improbable goal. Recent passage of the Clean Air Act Amendment appears to indicate that the zero discharge mentality maintains a considerable influence over legislation.

additional costs to agriculture and consumers of agricultural products be less than the benefits generated by cleaner water? Will those who benefit be able to compensate those who lose? Probably, the efficiency questions can only be answered within the context of a specific river basin. On the other hand, by examining a river basin, some generalities with respect to efficiency and equity may be revealed. The Colorado River Basin is the basin chosen for analysis.

PL 92-500 and the Colorado River Basin

A full description of the institutional setting in the Basin is uncalled for. However, some of the institutions that play an important role in the use of the river may be affected by pollution controls. In general, western water rights are based on the appropriation doctrine; that is, first in time, first in right. Each state controls its allocation of water among users, subject to interstate constraints. Most states allocate water rights to those uses termed "beneficial" by the allocating agency. These water rights may or may not be appurtenant to the land and may be transferred more or less freely, depending on the state regulations.

Description of the Region

The Colorado River Basin is large and physically, economically, and institutionally complex. The river has its headwaters in Wyoming, Colorado, and eastern Utah and significant other feeder rivers from New Mexico, southern Utah, and Arizona. The agriculture in the region varies considerably. Irrigated crops in the Upper Basin states (Utah, Wyoming, Colorado, and New Mexico) are generally limited to alfalfa, wheat and other small grains, and silage corn. Some fruit is grown, as are sugar beets, in a few areas. The Lower Basin states have longer growing seasons, and many cash crops are included in the rotation. Citrus crops, lettuce, tomatoes, and a variety of other high-value crops are cultivated both in the Salt River Basin of Arizona and the Imperial Valley regions. Estimations of the value of the marginal product of diverted water in irrigated agriculture range from a maximum of about $35 and an average of about $10 for the Upper Basin states (Anderson et al.) to $70 to $75 maximum and about $30 to $35 average for the Lower Basin states (Kelso, Martin, and Mack; Hedges and Moore). Other estimates from earlier studies show somewhat less difference in value.

Two regional organizations, the Upper and Lower Colorado River Commissions, have some jurisdictional power, as do the seven states served by the river and its tributaries (including California and Nevada). The water allocation between the states is governed by two levels of compacts. The Colorado River Compact divides the water between the Upper and Lower Basins and stipulates a given amount of outflow (7.5 million acre-feet) at Lees Ferry, Arizona. The division of water rights among states is governed by another compact for the Upper Basin states and has been a matter of judicial decision and agreements between the Lower Basin states. In addition, water has been allocated to Mexico by treaty. Thus, the water in the Basin is totally allocated in an "average" year. Further, the agreements and adjudications that were made were based on a series of greater-than-average flow years, so that water has been overallocated for the past years of lower flow. The institutional framework, as will be shown, may impose constraints that conflict with the water quality standards, particularly the zero discharge requirements.

While many pollutants may be found in the effluent of users of the river, salt content is the main pollution problem. This discussion focuses on the salinity problem. While high salinity may be unique to the rivers of arid West, many of the potential conflicts between agricultural production and water quality standards for salinity are relatively broadly applicable.

The salinity problem does have one important aspect that may be atypical of all river basins that have irrigated agriculture—water quality conflicts. Much of the salinity in the Colorado River is a result of natural sources rather than of man's activities. Some disagreement exists among researchers with respect to the amount of salt contributed by the natural sources; a few researchers estimate the natural loading to be from 30% to 40% of the total salt content, while others estimate as high as 75% of the salt is contributed by natural sources. Estimates made by Utah State University researchers indicate 26% or 702,300 tons of salt out of 2,676,000 total tons are contributed by irrigated agriculture in the Green River Subbasin; for the Upper Main Stream of the Colorado, 1,374,760 tons or 27%

of the 5,012,000 tons were from agriculture; for the San Juan Subbasin, 232,000 tons or 23% of the 1,010,000 tons were from agriculture; for the Lower Main Stream, 273,500 tons or 31% of the 882,260 tons were from agriculture; and for the Little Colorado River Subbasin, 18,550 tons or 16% of the 116,300 tons were from agriculture. Clearly, a major portion of the salinity problem cannot be attributed to irrigated agriculture.

The Effect of Water Quality Standards

Given the physical and institutional settings of the Colorado River Basin, what can be expected if water quality standards are imposed on irrigated agriculture? The first, and possibly the most critical, problem will be the enforcement of the standards in general and the zero discharge requirement in particular. Quantifying pollutants from each point source will require a monitor for every farm, if not by the enforcement agency then by the water distributing agency whose discharge in turn is monitored, in order that the cost of treatment (or fines) can be adjudicated. Monitoring groundwater return flows, which add considerable salt to downstream flows, would be economically infeasible if not physically impossible.

Second, if meeting the standards is expensive, particularly if the cost of monitoring is borne by farmers, then any loopholes that would allow escape from the standards will likely be implemented. For example, if irrigation canal return flows from a farm can be considered a point source, the farmer will likely adjust his irrigation practice to avoid the effluent point or conveyance. Natural seepage or water-spreading practices may replace concrete ditches returning water to larger irrigation canals. If fines are very heavy, as the law states ($5,000 for the first offense and up to $50,000 per repeated offenses), it seems likely that ponding or water spreading would be a cheaper alternative to a monitorable point source. Adding to the return flows to groundwater may increase the salt load, depending on the salt content of underlying strata. In much of the Upper Colorado Basin, impervious, salt-laden shale strata cause groundwater flows to pick up heavy salt loads, which often augment downstream surface water through springs and seepage. Thus, water quality controls may lead to a worsening of stream quality in lower reaches.

If the zero discharge standards are imposed on canal companies, as seems more probable given the magnitude of effort required to monitor each farm, then it appears likely that canal companies will be forced to construct end-of-pipe treatment plants. These plants will be quite complex, since pesticides and fertilizers will have to be removed along with the salt load. Current treatment costs for municipal effluent (biological oxygen demand, coliform, etc.) average between $25 and $50 per acre-foot.[2] The estimated cost of a desalinization plant is about $33 per ton of salt removed (Kleinman, Barney, and Litmus) or an average of about $80 to $85 per acre of irrigated cropland for the Colorado River Basin. For municipal treatment facilities, as plant size decreases unit treatment costs rise. If decreasing costs to scale also hold for desalinization, a small irrigation company would likely have extremely high treatment costs. Given current values of irrigation water in both the basins, a significant burden would be placed on agriculturalists. The construction and operation of treatment plants will likely have to be publically financed, with a payback procedure similar to the construction of irrigation dams and canal systems. Further, the fees levied on water users would likely be based on water diversions, rather than on effluent levels, because of the high cost of monitoring each farm in a system and because individual farms might avoid the effluent charge by the ponding or spreading techniques discussed above. This system of charges could be both economically inefficient and inequitable. In fact, such a distribution of charges could lead to encouragement of pollutant production (particularly fertilizers and pesticides), given the common property aspect of the treatment plant ownership.

There are some on-farm technological adjustments that can be made to reduce the pollutant levels of surface water. First, farmers can change their irrigation system to sprinkling. Second, farmers can develop a total containment approach similar to the measures planned by the steam-powered electrical generation and mining companies. The shift to sprinkling irrigation can reduce salt loading by a substantial amount, depending on rates of application and crop rotations (Hanks et al.). Several problems arise with sprinkling irriga-

[2] Current sewage treatment plants are not capable of removing these pollutants.

tion, however. Although salt outflow may be decreased, it is not eliminated by sprinkling.

There is a buildup of salt in the root zone with sprinkling, unless sufficient water is used to "flush" the salt out or unless tile drains are used to prevent capillary effects from bringing salt to the root zones. Even tile drains will not prevent salt buildup where irrigation water is already salt laden. Clearly, flushing would violate water quality standards and zero discharge almost by definition. If the surface is tile drained, the additions of salt to groundwater and thence to surface flows may be eliminated and the surface effluent managed. However, the imposition of zero discharge could eliminate the use of the drains even in the areas that have adopted the practice, since these drains can be identified as point sources. Without flushing or tile drains, yields and profits will decline substantially over time. This reduction in profitability has a compounding effect. Most studies show that, in order that sprinkler irrigation be as profitable as flood irrigation, rotation must change to include more intensive, higher valued crops (Meale, Cannon). Otherwise sprinkling yields either low or no profit, since the capital requirement is very high. Many of these high-valued crops in the Upper and Lower Basins are salt sensitive. Thus, if water quality constraints eliminate flood irrigation and force zero-discharge sprinkling, irrigated agriculture may have a limited role in at least the Upper Colorado Basin in the long run. The extent to which irrigation will continue in the Lower Basin is uncertain simply because of the higher valued crops. It is doubtful that marginal land could sustain the added costs of sprinkling, tile draining, or water treatment.

The alternative to sprinkling is total containment. Ponding for evaporation would be relatively inexpensive. Some have suggested that reuse of ponded water would reduce the effluent problem as well. Unfortunately, at least in large parts of the Basin, ponded water would be salty enough to inhibit production. In fact, many of the potential industrial users indicate that reuse of Colorado River water for cooling is questionable due to its high salt content.

The constraint on total containment by agriculturalists is neither economic nor technical. The institutional framework may prevent the practice for current levels of irrigation. The Colorado River Compact establishes the outflow required from the Upper Basin; similarly, the Mexican Treaty establishes outflow for the Lower Basin. If farmers pond water, there will be a reduction of flow in the river, since current consumptive use is about 50% to 60% of diversions in most areas of the Upper Basin. The return flows from agriculture would be reduced by about half in the Upper Basin and probably by the same percentage in the Lower Basin. Total containment could not be accomplished without some transfer of water rights, even within each state. Several of the states have either state laws or judicial decisions that require maintenance of downstream flows (return flows). There is obviously a "taking" of water rights involved with containment, although market compensation might be the method by which total containment could be practiced by a reduced number of irrigators. Even with total containment, water quality could decline in the Colorado River due to reduced dilution. Where high quality groundwater is used for irrigation, those flows would not augment the river. In fact, the likelihood of developing groundwater for new irrigation will be significantly reduced due to the zero discharge limitations. Those areas that have been developed, or are planned, using saline groundwater for irrigation would very likely have to be abandoned.

The total containment problem points out another weakness of PL 92-500 in situations similar to the Colorado River Basin. Water quality is a function of both pollutant loading and of dilution by additions of relatively clean water. The reduction of high quality return flows in areas where high levels of natural loading occurs may well cause a degradation of stream quality. Imposition of rigid standards like zero discharge could reduce the quality of the Colorado River as a result of wide-scale adoption of total containment by irrigators. At the very least, it is not certain that such standards will improve water quality.

Other technological controls have been suggested. Canal lining and selective retirement of irrigated land have been discussed. These two approaches will have some moderating effect of salt loading in the Colorado River, but only a small portion of the salt loading could be reduced (Utah State University). In addition, canal lining would probably cause significantly more water to require treatment, since seepage does reduce the amount of surface flows that can be identified as point sources. The incentive might be not to line

canals in order to avoid the treatment costs.

From the foregoing discussion, it seems possible that the implementation of water quality standards, especially zero discharge, in the Colorado River Basin may have a large detrimental effect on irrigated agriculture in both Lower and Upper Basins. In addition, the incentive to avoid the standards could lead to decreased water quality. The fundamental economic question is if benefits are gained, are these benefits greater than the implementation costs, and could those who benefit compensate those who lose?

Benefits and Costs

A general theoretical treatment of the externalities of pollution leads to the conclusion that, unless the pollutant is extremely harmful in very small concentrations, the social optimum will occur at a point where some externality exists (for example, Buchanan and Stubblebine). The zero discharge requirement is too restrictive, but the intermediate standards—best practical technology and best available technology—may also be too restrictive with respect to a social optimum. Figure 1 illustrates the economically efficient reductions in agricultural loading, where the marginal damage avoided just equals the marginal cost of control at R^* (Gardner and Stewart). For the Colorado River Basin, upstream salt loading has been the cause of downstream cost to municipal, industrial, and agricultural water users.

There have been several estimates of the reduction of downstream damages, given reduced levels of salinity at Imperial Dam. These estimates range from about $50,000 per year per milligram per liter (U.S. Environmental Protection Agency) to $250,000 per year per milligram per liter (Kleinman, Barney, and Litmus; Valentine). The costs of reducing the salt loading vary substantially. Some methods appear economically reasonable, some do not. The cost of conversion of agriculture in the Basin to sprinkler irrigation is estimated at between $1 and $4 million per year per diminution of one milligram per liter (Utah State University). Clearly, a large cost must be borne by upstream irrigators compared with a relatively small downstream benefit. Further, these values are averages; it is likely that some conversions to sprinkling might generate benefits equal to costs at the margin, but total conversion would pass the point of equal marginal cost and benefits, since marginal benefit would be expected to be falling or constant while marginal cost would be expected to be rising. Other methods, such as canal lining and irrigation retirement plans, have average costs approximately equal to the average benefit. These programs would not reduce the salinity by a great deal (perhaps 10%), yet these appear to be the economically feasible projects. Thus, the existence of externality costs at the social optimum is probable; however, the optimal level of upstream treatment is currently unknown. The same kinds of arguments may well apply to outflows to Mexico from the Lower Basin. Where the social optimum lies is subject for further empirical research, but it is almost assured that the social optimum in this case does not occur at zero discharge.

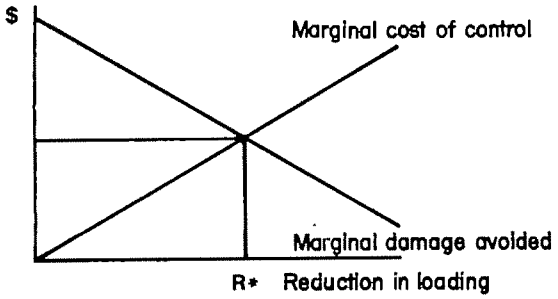

Figure 1. Optimum level of loading reduction

It has been shown that in at least one small Colorado River subbasin, the Virgin River Basin, significant reduction in salt loading requires a substantial diminution in irrigated agricultural acreage. This subbasin is relatively typical, with saline springs and erodable soils that contain moderate to high salt concentrations. In fact, the Virgin River Subbasin has less salt in the soil than the Mancos shale soils of the Cisco, Utah, region. Results of an interfaced hydrosalinity and linear programming model indicate that, in order to achieve a less than 10% reduction in salt loading for the subbasin, an almost 50% reduction in irrigated agriculture is necessary (Keith et al.). Foregone net returns to irrigated agriculture amount to a minimum of $1,000,000 to reduce the salt concentration by not more than 2 milligrams per liter at Imperial Dam. One implication that may be derived is that the social optimum probably would occur at a considerably less stringent controls than zero discharge.

Some Future Consideration

The Upper Colorado Basin contains energy resources that are currently being exploited or whose exploitation is being planned. While energy is not the subject of this paper, there may well be a significant impact on irrigated agriculture as energy develops and responds to water quality standards. First, the energy developments, including steam-powered electrical generation plants, oil shale development, coal mining, and synthetic fuel plants, will all be point sources; therefore, each will be subject to monitoring and the current permit system. Because of the high cost of treating water high in salt, current plans include total containment of waste water from both processing and cooling activities. Since all the water in the Upper Basin has been allocated, these energy developments will be forced to acquire water from current holders of water rights either by reassignment by the appropriate authorities or by purchase. Given the constraints on return flows, these energy producers will have to obtain diversion rights sufficiently in excess of their consumptive use that remaining downstream users have sufficient water available. Thus, less irrigated agriculture will exist than would be the case under less stringent water quality standards. In fact, the Colorado River Assessment Study (Utah State University) indicated that with the development of energy resources less loading will occur as irrigation is reduced, but concentrations will rise as a result of increased consumptive use of water in the total containment activity.

There are also some side issues with respect to municipal waste treatment, both for current residents and future populations of the Basin. There is considerable evidence that effluent from many municipalities is undetectable a short distance downstream from their discharge points. The existing regulation will require large investment in sewage treatment plants by those municipalities. This burden will fall more heavily on smaller communities that generate relatively less effluent than larger metropolitan areas. The water quality standards approach ignores both the substantial costs and the practically nonexistent benefits of pollution control for these municipalities.

There are also several planned water exports in the Upper and Lower Basins. While these exports are not identified as point sources of pollution, they may well have significant impacts on the water quality in the river. As water is withdrawn from the river, less dilution of the salt load takes place, and the concentration rises. These exports may be more significant to water quality than loading from either the agricultural or energy sectors, yet PL 92-500 will have no regulating effect.

[3] Consumptive use may be as low as 30% to 40% in some parts of the Upper Basin.

Summary and Conclusions

The application of water quality standards to irrigated agriculture will be, at best, difficult. Whether the law even applies to most irrigated agriculture is open to question. The ability to identify the sources of effluents or to monitor identified sources is doubtful. If the standards are applied, agriculturalists will have to alter their current practices and may be forced to cease irrigation due to economic infeasibility of meeting standards, particularly the zero discharge requirements. In addition, the benefits gained to downstream users will likely be much smaller than the costs borne by upstream users for achieving zero discharge. Irrigated agriculture will not be the only sector that is affected; the imposition of the rather arbitrary standards, including eventual zero discharge requirements, will impose very high costs on small rural municipalities in the Basin with little or no detectable improvement in water quality in the river. With the advent of energy development and large water transfers, the effluent standards may, in fact, worsen the water quality.

Apparently, PL 92-500 is an ill-conceived approach to the water quality problems that result from irrigated agriculture. Given the importance of irrigated agriculture to the West, the "legalistic" physical standards approach may lead to a loss in social welfare rather than a gain.

Discussion

Norman K. Whittlesey

The paper by Robie is primarily a series of observations of legal, economic, and institutional problems highlighted by a recent two-year drought. Apparently, the abilities to adjust to lower water supplies exceed the previous expectation of most people. This result should not have been surprising since much of the arid world survives very well using much less agricultural and municipal water than we do.

Any thoughtful economist should have anticipated that water use will be high when it is cheap and plentiful and that, even in the short run, adjustments can be made to raise the average productivity of water as it becomes more scarce. Robie expressed surprise at the willingness of farmers to pay more than $40 per acre-foot for water. However, in a longer run setting, we should expect such a phenomenon to be common with concomitant adjustments in other resource values, particularly that of land. As time passes and the opportunities and incentives for adopting different technologies and management practices are presented, we should expect the ability to survive with less water to improve significantly. What we have seen are normal adjustments to a resource having greater relative scarcity.

On further thought, we should not be so surprised by a drought of this length or severity when our experiences into the past are so brief. Archeological research collecting weather information from the past 5,000 years has shown that equally or more severe droughts have persisted for periods of twenty to forty years. Thus, scientists, including economists, should expand their thoughts and research to consider the necessary preparations for and potential adjustments to such a phenomenon. We might take heed of Kelso's comments in the fellow's lecture and make plans that do not require using all available resources all the time.

The paper by Burt, Cummings, and McFarland provides an analytical construct for estimating optimal rates of groundwater mining. The authors use linear programming to generate data for a function that in turn estimates income for alternative levels of capital stock and groundwater withdrawal rates. They show that, as the discount rate goes up, there is a greater willingness to mine the groundwater and capture its value in the present rather than preserve the water for future use. The higher the discount rate, the more mining that is allowed before the desired steady-state level of groundwater stocks is achieved.

While this is a neatly packaged device for generating such information, the result is exactly what one should expect. So, while the Burt, Cummings, and McFarland procedure or others could be used to provide this kind of information, there remains the important question of how it can be put to use. It is not obvious how local or state policy makers are going to be led to the optimum discount rate or rates of declines in the static water level. Those who ultimately choose discount rates and, in turn, the rate of groundwater mining are often politically elected or appointed. This leads to a very short planning horizon and implicitly imposes a high discount rate on the decision process. The result too often is to exhaust the resource in a relatively short time period in order to satisfy the short-term demands of political constituents. The opportunities for using the water are eliminated for the future when societal needs for potable or fresh water may be much greater than at the present. Kelso's reversability criteria are violated.

Some factors that need consideration in a water-mining situation but not adequately discussed in this paper include: capital assets should not require more rapid depreciation due to declining water levels than their normal wear-out period; the impact of rising energy costs or energy shortages anticipated for the future should be considered; and, importantly, the application of such information cannot be left entirely to the ingenuity of policy makers. It would be interesting and useful to attempt to calculate the optimal discount rate for satis-

Norman K. Whittlesey is a professor of agricultural economics, Washington State University.

fying long-run societal needs in such a setting. There are remaining questions of who gets to capture the wealth from the water, how to tax its use, and who should be the last (first) to quit pumping. It seems that the present laws for water appropriation in the West are no longer adequate for allocating scarce groundwater resources that properly belong to all of society. These are problems that have largely been left to the politicians and institutions. The economist could offer much more than in the past.

Keith properly identifies the Federal Water Pollution Control Act Amendment of 1972 (PL 92-500) as having been directed at "point sources" of pollution. However, he proceeds to assume that the same standards will automatically apply to irrigated agriculture. It is my understanding that the rules, standards, and methods of enforcement that may eventually be applied to irrigated agriculture are yet to be determined. While there undoubtedly will be increased attempts to reduce the pollutants associated with irrigation return flows, the methods of achievement and levels of abatement are yet unknown. Certainly the assumption of zero discharge is not valid at this time.

We should dismiss zero discharge as a constraint on agricultural water use and proceed to consider more realistic solutions to this problem. It is most likely that such things as appropriately applied best management practices or best available technology will ultimately lead to the desired societal solutions. This attitude then opens up the possibility of a number of economic, legal, and institutional instruments to influence pollution abatement, which went unconsidered by Keith. These include taxes on inputs such as water and fertilizer, bribes (compensation) to influence the choice of irrigation system, water rationing, and constraints on crop selection for specific soil types or slopes, to name a few. Certainly, little pollution abatement can be achieved without imposing some costs on some segments of society. However, research in the Yakima River Basin of eastern Washington indicates that up to 50% of current levels of pollution from irrigation return flows can be abated at relatively low cost to society. Abatement levels greater than 50% will face rapidly increasing costs, and the distribution of these costs will depend upon the method(s) employed to effect the control and the estimated distribution of benefits derived. Of course, the experience of each irrigated area will differ.

Another fundamental error underlying some of the conclusions by Keith is the assumption that irrigation diversions will (or must) remain constant following the achievement of improved water use efficiencies on the farm. The movement to better management or more efficient irrigation systems need not result in less water in the Colorado River. The dilution effect of reduced diversions could be very helpful in achieving desired improvements in water quality.

Keith does properly recognize the importance of measuring the benefits from pollution abatement as the relevant criterion for determining the desired level of abatement. This is an area lacking the proper attention of economists to date. We have focused elaborate models on the cost side of environmental improvement without adequate regard for the benefits to be derived from such activity. Until we provide decision makers with better measurements of such benefits, there will continue to be controversy over determination of the proper level of abatement. A representative of the Sierra Club or Friends of the Earth will most certainly have a different view of what should be achieved than a representative of the agricultural sector. Thus, I would encourage any efforts that will provide a better assessment of the benefits to be derived from abating pollution from irrigation return flows. The choice of abatement levels and the distribution of their costs would then become much easier.

The Recent Performance of Rural Financial Markets

Agricultural Credit Policy in Brazil: Objectives and Results

Paulo F. C. de Araujo and Richard L. Meyer

A number of developing countries have stressed credit policies to achieve agricultural goals. It is frequently difficult, however, to evaluate their effect because the amount of funds involved has been small or their impact has been masked by other development policies. The Brazilian case is revealing because huge amounts of credit have been channeled to agriculture, and credit policy stands out as a key component of agricultural policy. Thus, the Brazilian experience provides insights into what countries might expect if and when they assign credit policies such an important role. Furthermore, commercial banks have been used almost exclusively to supply the credit rather than creating new specialized agricultural credit institutions. Thus, the Brazilian case provides some evidence into how an existing banking system can be used to service agricultural credit needs in a developing country. This paper analyzes Brazilian policy objectives and the impact of credit on agriculture.

Brazilian Agricultural and Credit Policies

Like many Latin American countries, Brazil has heavily regulated its financial markets in pursuit of development goals (Eckaus). It is unique, however, because of the energy and initiative with which it has pursued conventional and innovative prescriptions in the financial sphere (Yusuf). Portfolio ceilings and quotas, discount mechanisms, and reserve requirements have been extensively employed to affect bank behavior in developing countries (Johnson). These methods plus interest rate controls and regulations on bank mergers and expansion have been used in Brazil. The usual indirect mechanisms of monetary control have also been used to influence the supply of credit.

Brazilian objectives for this intervention include modernization and increased efficiency in banking, enlarged financial services to less developed regions, and increased capital availability for particular sectors including agriculture. The strategy explicitly attempts to alter bank behavior through selective controls so resources flow to socially desired sectors and activities. The magnitude and comprehensiveness of the strategy suggests a "supply-leading" relationship between financial and economic development (Patrick).

The institutional credit system for agriculture consists largely of private and "official" banks (Meyer et al.). Official banks have various degrees of state and federal government ownership and capital and hold public sector deposits. The National Monetary Council and Central Bank created in 1964 provided the federal government with an effective means to control bank behavior. Furthermore, a large part of agricultural credit comes from funds administered by the Central Bank and/or the federal Bank of Brazil.

The stated objectives of agricultural credit were established in 1965 by the Agricultural Credit Law 4829: (*a*) finance a portion of operating costs of agricultural production and marketing, (*b*) stimulate capital formation, (*c*) accelerate the adoption of modern technology, and (*d*) strengthen the economic position of farmers, especially small and medium ones. An implicit but very important objective ap-

pears to have been the use of credit subsidies to compensate farmers for the price and exchange rate controls designed to stimulate industrialization and control inflation. Moreover, credit policies have been used to address short-term problems like high fertilizer prices and the 1975 coffee freeze. Combining credit controls with product pricing policies has resulted in a comprehensive system for influencing factor use and output in agriculture.

A vast number of rules, regulations, programs, and subprograms have been applied to agricultural credit. Each program has specific objectives, interest rates, and repayment schedules. Three general features of agricultural credit policies need to be emphasized. First, nominal interest rates have been controlled at rates lower than those permitted for other loans. During the last decade, these controls resulted in negative real rates of interest (i.e., nominal interest rates lower than the rate of inflation). Second, incentives and controls have been used to induce banks to lend more of their own deposits and/or government funds to agriculture. Third, nominal interest rates for small loans (supposedly made to small farmers) have been set 1 or 2 percentage points below large loans.

Credit and Performance of the Agricultural Sector

The first major result of Brazilian credit policies has been a sharp expansion of formal credit supplies. Table 1 shows loans made each year and agricultural production for the 1960–75 period. Columns 1 and 2 list operating loans, usually with terms of less than a year, which represent about half the number and value of loans made in recent years. The remainder of the credit is split between marketing loans[1] with terms of a few months and investment loans payable over several years.[2] In this period, agricultural output rose 2.3 times. New loans made per year rose almost 15 times. The ratio of operating loans to agricultural output (column 6) rose from 0.07 in 1960 to 0.27 in 1974, while the ratio of total loans to output rose from 0.13 to 0.59. In 1975, the first ratio jumped to 0.37 and the second to

[1] Substantial amounts of marketing loans go to individuals other than farmers. Thus, column 2 underestimates the total short-term credit obtained by farmers, while column 4 overestimates total credit.

[2] Little institutional credit is available for farm real estate mortgages, so investment loans are lent largely to finance machinery, livestock, and perennial crops.

0.83 due in part to major funding for drought relief and coffee recuperation. These ratios are among the highest found in most other Latin American countries in the late 1960s (Adams).

Piza compares the indebtedness of agriculture relative to other sectors. He found the credit to output ratio for agriculture grew much faster in recent years. Although Brazil's general economic development strategy is oriented towards accelerating development through financial means, the agricultural sector has been especially favored with subsidized credit.

No comprehensive study exists on agricultural capital formation. Schuh cites data suggesting the structure of farm capital shifted away from real estate between 1940 and 1965, while the share in equipment rose. The 1970 census shows that land and buildings represented 68% of total capital assets, 18% in productive and work animals, 9% in permanent crops, and 5% in farm machinery and vehicles (Brazil, Fundacao Instituto Brasileiro de Geografia e Estatistica). It appears that the value of land and buildings still commands a large share of farm capital because of increases in farming area and land prices. Some of the rapid increases in credit may have been capitalized in land prices.

Credit policies have encouraged the adoption of both biological and mechanical technology. Programs have been introduced to finance so-called "modern inputs" including improved seeds, fertilizer, lime, agricultural chemicals, and livestock rations. Nominal interest rates have varied from 0 to 7% much of the time. Likewise, purchasers of domestically manufactured machinery have benefited from five- to eight-year loans with nominal interest rates ranging up to 15%, occasionally with a two-year initial grace period. Chemical fertilizer use rose from 380,000 metric tons in 1966 to more than 2 million in 1976 (Araujo et al.). Allegedly, the quantity of fertilizer supposedly financed in some regions has exceeded the amount actually sold. Domestic tractor production per year grew from 6,300 units in 1967 to over 62,000 in 1975 (Brazil, Instituto de Economia Agricola).

For the census, farmers reported investing Cr$4.4 billion (in cruzeiros) in on-farm investments in 1970. Of this total, Cr$2.2 billion was spent for machinery, livestock, and permanent crops, all of which were eligible for credit. The Central Bank reported Cr$2.5 billion in new institutional loans for agricultural investments that year (Brazil, Banco Central). Over 50% of the investment loans were reported for machinery purchases, and almost two-thirds of these loans were made in the states of Rio Grande do Sul, Parana, and Sao Paulo, which accounted for over 75% of the tractors reported on farms in 1970. It is quite likely, then, that credit for investment has been highly correlated with new machinery purchases. This conclusion is consistent with the tractor demand model estimated by Sanders for 1950–71. The variable for real value of tractor financing overshadowed the variable measuring tractor price relative to agricultural wage rates.

Distribution of Farms and Credit

Table 2 shows the size distribution of farms as reported in the 1970 census.[3] The total number of farms increased from 3.3 million in 1960 to 4.9 million in 1970, while the total farm area increased from about 250 million hectares to almost 295 million. Over a million new farms were added to the less than 10 hectare group, while the average size decreased from almost 4 to 3.6 hectares. The inverse relationship between farm size and value of production noted in several countries was found in Brazil in 1970. The first two size strata represented 90% of the farms, 23% of the area, and 58% of the production. Units of 10,000 or more hectares represented less than 0.1% of the farms, 12% of the area, but only 2% of the production.

Surprisingly, almost 90% of the Brazilian farms reported no credit from any formal or informal source in 1970. Even allowing for possible data limitations in the census, credit use was much less widespread than anticipated. About one-fourth of the farms in the upper three size strata reported receiving loans. Only 5% of the farms in the smallest strata reported loans. Thus, over 90% of all farms in the country were still untouched by credit programs in 1970.

Table 2 also reports the distribution of total volume of credit. Government entities provided almost 80% of the Cr$4.1 billion in credit reported in 1970. The two smallest farm size strata received far less credit than their share of farm numbers, while the three larger groups received far more. Considering farm area,

[3] See footnote b, table 2, regarding the definition of a farm used in the census.

Table 2. Distribution of Farms and Value of Credit Received, Brazil, 1970

Farm Size Strata (Ha.)	Farms	Area[a]	Production	Sources of Credit: All Sources	Individuals	Government Entities	Private Entities
				%			
Less than 10	51.1	3.1	17.8	5.5	13.2	4.2	8.5
10 to less than 100	39.3	20.4	40.0	33.1	35.1	33.4	29.4
100 to less than 1,000	8.4	37.0	29.3	41.8	30.5	44.2	34.0

Source: Brazil, Fundacao Instituto Brasileiro de Geografia e Estatistica.
Note: In the Brazilian census, farms are defined as "establishments" (Brazil, Fundacao Instituto Brasileiro de Geografia e Estatistica). A farm is a unit with one or more adjacent parcels under a single administration. Two nonadjacent parcels are treated as separate farms even if they are under a single administration. Likewise, parcels are treated separately even though owned by the same person if they are rented or sharecropped to two different persons with separate administration.
[a] An unknown bias exists in these data due to the farms not reporting size.

however, the first three strata received more credit than their land share. Considering value of production, the two smallest strata received less credit than warranted by their production, while the 100 to 1,000 group appeared to be especially favored with credit from government entities. Thus, according to the 1970 census, Brazilian policy makers had not succeeded in increasing agricultural credit for small farmers.

An analysis of the regional distribution of credit showed that approximately 75% went to more commercialized agricultural regions. Farmers in the state of Sao Paulo alone produced over 20% of the 1970 agricultural output and received one-fourth of total credit. Estimates of that state's credit to output ratio were even higher than for the rest of the nation. Results from farm surveys suggested that the state was increasing the share of credit going to small farmers.

Conclusions and Implications

Brazilian policy makers have established a complex set of controls and incentives to increase the quantity and lower the cost of agricultural loans. The volume of formal credit lent to farmers has sharply increased. But most farmers still do not receive credit, and the amount going to small farmers is especially low. Agricultural output and the use of some modern inputs have expanded. However, since value of production is a criterion for lending, it is difficult to establish a clear line of causality between credit and agricultural performance. There probably has been some substitution of external for internal funds.

The banks' response to the distortions introduced in the financial market is understandable. Compensating balances and noninterest costs and fees are widely used to increase returns from agricultural loans. Banks with a clear profit orientation have been especially reluctant to increase long-term agricultural lending. Loan procedures are cumbersome and increase borrowing costs.

Two important unanswered questions exist regarding the Brazilian experience. First, what would have been the demand for credit if agriculture would have been less discriminated against through price controls, overvalued exchange rates, and export controls? Second, would bank performance have been better, especially on equity grounds, if there would have been more incentives for agricultural lending? The two questions appear to be related. A justification for subsidized interest rates is to offset the discrimination of other policies. But interest rate controls reduce bank profitability. Thus, a logical tendency by banks is to reduce costs by lending to large farmers and to use nonprice methods to allocate credit.

Commercial banks can play an important role in financing agriculture in developing countries. The Brazilian experience suggests that establishing an appropriate set of incentives is crucial in affecting bank behavior. Flexible interest rates and simplified lending procedures are essential. General lines of credit should be created to meet agricultural development objectives. A special line of

credit, including loans for land purchase, is probably required if the economic position of small farmers is to be improved. However, the proliferation of specific credit programs to resolve specific short-term agricultural problems must be avoided.

Credit Policies and Rural Financial Markets in Bolivia

Jerry R. Ladman and Ronald Tinnermeier

The early works of Patrick, Gurley and Shaw, and more recently McKinnon and Shaw stress the important role of financial markets in influencing the extent and pattern of economic development. Adams and Gonzalez-Vega were early authors to examine the specific role of rural financial markets (RFM's) in mobilizing savings from and delivering credit to farmers in less developed countries. There are three major separate but interdependent roles that RFM's are expected to perform: mobilize rural savings, allocate credit among productive activities in agriculture, and integrate the RFM's with the capital markets of the rest of the economy and the world. Often a fourth role of income distribution is added, i.e., ensuring that credit is directed to the potentially viable small farmer.

The development of Bolivian RFM's in many ways serves to illustrate not only the nature of the institutional and structural unfolding of RFM's in the course of modern day development but also to show how well-intended policy measures—many of which were induced by foreign donors and have been rather ubiquitously applied throughout the third world—have been inadequate and often have led to what are considered undesirable results especially in directing credit to the target group of small farmers. Thus, this paper proposes to show the stagewise development of the formal Bolivian RFM's, analyze the influence of agricultural and credit policy in the development and performance of these RFM's, and set forth some policy recommendations for directing more credit to the large number of Bolivian small farmers.

Jerry R. Ladman is an associate professor of economics and director of the Center for Latin American Studies, Arizona State University, and Ronald Tinnermeier is an associate professor of economics, Colorado State University.

Research for this paper was supported in part by the U.S. Agency for International Development, Bolivia. The Agency is not to be held responsible for the content of this paper.

The Development of Bolivian Agriculture and RFM's

Prior to the Revolution of 1952, Bolivia had little need for well-developed rural financial markets. Apart from a strong tin-mining industry, the country had progressed little since colonial times. Political instability reigned; little manufacturing existed; and most of the population was Indian, living on large estates in the high mountain plains and valleys as traditional peons or farmers of small plots. Commercial agriculture was not widespread, and the country imported basic food stuffs and exported virtually no agricultural products. After the Revolution the major tin mines were nationalized, and the large landed estates were broken up and parceled out to the campesinos under an extensive land reform program. A major program was launched to develop the sparsely populated tropical plains east of the Andes (Oriente) where petroleum and tropical hard woods were located and fertile soils offered potential for agricultural and livestock activities. Considerable foreign economic and technical assistance poured into the country, especially that of the U.S. Agency for International Development (AID).

The government established major goals of import subsitution of basic food stuffs and higher incomes for the beneficiaries of land reform. Although offices were established within the Ministry of Agriculture for the standard activities of extension, research, etc., these programs had difficulties due to the lack of financial support and trained personnel. Agricultural credit was considered to be a main policy instrument, and the Agricultural Bank of Bolivia (ADB) was the main source. It was not until the 1970s, given the reorganization associated with the land reform and the uncertainty and consequent instability associated with the new leftward leaning government, that the agricultural sector began to

grow rapidly. Growth rates of 2.1%, 3.9%, and 6.7% were observed for 1973, 1974, and 1975, respectively. A number of factors contributed to this growth. Perhaps most important was the military coup of 1971, which established a conservative but progressive-minded government that created an ambiance of political stability. Second, by this time the Oriente flourished under rice, sugar, and livestock production and also entered a favorable cotton export market. Third, the land reform program was consolidated such that many of these farmers were in a position to enter commercial production. Fourth, considerable foreign assistance was directed to the sector—in 1971–73 it accounted for 30% of the agricultural budget (Wennergren and Whitaker).

Agricultural credit facilitated this expansion, and the partial development of more extensive RFM's has been observed since 1967. As shown in table 1 the real value of the annual flows of agricultural credit from the Bolivian banking system grew 4.6 times during 1967–75. In 1967 the ADB accounted for over 90% of this credit, but by 1975 the percentage had fallen to 54, indicating important, absolute, and relative increases by the commercial banks. (In 1975 about 28% of the total agriculture credit was extended by the government's State Commercial Bank and 18% by the several private banks.)

In spite of this impressive increase and structural change there are a number of indicators that Bolivian RFM's were not performing the previously specified major roles well. First, there is little evidence that rural savings are effectively being mobilized, particularly among small farmers. Although Bolivians experienced an eight-fold increase in real savings deposits in banking and nonbanking institutions during 1966–75, most institutions and offices are located in major urban centers and, apart from some relatively minor cases, cater almost exclusively to urban clientele (Ladman, Tinnermeier, and Torrico). Furthermore, the ADB does not have a savings account window. It is expected, however, that medium and large-sized farmers have savings accounts in the cities.

Second, credit was being distributed disproportionately to the Oriente and to medium and large-sized farmers rather than to the campesinos in the high plains and mountain valleys. Almost all private bank credit and 70% of the loan volume under the AID financed rediscount program (FRA-1) went to the Oriente, while three-fourths of the ADB credit during 1964–74 went to the same region (Ladman, Tinnermeier and Torrico).

Third, Bolivian RFM's do not have strong linkages with domestic and foreign financial markets except those that are forced by the Central Bank and foreign aid. Monetary savings are not being extensively generated, and commercial banks tend to steer away from agricultural loans. Agricultural lending would likely be considerably reduced were it not for foreign aid earmarked for that purpose of which most must be used to cover the decapitalization created by the severe delinquency problem experienced by all banks. The average annual delinquency rate for the ADB between 1972 and 1975 was 44.5%. If a number of previously delinquent loans had not been refinanced, the rate would have been even higher (Banco Agrícola de Bolivia

Table 1. Annual Credit Flows to Agricultural Private Sector in Bolivian Banking System, 1967–75 (Millions of 1966 Pesos)

Year	Total Agricultural Credit	Percentage of Total Agricultural Credit		Commercial Bank Agricultural Credit as Percentage of Total Commercial Bank Credit
		Agricultural Bank of Bolivia (ADB)	State and Commercial Banks	
1967	41.6	90.1	9.9	0.8
1968	45.5	74.0	26.0	1.9
1969	79.7	82.8	17.2	2.2
1970	74.1	74.3	25.7	2.9
1971	122.3	43.9	56.1	9.0
1972	178.4	61.0	39.0	5.6
1973	280.3	63.4	36.6	7.6
1974	207.6	66.2	33.8	6.4
1975	192.1	53.7	46.3	7.6

1977).[1] In the same time period the State Bank and the private banks were experiencing rates of 30% to 50%.[2] In fact, primarily due to delinquency problems, the State Bank decided to withdraw from agricultural credit in 1976.

Credit Policy and Its Effectiveness

As noted previously, prior to 1967 Bolivian agricultural credit policy relied on ADB to finance agriculture. This bank was established in 1942 and in 1954 received its first foreign loan from AID. In the 1960s it was the beneficiary of several other AID, Inter-American Development Bank, and World Bank loans aimed at increasing domestic production of basic food stuffs. Concessional interest rates were also utilized not only by ADB but also by the Central Bank for the commercial bank agricultural loans. The low levels of commercial bank lending suggest the rates were not successful in inducing agricultural lending.

In 1967 the Central Bank established a policy to force the flow of commercial bank credit to agricultural and other productive activities. It required each bank to lend at least 70% of its loan portfolio to productive sectors by 1971. To facilitate this requirement the Central Bank expanded an existing program of special rediscount credit lines for agricultural loans. Foreign aid played an important role through the Special Fund for Economic Development and the FRA-1 and the FRA-2 programs financed by AID in 1967, 1972, and 1975, respectively. Loans refinanced by these special lines accounted for much of the increase in agricultural lending since 1967 in the State Bank, ADB, and private credit. In addition ADB received extensive external financing not only by AID but also by the World Bank, the Inter-American Development Bank, and the Banco do Brazil. How have these policies contributed to the performance of Bolivian RFM's?

Delinquency is perhaps the most threatening problem to the agricultural banking system in Bolivia. Not only does it decapitalize the institutions and increase their reliance on foreign assistance but it also discourages lending to agriculture. The present-day Bolivian problem in many respects is due to crop failures and unfavorable prices reflecting the lack of supportive infrastructure, appropriate technology, and an adequate marketing system. Another major reason is the lack of absorptive capacity by the credit institutions to appropriately administer the large volumes of new agricultural loans under the special lines of credit. It is little wonder that the State Bank experienced so many loan failures when that institution did not have adequate professional staff to properly analyze and supervise credit.

Bolivia also suffers from a nonrepayment mentality. Bankers and borrowers alike accept the slightest pretext for farmers not repaying. Unfavorable natural conditions and poorly designed loans feed this attitude. Historically, loans have often been made, especially to larger farmers, on a political basis. In many such cases the borrower has almost assumed he had the right not to repay because he knew that legal pressure would not be brought against him. In recent years this has been especially prevalent in the Oriente for cotton and soybean loans, which account for a very significant portion of the delinquent portfolio. A factor that accentuates this practice is the concessional interest rate policy, which encourages borrowers to seek credit for ostensibly agricultural purposes but which in fact is directed to other activities or investments (agricultural illusion). This situation is exacerbated when, due to high rates of inflation such as Bolivia experienced in 1972 through 1974, the real rate of interest is in fact negative and results in an income transfer to borrowers. Clearly, policy has not mitigated but rather worsened the repayment problem.

Bolivia has few policy instruments designed to mobilize rural savings. The ADB does not have a savings window, and most commercial banking is confined to urban centers. Most cooperatives have not been successful in generating savings, and credit unions are only beginning to move into rural areas. Our case studies show that small farmers hold cash reserves and also have relatively liquid investments in livestock. Few, however, know anything of formal savings institutions. The Central Bank has had a minimum nominal interest rate policy on commercial bank time deposits of about 10% over the last ten years. Given inflation and the opportunity cost of money it might be argued this rate is too low; however, the recent large increase in savings in the

[1] Delinquency rates are computed as percentage of outstanding loan portfolio at the end of the year.

[2] For example, during 1972–75 the percentage of loans repaid under the special credit line program (FRA-1) were 20%, 35%, and 43% for the ADB, the State Bank, and the private commercial banks, respectively.

urban centers suggests that other factors are also important. In rural areas an important factor is the lack of an institutional structure to encourage savings.

The Bolivian government in its efforts to reduce agricultural imports and to take advantage of the favorable world cotton market made the conscious decision to direct the bulk of credit to the Oriente region. No doubt they reasoned this was the most rapid and least-cost way of obtaining additional output. If the RFM's were functioning correctly, this would mean resource productivities were higher in this region. Data are not available to measure this. Nevertheless, it does appear that existing governmental policy has created some inequities in the system. Certainly concessional rates of interest, especially in periods of high inflation, have biased credit towards capital-intensive investments leading to regional and on-farm misallocation of resources. Furthermore, these rates encourage agricultural illusion, which leads to intersectoral and regional misallocations. It is widely believed that many of the cotton and soybean loans in the Oriente went for other purposes including foreign investment.

The import substitution and export policies also exacerbated the regional distributional disparities, since the activities supported by these policies are heavily concentrated in the Oriente. This is a somewhat paradoxical result for Bolivian agriculture and illustrates conflicts among policy goals, since credit was not directed in the main to the beneficiaries of land reform.

There has been considerable rhetoric about financing campesinos, but the evidence shows, both in terms of numbers and volumes of loans, that most credit has gone to medium and large-sized farmers, much of it in the Oriente but also to these same select groups in the mountain valleys. The bulk of the small farmers who live in the altiplano and mountain valley regions were untouched. Nevertheless, it is now recognized that, for the long-run interest of social and economic development, credit and other resources must be directed toward this large mass of farmers. To this end Bolivia with AID's encouragement and funding developed two small farmer credit programs in 1974. One, FRA-2, was for a special line of credit to be rediscounted to the commercial banks and ADB for loans to small farmers. The second was a small farmer supervised credit program administered by ADB. In 1975, AID funded a program to develop credit cooperatives among small farmers. At this point the programs appear to have been relatively successful in providing credit to these farmers. Delinquency has not been a major problem to date. They would appear, however, to result in high transactions costs for both farmers and banks.

Several policies were established to force linkages between RFM's and other financial markets. Foreign aid has been effectively tapped; during 1966–76 foreign donors committed over $92 million for agricultural credit (Ladman, Tinnermeier and Torrico). Special credit lines utilize not only foreign aid but also government revenues. In addition, commercial banks must employ part of their own capital in financing these loans. Without these interventions it is very unlikely that many funds would have flowed to agriculture through the banking system. On the other hand, concessional interest rate policy has inhibited the flow of funds to agriculture. The low rates charged by ADB and the commercial banks relative to their borrowing costs on the open market leave little margin to cover operating costs and risk and to provide for capital growth. There have been no policies directly aimed at mobilizing rural savings.

Conclusions and Policy Recommendations

Although it is easy, as we have done, to point out the failures and problems of rural financial markets and credit policy in Bolivia, the country should be commended for the progress that it has made in financing agriculture given that only twenty-five years ago the country was considered to be one of the most traditional and less developed countries in the world and one with little development of financial markets, much less RFM's. Considering the major steps that were required to try to overcome the institutional structure that inhibited growth, the lack of human capital and expertise in agriculture, and the political instability, it is somewhat remarkable that the RFM's have progressed to their present level. It is clear that this progress would not have been attained without massive foreign assistance. Nevertheless, as noted previously, many of the policies employed gave rise to undesirable results. It appears that Bolivia has crossed the first stage of establishing the rudiments of an RFM and now needs to concentrate on the

second stage of consolidating, correcting for past policy errors, and adding to the RFM structure. On the basis of the findings in this paper, the following policy elements seem to be called for during the second stage.

(*a*) The concessional interest rate policy should be revised in order to increase returns to lenders and thus stimulate their lending to agriculture, reduce agricultural illusion and raise the social marginal productivity of credit, stimulate the linkages between RFM's and other financial markets, and reduce the delinquency problem.

(*b*) An appropriate deposit rate and institutional structures should be established that will mobilize rural savings in order to increase the supply of loanable funds.

(*c*) More attention should be placed on small farmer credit programs with special emphasis on the capacity of existing and alternative institutional forms of the country to serve their credit needs.

(*d*) The absorptive capacity of lending institutions must be increased. This has three dimensions: upgrading and training of bank personnel not only in matters directly related to agricultural credit but also to bank management, the development of more efficient credit delivery systems within the existing institutions, and experimentation with alternative institutions such as cooperatives and credit unions.

(*e*) Immediate attention must be focused on the serious loan repayment problem and its solution. The current delinquency rates directly affect the financial viability of both the lenders and borrowers and must be significantly reduced for the RFM's to function effectively.

(*f*) An appropriate set of policies should be developed that support or condition the overall functioning of RFM's but that are not sufficiently discussed in this paper, including policies in the areas of marketing, prices, trade, infrastructural development, technology development, and dissemination among others.

Some Current Aspects of Agricultural Finance and Banking in the United States

Emanuel Melichar

For the past twenty years or so, farm credit markets and mechanisms in the United States have been recommended to others as models worthy of emulation. Analysts commenting on overall current developments have generally concluded that "credit-worthy" operators of commercially viable farms could obtain "adequate" financing at "reasonable" rates and other terms. It is true that many specific aspects of the system were continually being questioned and reexamined—whether groups such as expanding farmers, beginning farmers, or marginal operators were obtaining economically or socially desirable amounts or terms of credit; whether optimum terms were being used for machinery and other types of loans; and whether certain lenders such as small rural banks could cope with increasing individual and/or total farm loan demands (Melichar 1975). But these concerns represented "fine-tuning" of a system with which most borrowers, lenders, and analysts were generally pleased (Brake and Melichar).

In discussing the successful performance of U.S. farm credit markets, analysts generally emphasize the diversity of lenders meeting various farm loan demands and the suitability of lending terms and techniques. Another integral aspect, however, is the very favorable farm loan repayment record that has generally prevailed since the beginning of World War II and which certainly underlies the heralded responsiveness of lenders to farm loan demands. The lack of severe farm loan repayment problems in the 1950s, during what was regarded as a postboom era, made a profound impression on lenders and on research workers in farm finance. This favorable experience led them first to accept greater relative use of debt financing and in short order to actively encourage more highly leveraged financial positions as a means of increasing the growth rate of the income and wealth of individual farmers. This paper examines the possibility that the coincidence of these attitudes with the boom in farm capital expenditures and land prices that began in 1972 may culminate in the reappearance of problems that U.S. farm credit markets have not faced for nearly four decades.

In its 200 year history, U.S. agriculture has experienced a number of boom-bust sequences that dominate its financial history. Jones and Durand note that four major farm investment and land-price booms preceded World War II, with each followed by about two decades of severe farm mortgage debt distress. The boom of World War I was triggered when operators' real net farm income jumped by 48% between 1916 and 1917. In spite of subsequent annual declines that by 1920 had pushed such income below its 1916 level, capital expenditures and land prices rose substantially until 1920. The boom ended when farm income virtually collapsed in 1921 and remained relatively depressed during that decade. The national index of farm land prices fell during each year of the 1920s, registering a total decline of 33% by 1929. The effect on farm lenders was correspondingly grave. For example, nearly 6,000 commercial banks failed during the period 1920–29, most of them in rural states. As is well known, the onset of the Great Depression further aggravated these farm financial difficulties.

After this period of financial adversity, the farming sector experienced another boom during 1941–52. This boom was followed by widespread financial problems that were characterized as a "cost-price squeeze" but not by general debt-repayment distress. The primary

Emanuel Melichar is a senior economist in the Division of Research and Statistics, Board of Governors of the Federal Reserve System, Washington, D.C.

The analyses and conclusions presented are solely those of the author and do not necessarily reflect the views of the Board of Governors or of other members of its staff.

new factor thought responsible for this result was the government price support program for major crops, which limited the decline in net farm income. Financial innovations such as amortization and longer maturities of farm mortgage loans, federal insurance of bank deposits, and federal lending programs were also considered to have been helpful.

Yet another boom began in 1972. With the aforementioned programs and arrangements still in place, most farm credit market participants and analysts appear to have implicitly adopted a sanguine view of the postboom future, in which experience more adverse than that of the 1950s is regarded as improbable. A hallmark of this view is that farm land prices are not likely to fall significantly, if at all. Apparently, any postboom financial distress is expected to be mild or of short duration.

This view may be, in part, still another legacy of the experience of the 1950s; thus, it may be useful to take note of the many differences between the financial situation then and now. First, however, some major uncertainties should also be noted. For instance, at the end of the earlier boom it turned out that farm land prices were consistent, on average, with the level at which the federal government was initially willing to support the prices of major crops. The postboom fall in the national index of land prices was limited to a slight decline in a single year, 1953. The degree of compatibility directly after this boom remains to be revealed. Recall, also, that analysts in the 1960s agreed that the combination of decreasing unit costs of production and stable, supported output prices was the chief factor responsible for the upward trend in land prices after 1953 (Brake and Melichar, p. 442). A high rate of technological advance and relatively stable prices of inputs such as fertilizer and fuel contributed much to the steady reduction of unit costs. At present, the near-term return of such favorable trends seems doubtful.

In addition to these uncertainties, there are several major differences between the current financial situation and that of the early 1950s. The boom that followed World War II was unique in that, for a number of reasons, it did not develop the financial excesses present in earlier booms and perhaps in the current one as well. First, the period of relatively favorable real farm income that fueled the boom was of extraordinary length. Operators' real net farm income rose by 79% between 1940 and 1942, maintained that level for seven years (1942–48), and then held at a level only about a fourth lower for another four years (1949–52). Operators' real net farm income rose by 103% between 1971 and 1973 to trigger the current boom, but, in sharp contrast, it has since fallen significantly in each succeeding year and by 1976 was back at approximately the 1971 level (Melichar and Sayre 1976).

Because of the longer period of relatively high income and also because machinery and construction materials were relatively scarce during the first half of the earlier boom, farmers' liquid financial assets (currency, bank deposits, and U.S. savings bonds) had by the end of the boom risen to a level of 8.5% of total assets, more than twice the present level of 3.5% (Melichar and Sayre 1976). Rural commercial banks were also very liquid at the end of the previous boom, in contrast to their present tight situation, which will be detailed later.

Finally, and perhaps most importantly, debt played a limited role in financing the earlier boom. To begin with, total outstanding debt declined through 1945. Outstanding debt then doubled between 1946 and 1953, but the absolute increase was small compared with the large capital flows of that period. In this respect, the earlier experience was a highly untypical boom.

It is characteristic of most booms that euphoric projections of future income streams are widely accepted by participants, both borrowers and lenders. But during and immediately after World War II, most participants expected a rapid retreat to prewar levels of commodity prices and income. In addition, they (and farm finance analysts as well) were highly cautious toward use of debt as a result of the disastrous experience of preceding decades. These expectations and attitudes inhibited both capital spending and the development of highly leveraged financial positions. In the postboom era of the 1950s, therefore, there were comparatively few financial excesses to unwind. The farming sector entered the period with relatively large credit reserves—especially after the level of land prices proved sustainable—and with a major lender group, the rural commercial banks, in a good position to accommodate loan renewals and new loan demands.

The current boom and its financing present significant contrasts with this earlier experience, which may be explored with the aid of tables 1 and 2. A sharp increase in each of the

borrowing, measured by the net increase in outstanding debt, or from internal resources (calculated residually as capital flow less the increase in debt). Internal financing continues to be the major source of funds, but debt financing has increased sharply. In studying capital flows and their financing from internal and external sources, Tostlebe found it useful to observe the behavior and level of several ratios that express meaningful relationships among these series. Four categories of such ratios are presented in table 2, each responsive to a specific analytical question.[1] The ratios in part A of table 2 indicate the relative burden that the capital flow imposes on the cash flow of the farming sector (cash flow is also used for consumption and nonfarm investment). The relative burden increased significantly during the early and mid-1960s but has not risen since above the levels reached in 1965–67—a pattern that reflects the behavior of its capital formation component.

Part B shows the proportion of cash flow allocated to financing of capital flow. Surprisingly, in view of the huge cash flow of 1973, the proportion of cash flow allocated to internal financing both then and in the next two years was no higher than in the 1950s and early 1960s and lower than in the five years preceding 1973. Ratios in part C represent an attempt to derive an indication of the relative debt repayment burden presented by ongoing increases in debt. These indicators reached new high levels after 1971. Cash flow will have to rise in the future to keep this indicated increase in relative repayment burden from materializing. If, as in the 1950s, cash flow fails to rise, repayment of past borrowings is more likely to be burdensome.

It is evident that the farming sector has in recent years allocated less of its income stream to financing of capital flows and that it has employed increased debt financing relative to that income stream. In the 1950s such a shift occurred under the pressure of falling income, but in 1973 and 1974 a further shift occurred in the face of relatively high aggregate cash flow and income. One explanation is that these aggregate series may reflect a concentration of increased debt among a relatively small proportion of farmers, primarily among those who significantly expanded their operations. If future income should fail to meet their expectations, financial "excesses" may be revealed among this group.

Ratios in part D of table 2 simply show the percentage of capital flow or capital formation that can be regarded as financed by the increase in debt. The relative role of debt in financing capital formation during 1972–75 (64%) is the highest since that found by Tostlebe for 1915–19 (76%) and in particular far exceeds that during even the final stage of the last boom (28% in 1950–52).

In short, the current capital spending and land price boom has been debt financed to an extent not experienced since 1920. Thus, some apprehension about the near-term finances of the farming sector appears justified. Research and policy attention to means of dealing with financial stress seems in order.

All major lender groups have participated in financing the boom, but some have been more active than others and have increased their share of total outstanding farm debt. The cooperative farm credit system increased its share from 23% in 1970 to 31% in 1977, and over the same period the share held by commercial banks rose from 28% to 30%.

Each of these two groups has certain advantages and disadvantages, vis-à-vis the other, with respect to ability to cope with a period of financial distress in agriculture. For instance, the cooperative system, in contrast to most banks, has all of its loans in agriculture, but they are nationally diversified, whereas the loans of most banks are concentrated in a small region. Banks' sources of funds, consisting at rural banks mostly of local deposits, may suffer with reductions in farm income, while the cooperative system's sources would be largely unaffected by that event. On the other hand, extensive farm loan problems would eventually affect the cooperative system's ability to raise funds and would also increase their cost, whereas, with their deposit insurance and their more diversified portfolio, the supply of funds at many banks might be relatively unaffected by similar farm loan experience.

After considering such factors, it appears that the lending institution most vulnerable in the event of adverse farm loan experience is the small rural bank that is heavily involved in

[1] The ratios shown on a "net" basis represent an alternative but parallel approach, in which capital consumption (depreciation allowances and accidental damage) has been subtracted both from cash flow and from the capital formation component of capital flow (see the addenda to table 1). This approach implicitly assumes that the funds designated in the national accounts as capital consumption allowances are used to pay for an equal amount of capital expenditures. Thus, one focuses on net capital formation and net capital flow and examines how these flows are financed from net income and the net increase in debt.

farm lending and at which farm income trends significantly affect deposit growth. Data in table 3 indicate that perhaps one-third of all commercial banks are currently in this category (last two columns of the table) and that such banks account for over one-half of all farm loans at commercial banks.

The most vulnerable group isolated in table 3, in the last column, is that comprised of the 2,100 banks with more than half (an average of 64%) of their loans in farming. While 15% of the nation's banks are in this group, and it accounts for 26% of all farm loans outstanding at banks, these generally small institutions hold only $20 billion, or 2.4%, of the nation's bank deposits. This sum is less than the deposits at each of the nation's three largest banks. Obviously, should adverse farm financial experience develop, it may prove desirable or necessary to give this group of banks attention and assistance very disproportionate to its relative importance in the nation's banking system and financial markets.

Given the inherently risky situation faced by these undiversified banks, it is disturbing to find in table 4 that their relative liquidity has very recently been drastically reduced, on average, from that maintained since the late 1960s. This development has resulted from the adverse impact of falling farm income on deposit growth and on loan repayment, as well as from new farm loan demands resulting both from falling income and from the need to finance increased stocks of grain (Melichar 1977). These trends are continuing as of mid-1977 (Melichar and Sayre 1977). Clearly, if the farming sector is now entering a postboom period, the small rural banks are in a far different situation than the one characterized by their highly liquid positions of the early 1950s. Again, research and policy attention might

Interest Rate Restrictions and Income Distribution

Claudio Gonzalez-Vega

Credit has been one of the most important components of the strategies for development in the agricultural sector of low income countries (LIC's). Not only is the input provided—money—fungible but an infrastructure, the banking system, is available for its supply, and it can be administered at a significant distance from the farm, unlike other inputs. Because credit programs are easier to implement than another type of program, there has been a rapid expansion of the volume of agricultural credit granted by formal lenders in LIC's.

Two important and universal features of this expansion have been the the concentration of the loaned funds to a select clientele and the low rates of interest charged. Only a small fraction of the farmers of LIC's receive formal credit—about 5% in Africa and 15% in Asia and Latin America (Donald, IBRD). This concentration is also reflected in the distribution by size of the loans granted. Consider Honduras, an intermediate case in Latin America, where in rural areas the outstanding credit per capita is $35, but only 10% of the rural families have bank loans. Out of every ten families, nine receive no formal loans and one receives a loan of $2,100. Moreover, among those obtaining credit, 9% receive about 81% of the total money loaned.

The rates of interest have been low because they have been maintained at about the same rates as those charged in countries rich in capital and have not reflected the opportunity cost of capital or its shadow price in LIC's. Also, the supply and demand for formal loans have not been equated, and this has generated excess demand, which has required nonprice rationing. Bank interest rates have been lower than those charged by informal lenders, and they have frequently failed to cover the cost of granting credit. In particular, because they do not cover the cost of entering into additional markets, the low rates have prevented formal lenders from serving marginal clients, making it necessary to subsidize financial institutions—for their survival. Also, low interest rates have transferred a substantial subsidy to privileged borrowers. Finally, they have implied ceilings on the deposit rates paid on savings, and in inflationary LIC's, they have been negative and unpredictable in real terms. Interest rates have not been low because of market forces, higher productivity, or financial innovation; rather, they have been imposed by usury laws and central bank regulations. These administered rates have been kept fixed at low levels despite changing circumstances, but their rigidity has not prevented the real rates from affecting allocative efficiency, institutional viability, growth, employment, equity, and income distribution in the rural areas of LIC's. This paper examines their impact on the latter.

Any farmer's net income is a function of his internal productive opportunity and other investment options as well as his command over the resources necessary to take advantage of them. The farmer's control over resources depends in turn on his own endowments and on his access to external finance. In fragmented markets, these opportunities, endowments, and access to finance are poorly correlated. Many farmers, each with his own unique set of endowments and opportunities, are so isolated that they earn a wide range of rates of return (McKinnon). These farmers face very different income growth potentials, which are reflected in the distribution of income.

The impact of access to external finance on income distribution can be illustrated by referring to three financial regimes. First, consider a group of farmers under conditions of self-finance. Each will be able to exploit his opportunities only to the extent allowed by his endowment. Farmers with larger endowments will earn higher incomes. However, the value of the marginal product of the inputs used will

Claudio Gonzalez-Vega is a professor of economics, University of Costa Rica, San Jose.

be higher, *ceteris paribus,* when the farmer's own endowment is small and his productive opportunity is good. Even though the large farmers may use superior production techniques and have larger endowments, if their endowments are better than their opportunities, given the cumulative biases of income growth processes and of diminishing returns, the value of the marginal product of the inputs employed may be lower for them than for the small farmers.

In the previous case, if direct external finance—the transfer of resources via loans from large to small farmers—is possible, the net incomes of both classes of farmers will increase. Moreover, if the value of the marginal product of the inputs declines faster for the small farmers than for the large farmer, in view of the relatively limited entrepreneurial ability and small endowment of other fixed inputs of the former, the absolute and relative net gain in income as a result of the loan will be greater for the small farmer than for the large. Thus, in addition to its allocative effect, direct external finance improves income distribution (Gonzalez-Vega).

A similarly favorable distributive impact takes place under a regime of indirect external finance, when credit is granted by an institution that also collects savings. Consider two farmers with identical production opportunities. Under the conditions of self-finance, if their endowments are equal, their incomes are equal, but if not, the farmer with the larger endowment earns a higher income. However, if both farmers have access to credit, their incomes are equalized. Therefore, the extent to which differences in income are due to differences in endowments is reduced by access to credit. This distributive property of access to credit is also present in a dynamic situation where opportunities can be improved through technical change. In sum, the more fragmented the capital markets are, the more diverse their individual participants will be; and the more dynamic and risky the available opportunities are, the more crucial access to credit will be in determining income growth potentials and income distribution.

Financial intermediation is not free, however. The costs are social because the resources used for credit could have been devoted to increasing output elsewhere. The costs are private as well because lenders have to compete for the resources in the market. On the other hand, credit is not a homogeneous product. There are many dimensions of credit: short term and long term, agricultural and industrial, large and small borrowers. Each one of these dimensions is a separate product with its own peculiar cost function.

Once the various dimensions of credit and their costs are distinguished, it is clear that the socially optimum, competitive rates of interest, will not be the same for all farmers. A social optimum requires that each farmer be granted a loan of a size that makes the marginal cost of lending equal to the value of the marginal product of the inputs purchased with it and, in turn, to the rate of interest charged. If a larger loan is granted, more resources are spent in administering it than are generated by the additional production induced, with a net loss to the society. Therefore, the optimum rates of interest will be higher, *ceteris paribus,* the better the productive opportunity, the smaller the endowment and the higher the marginal cost of lending to a given farmer are.

Similarly, a profit-maximizing lender in a monopolistically competitive market will try to segment it on the basis of demand elasticities or of marginal costs in order to charge different rates to different borrowers. If more inelastic demands and higher costs are associated with small farmers, the rates charged to them will be higher.

If restrictions are imposed on rates of interest, lenders may practice credit rationing, i.e., granting smaller loans than those demanded at the rate charged. From the point of view of the individual borrower, rationing implies an excess demand for credit at the rate of interest paid (Jaffee, Eckaus). Generally, a lender restricts the size of a loan if the marginal cost of granting it is higher than the imposed rate of interest. If a larger loan is granted, the added costs would be greater than the revenues and his expected profits would decline. Since marginal cost is an increasing function of the size of any individual loan (Gonzalez-Vega), the lender can reduce his marginal cost and equate it to the level of the imposed rate by reducing the size of the loan. If this rate becomes sufficiently low, dropping below the average variable cost, rationing takes the form of exclusion from the lender's portfolio.

The possibility that a borrower will be rationed depends on the relationship between the marginal cost and the demand functions faced by the lender and on the nature of the restrictions. The slower the marginal cost rises as the size of loan increases, a function of risk, and the faster the quantity of credit demanded increases as the rate of interest declines due to

the behavior of the value of the marginal product of the inputs, the less likely is rationing. The low ceilings imposed on rates of interest for loans in LIC's have led to widespread rationing, as evidenced by quotas, long delays in disbursement, and other quantitative restrictions. While the loans received by most farmers have been smaller than those demanded at the low rates, a few privileged borrowers have obtained all the credit they have demanded at the restricted rates. Although this preferential treatment reflects the influence of social and political power, the result can also be explained by purely economic considerations related to the profit-maximizing behavior of private lenders and to the survival behavior of public lenders.

Furthermore, given empirically relevant values of certain parameters, when the ceilings imposed on interest rates become more restrictive—due to inflation, increased lending costs, or the frequent practice of granting preferential rates for specific activities—the size of the loans granted to nonrationed borrowers increases and to rationed borrowers decreases. This is the "iron law of interest rate restrictions" (Gonzalez-Vega). As the ceiling becomes lower, nonrationed borrowers move along their demand curves, demanding and receiving larger amounts of credit at the lower rate. On the other hand, rationed borrowers move along the lender's marginal cost curves of granting credit to them, and the lender grants them even smaller loans than before, although they, too, demand larger loans at the low rate.

Small farmers are rationed credit long before the larger ones because the costs of lending per unit loaned are inversely related to the size of loan. The iron law of interest rate restrictions implies that the size of loans granted to large farmers increases and the size of loans granted to small farmers decreases as interest ceilings become more restrictive. This, in turn, leads to a reduction in both the absolute and relative shares of credit small farmers receive from formal lenders; that is, the ceilings redistribute the credit portfolios in favor of large farmers, contributing to the concentration of income in the rural areas of LIC's. Moreover, given the high cost of lending to rural clients, the ceilings usually exclude the majority of the small farmers in LIC's from access to formal credit. It is these excluded farmers—the smallest and the poorest—who suffer the most significant loss as a consequence of the ceilings.

Subsidized interest rates are frequently recommended as the only mechanism for effecting income transfers to small farmers that is politically feasible or administratively possible. Unfortunately, credit in general and subsidized interest rates in particular are very inefficient for income redistribution. Subsidized rates affect income growth potentials through their effect on the access to resources that different classes of farmers have and have a direct effect on income distribution. The grant transferred is directly proportional to the size of the loan. The larger the loan, the greater the unrequited transfer. Since loan size and borrower size are positively correlated, the amount of the grant becomes a direct function of the borrower's wealth. The large borrowers receive large subsidies, while the small borrowers who constitute the target of the strategy receive, at best, small loans with their implicit subsidy. Nonborrowers—the smallest and the poorest farmers—receive no subsidy at all. This necessarily makes income distribution worse.

Interest-rate ceilings have affected not only the distribution of agricultural loan portfolios: they have also influenced the total value of these portfolios. Through their impact on the rates of deposit, they have reduced the total volume of savings mobilized by the formal financial markets (Shaw). Also, through their impact on the profitability of lending to agriculture, they have reduced the share of the agricultural sector in credit volume. They have also reduced technical efficiency in lending and have sometimes even induced a reduction in the volume of informal credit.

On the other hand, low interest rates cannot eliminate the monopoly of money lenders in the rural areas of LIC's, since they restrict access to formal credit. Low interest rates cannot create the missing physical inputs, the missing markets, or the missing technologies that keep the productivity of farmers low in many LIC's. At a sufficiently subsidized rate, credit could in such cases make an investment opportunity appear profitable to the few privileged borrowers receiving the underpriced resources, but it will not make it more profitable socially. Once the inputs, markets, and technologies are available, subsidized credit cannot stimulate adoption of the innovations unless large enough loans are granted to large numbers of farmers. Subsidized rates, however, lead to rationing and exclusion. Access to formal credit can do a better job even at fairly high rates of interest as long as these

rates are lower than those charged by informal lenders.

Therefore, except in a few cases that are empirically unimportant, the arguments for low interest rates are invalid. The important thing is access to credit. The policies that have attempted to keep the price of credit low have modified access in undesirable ways. As a result, these policies have not only reduced both the allocative efficiency and the viability of financial institutions but they have also contributed to concentration of income within the rural areas of low income countries.

The Role of Risk Transfer Institutions in Commodity Policy (Gary L. Seevers, Commodity Futures Trading Commission, Chairperson)

Commodity Futures Exchanges and the North-South Dialogue

Mark J. Powers and Paula Tosini

During the last decade increased attention has been given to the role commodity futures exchanges might play in international commodity policy. There have been suggestions (McKinnon, Houthakker) that national and international agencies, whose goal is the stabilization of commodity prices, should find it less costly to intervene in futures rather than spot markets. Recently, several less developed countries (LDC's) have requested assistance from the industrialized nations in increasing access to commodity exchanges located in developed areas (Conference on International Economic Cooperation). Many developing countries have also asked for help in establishing futures markets in their own countries (U.N. Committee on Trade and Development 1977).

The purpose of this paper is threefold: (*a*) to report on LDC's participation in U.S. markets and discuss related public policy issues, (*b*) to explore the positive externalities that might be generated in LDC's that establish their own futures markets, and (*c*) to identify certain issues related to the role of futures markets in international commodity agreements. Although this latter topic is only peripherally related to the first two subjects, it is important because, at the same time we are seeing a growing interest by LDC's in using futures markets, we are also faced with proposals for international commodity agreements that combine governmental activity in futures and cash markets.

Mark J. Powers is chief economist and Paula Tosini is an economist with the Commodity Futures Trading Commission, Washington, D.C.

Developing Countries and Commodity Markets

Futures markets for primary products provide several potential benefits for developing countries—risk transfer, a system of forward pricing, improved market information, reduced search costs, alternative buyers and sellers, and development of the local financial infrastructure of the country in which the exchange is located. Alternative buyers and sellers (in the form of speculators) give the pricing process greater visibility and liquidity and should be particularly important in monopsonistic markets that many producers within developing countries face (U.N. Committee on Trade and Development 1976). Futures trading might also encourage the development of forward supply contracts using the futures price (taken as a given by both parties) as the index for transfer pricing.

Further, to the extent that exchange pricing integrates the LDC's markets into world markets, the price elasticity of the exchange-traded commodities should increase. For example, if palm or coconut oil were traded on futures exchanges, then to the extent that this causes their prices to move more closely with those of other fats and oils, one should expect a rise in the market elasticities of the individual oils. With the exception of the development of the local financial infrastructure, these benefits of futures trading should accrue to primary producing countries regardless of the location of the exchange.

Three issues concerning LDC's and commodity markets are examined below: the accessibility of U.S. markets to foreigners, the nature of the positive externalities generated

Foreign Participation in U.S. Markets

The extent of current foreign participation in U.S. futures markets can be deduced from data on foreign traders' activities for the nine month-end dates from June 1976 through February 1977. Although this information covers only the large foreign traders, it is believed to be a good indication of overall foreign participation in U.S. markets.[1]

The data in table 1 represent traders from sixty-three different countries and indicate that the total number of reporting foreign traders is small. Further, most of them were located in Canada, Western Europe, and Australia. As one would expect, foreign traders were concentrated in the grains and soybean complex, foreign foodstuffs, industrial commodities, and precious metals.

The data in table 2 show that, except for foreign foodstuffs (coffee, cocoa, and sugar), the average percentage of open interest accounted for by large foreign traders was quite small, ranging on the long side from 1.5% for precious metals to 11.5% for industrial goods and on the short side from 1.9% for livestock and meat to 5.9% for financial instruments. Very little of the foreign participation came from the LDC's, with the exception of coffee (table 3), in which an average of 16.1% of the long open interest emanated from Central and South American accounts.[2]

Although these data suggest that foreign participation in U.S. markets was, on average, relatively small and that the LDC portion of that trading was very small, there was a good deal of variation in the amount of foreign par-

[1] These data, and those used in tables 1 through 3, were obtained from daily reports filed by futures commission merchants for each of their customer and house accounts that had a reportable position in a specific commodity future (for example, July soybeans). At the time of this study, a reportable position was fifty or more contracts in a single silver or cotton future, forty or more contracts in a single grain or soybean future, or twenty-five or more contracts in a single future in any other commodity.

These reports, called CFTC series '01 reports (the initial digit varies with the particular commodity), generate data needed for market surveillance by the Commission. Information on the position of individual traders is exempt from public dissemination under the Freedom of Information Act. The CFTC has not, to date, routinely published aggregated data based on the '01 reports.

[2] Since Central and South American nations are major producers of the coffee consumed in the United States, it may seem puzzling that their participation was largely on the long side; as producers one would expect them to be short hedgers. Several possible explanations emerge: (*a*) the accounts could be speculative, (*b*) they could emanate from exporters who had signed agreements to deliver coffee but had not, at the time, obtained the coffee domestically, or (*c*) the long positions could be held by exporters anticipating the need for stocks to replenish pipeline inventories.

The range shown in the tables represents the range of these maximum percentages within a commodity group. U indicates the upper end of the range; L indicates the lower end of the range.

[c] Less than 0.05%.

ticipation. For example, on one month-end date nearly 31% of the short positions in one precious metal was held by accounts from Southeast Asia. Also, on one month-end date, 25.2% of the long positions in coffee was held by Central and South American traders.

In summary, the above data do not support a contention that foreigners have lacked access to the U.S. markets. On the other hand, neither do these data support an assertion sometimes made that U.S. commodity markets are regularly dominated by foreign interests. This latter notion has led to repeated calls for a regulatory policy to "protect the markets"—a public policy issue that involves the trade-off between open access to the markets and potential market abuse by foreign interests that may be beyond the influence of U.S. law.

Good arguments can be made in favor of maintaining, as much as possible, open access to U.S. markets. Competition requires freedom of entry and exit, with markets reflecting all factors affecting price, including possible collusive policies followed by foreign countries. Even if foreigners are not granted access to U.S. markets, these institutions are not, in most instances, immune from collusive or manipulative actions taken in an alternative foreign market. Lastly, it can be argued that it is best to "have them where we can watch them."

Counterbalancing this open-access argument is a concern that foreign nations are privy to information about supply and demand conditions for some commodities that, irrespective of its informational value to the marketplace, provides them an unfair advantage. Second, where the commodity being traded is produced in only a few countries, it may be

relatively easy for several foreign nations to agree on collusive policies that can have a pronounced influence on the futures market. Finally, there are limited regulatory sanctions that can be effectively imposed against a foreign trader guilty of collusive or manipulative actions on the U.S. markets.

Despite the strength of these latter arguments, and because of the relatively small amount of direct foreign participation in U.S. markets, the most appropriate public policy approach to this issue appears to be maintaining open access to U.S. futures markets while improving the public information on foreign traders' activities in these markets.

Establishing Commodity Exchanges in LDC's

Requests by LDC's for assistance in establishing commodity exchanges normally reflect false hopes that a local futures exchange could increase a country's market power and control over its export markets, result in higher prices, and improve a country's international image. Further, there is a general belief that, if they just "will" the existence of a commodity exchange in their country, such a market will spring forth full blown as Athena from the head of Zeus.

Although these objectives are not likely to be achieved through a commodity exchange, a number of LDC's are nevertheless pursuing the establishment of exchanges. This section of the paper examines some of the issues related to developing commodity exchanges in LDC's, with particular emphasis on exchanges as multiplier-type institutions that provide linkages useful in the development of an economy.

Commodity exchanges are financial institutions, and futures contracts are financial instruments. Exchanges can thus be useful in mobilizing the savings available in a society and stimulating investment. Typically, the low savings levels in developing countries result not only from the subsistence living standard of a large portion of the population but also from the lack of an adequate infrastructure to mobilize savings.

The contribution of an exchange to the savings-investment flow and the capital stock depends most heavily on the participation of speculators and the existence of a clearinghouse. The role of speculators is important, since they provide not only the liquidity and

market positions to carry the hedge load at low cost but also large amounts of financial resources that ultimately become available for investment.

The clearinghouse acts as the financial center for the exchange—verifying and guaranteeing transactions, collecting and dispersing settlements. Clearinghouses that undertake these responsibilities require large amounts of funds that are obtained through cash deposits (called margin) made by both parties to the transactions. These funds, drawn from diverse locations within and outside the country, generate local bank deposits and bank reserves for lending. For example, in Chicago, where 75% of U.S. futures trading is conducted, it is estimated that clearinghouse members maintain daily cash balances of approximately $200 million to meet daily settlements, plus another $800 million to $1 billion in margin deposits, usually denominated in T-bills (estimates obtained from Chicago banks, see Powers). A significant proportion of these funds (the exact amount is not known) are generated outside of Chicago, mainly in California, Texas, New York, and Iowa, where, along with Illinois, the largest number of futures traders are located. It seems doubtful that these funds would have been deposited in Chicago had the exchanges not been located there.

The accumulation of these deposits in one locale generates some obvious economies of scale in the lending function and establishes a level of commodity lending expertise not normally available elsewhere. Thus, it is no accident that banks that act as the principal depositories for such monies also tend to become the leading banks in lending for the production, processing, storing, and marketing of commodities.

These bankers learn that hedged collateral is less risky than unhedged collateral. Consequently, less equity may be required of hedged borrowers, and lower interest rates can be proffered to customers pledging hedged collateral. The impact of this activity on real investment could be significant. The lower interest rates proffered could result in a movement down the marginal efficiency of investment schedule as the supply of loanable funds increases. Further, it could also produce an outward shift of the investment schedule and a change in the ranking of alternative investment projects. To illustrate, Robert Parrott, vice-president of Central Soya Company, Inc., stated at a Commodity Futures Trading Commission (CFTC) hearing that without the broiler futures market his firm might still have made an investment in broiler production, but it is likely that the size of the investment would have been significantly reduced. Because the futures market allowed the firm to reduce risk, it lowered the required rate of return on funds allocated to the broiler enterprise.

In addition to mobilizing domestic savings, an exchange may also attract foreign exchange earnings that one would expect to impact first on the aggregate demand function and ultimately on the savings-investment flow. As a consequence, the investment level in the country should rise. Such foreign exchange earnings should increase a country's hard currency reserves. Furthermore, to the extent that an exchange attracts foreign speculators, it shifts to outsiders risks that might otherwise be carried by the domestic economy.

Foreign exchange earnings can be generated by a commodity market from commissions paid to domestic brokers by foreign traders, interest earned on margin deposits at the clearinghouse, and the excess (if any) of foreign participants' losses over their gains. Further, the existence of the exchanges frequently generates considerable business in physicals. The size of these earnings on invisibles can be significant in a country's balance on current account. A recent survey by the Bank of England indicates that from June 1974 through May 1976 the British commodity futures markets generated inflows of about 148 million pounds sterling. In addition, another 245 million pounds sterling were generated in physicals.

Of the three elements affecting the balance-of-payments flows from futures markets, the most variable is the gains and losses by foreign traders—speculators, hedgers, and straddlers. If foreign speculators lose more than they win, their net losses represent a balance-of-payments credit; if they are successful, their net gains represent a balance-of-payments debit. If one assumes that foreign hedgers are long hedgers who buy the cash product and export it from the LDC, any losses suffered in the futures market will result in a positive flow of funds into the LDC. If there are gains on the futures positions, those gains will represent domestic currency that can be applied against the purchase of the product. Accordingly, these gains by long foreign hedg-

ers represent a foreign exchange opportunity cost for the LDC because, had the product not been hedged, additional external funds would have been earned from the sale of the cash commodity. To the extent the foreign hedgers are short hedgers and suffer losses (gains) on their futures positions, the balance-of-payments flow will be positive (negative).[3]

The potential balance-of-payments flows associated with straddle positions are a bit more complex and unpredictable, depending upon the relative distribution of straddles, the degree to which one country's price adjusts relative to the other country's price adjustment, and changes in price levels. Assume there are two futures markets for the same commodity, one located in an LDC (the secondary market) and one located in a developed country (the primary market). Assume also that straddles are entered into only when the markets have moved away from their normal equilibrium and that all straddles are accurately successful, i.e., the market always returns to its appropriate equilibrium. Then, if straddlers in the two countries are equally distributed between the markets, and if following a situation of disequilibrium one country tends to adjust more than the other, then the country that adjusts more should experience an outflow of funds with respect to the other country. According to McClay, the loser is more likely to be the country that is the secondary market or, in this instance, the LDC.

McClay also shows that when the price level changes during the life of a straddle, the balance of payments of the secondary market is affected more unfavorably by a predominance of wide straddling (long the market that is normally lower and short the market that is normally higher) in a price fall or narrow straddling (long the market that is normally higher and short the market that is normally lower) in a price rise. In the long run, he believes that price level changes are also likely to be more unfavorable to the secondary market than to the primary market.

If it is true, as stated earlier, that many LDC's want commodity markets for the wrong reasons, it is probably equally true that many countries that want exchanges are not sufficiently developed to support them. An exchange requires a threshold level of infrastructure in order to emerge as a viable institution. The following elements are important in measuring that threshold level.

(*a*) Fast and efficient communications, both domestic and international, are necessary in performing the all important information dissemination function of the exchange and in providing the key element of visibility.

(*b*) Grades, standards, and quality control procedures of a minimal nature are needed to describe the commodity accurately in contract specifications.

(*c*) Minimal transportation and storage systems must be available to move products from buyers to sellers.

(*d*) A financial system capable of supporting capital transfer, short-term credit needs, and special types of debt instruments is necessary to facilitate the functioning of the clearinghouse.

(*e*) The potential for commercial hedging must exist. Experience in the United States has taught that the broader the potential hedge participation, the greater the chance that a market will function properly and that commercial users will benefit from the exchange's operation. Experience also demonstrates that most producers do not hedge.

(*f*) A legal system that recognizes and enforces the rights and duties embodied in contracts is important in generating confidence in an exchange.

In addition, as noted in the preceding section, international access to the market and speculative capital are important elements in determining the viability and economic contribution of an exchange. International participation allows risks inherent in the domestic economy to be dissipated over the wider international market and provides important linkages between the domestic economy and world markets. Central to attracting this foreign participation is foreign currency convertibility at reasonably low cost and risk. Speculative capital provides liquidity and competition in the marketplace and generates many of the externalities associated with the exchange. Ironically, many LDC's who want commodity exchanges also condemn speculative participation in the markets as unnecessary and evil.

Even with all of these elements present in an LDC, there may still be many impediments to the development of a properly functioning commodity exchange. It takes time and a great

[3] Space does not permit an exploration of other possible cases in which the balance-of-payments effects might be different. However, it appears that in most instances these cases should produce balance-of-payments repercussions similar to those associated with foreign speculation.

deal of educational effort to build credibility, confidence, and understanding of an exchange and its role.

Futures Markets and International Commodity Agreements

Concurrently with their exploration of increased use of futures markets, LDC's have pursued widely publicized efforts to obtain assistance from industrialized countries in establishing a Common Fund to finance buffer stocks in major commodities. Interesting theoretical and philosophical questions are raised by LDC's simultaneous pursuit of buffer stock financing and access to futures markets. These issues include the compatibility of the two institutions and the extent to which (as has been suggested by McKinnon and Houthakker) official intervention (either by LDC's acting as a group or jointly with developed countries) in futures markets is a viable substitute for buffer stocks. Unfortunately, this is an area that, at present, involves many unanswered questions that cannot be settled here. However, since the relationship between futures markets and buffer stocks involves significant policy issues, it appears worthwhile to raise questions whose further consideration should provide insights and inputs to policy recommendations.

The explicit goal of buffer stock programs is to decrease price variability and possibly (depending on the direction of quantity changes) income variability. An implicit objective of buffer stock programs often appears to be stabilizing commodity prices at levels that would be, on average, higher than those that would have been established by market forces alone. Alternately, authorities could buy and sell contracts in the futures market in their attempt to reduce price fluctuations or maintain commodity prices at higher than equilibrium levels. Price elevation, however, is not an appropriate economic objective for either buffer stocks or forward market intervention. The tenets of welfare economics dictate that when a good's price reflects its social as well as its private costs and benefits, it is inefficient for the government to influence that price to effect a redistribution of income. Rather, lump sum taxes and transfers are considered the preferred means of income redistribution.

In addition, the use of buffer stocks to keep prices of primary goods above their long-term equilibrium level should be expected to encourage overproduction and to leave the buffer manager, as buyer of last resort, with an ever-growing stockpile of the commodity. In order to maintain futures prices above their long-run equilibrium level, authorities would normally be holding net long positions and taking losses on these contracts as they neared maturity. Further, such price-supporting activities would necessitate taking delivery on futures contracts. In such a situation, intervention in the futures market would become less a substitute for the maintenance of buffer stocks than an alternate means of obtaining these stocks.

Furthermore, if authorities attempt to elevate prices in futures markets, speculators should soon realize that the futures price is an upwardly biased estimator of the expected spot price in the future. Speculators would therefore be likely to join producers in selling short in the forward market. Official eagles would become sitting ducks, providing one-way options to speculators (as happened to numerous central banks that resisted currency devaluations or revaluations during the 1960s and early 1970s).

Houthakker and McKinnon,[4] comparing official intervention in domestic spot and futures markets for agricultural products, conclude that intervention in futures markets should be the less costly means to reduce the variability of farm prices. Houthakker extended his analysis to apply "not only to the domestic commodity markets, but perhaps even more to the international ones. . . . Buffer stocks schemes . . . involve considerable financing; by working through the futures market, as proposed here, the financial aspects can be considerably improved" (p. 59).

Several empirical and theoretical issues arise in choosing between official intervention in futures or spot markets to stabilize commodity prices. First, the mechanism that transmits price changes from the futures to the spot markets must be strong enough so that intervention in one market can be considered a good substitute for intervention in the other. It is interesting to speculate how many of the

[4] McKinnon's prescription was for the government to make a market in the far distant (beyond the next crop year) futures contract so that primary producers could hedge their future income, yet make their planting decisions on the basis of more timely data. Houthakker suggests that the government buy and sell futures contracts to reach target prices (based on a three-year moving average of past prices) for the six- to nine-month futures market.

several score active futures markets would possess the depth, breadth, and resiliency to withstand official intervention and to transmit, predictably, price changes to the spot market.

In this respect, the market for forward foreign exchange might be illuminating. There is a rich literature, starting with Keynes, that theorizes that the (annualized) discount of a country's forward exchange rate over its spot rate should equal the short-term interest rate differential in favor of that country. Thus, by influencing the forward exchange rate (with interest rate differentials unchanged), the spot price of foreign exchange should be changed in the same direction and by the same amount.

Despite the elegance and intuitive attractiveness of the interest-parity theory of the determination of forward and spot exchange rates, this exact relationship has seldom been seen empirically, in part because of the market conditions in many financial centers. Capital controls inhibit arbitrage transactions, forward markets are normally less well developed than spot markets, and the opportunity cost of interest arbitrage should rise with the proportion of portfolios held in a foreign currency.[5]

Second, when there exists a stable and predictable relationship between futures and spot prices, it might be asked (as McKinnon and Houthakker do) which form of intervention should be less costly for a given quantity of price stabilization. Under the *ceteris paribus* assumption made by these authors, intervention in futures markets would appear to require a smaller net outlay of resources. However, this issue may not be one in which marginal cost-benefit analysis is applicable. Extensive official buying and selling on futures markets by an international fund could alter the nature of commodity markets by changing the magnitude and direction of the positions taken by private participants in the market.[6] Thus, two further questions arise. (*a*) What is the nature of the trade-off between price stabilization through official intervention and the weakening of futures markets? (*b*) How does this trade-off change as a function of which market (spot or futures) is used for official purchases and sales?

Third, McKinnon and Houthakker implicitly assume that of the three groups of market participants—hedgers, speculators, and arbitrageurs—officials should play the role of stabilizing speculators or market makers. However, developing countries might be better served by acting as hedgers, taking advantage of opportunities for transferring price risks. As noted by Tomek and Gray, producers' incomes will be stabilized by their hedging expected production in the new crop futures market if futures prices vary less than cash prices from year to year. This third point provides the basis for an important policy consideration, namely, whether private sector activity in futures markets can stabilize prices comparably with buffer stock management in cash markets or official intervention in futures markets. The existence of a futures market should encourage the development of storage facilities and the carrying of inventories by the private sector and thereby should have a leveling effect on prices over time.

The choice between private futures markets or official intervention in the cash or futures markets to stabilize prices is a philosophical, as well as a theoretical and empirical, one. The promotion of futures exchanges to shift risk and encourage the private holding of inventories is an approach that emphasizes a solution in the private sector. The publicly held buffer stock approach involves, of necessity, a significant degree of official management of major markets. The ramifications of official intervention in futures markets may be quite large and unfavorable. Caution appears advisable lest, in the quest for a slightly less expensive means of smoothing price fluctuations, a viable and important pricing institution, with all of its positive externalities, might be weakened. If LDC's develop futures markets, officials of these countries should be discouraged from intervening in such markets, since such a policy would undoubtedly doom a new market.

Summary and Conclusions

Access to commodity exchanges may make important contributions to the ultimate objec-

[5] Interestingly, during the period of generalized floating the financial press reported that only the Bank of England has undertaken significant intervention in the forward market, as the British central bank had done during the mid-1960s (at which time it suffered significant losses when sterling was eventually devalued in 1967). The question may be asked why Britain, but reportedly no other major country, chose to use forward as well as spot intervention to moderate fluctuations in the price of its floating currency. The answer may lie in the special characteristics of the British situation: an open economy, a depreciating exchange rate, dwindling reserves, a developed forward market, and few limitations on capital inflows.

[6] Of course, as Gray suggests, the *ceteris paribus* assumption might also be inapplicable following significant official buying and selling in cash markets.

tives of LDC's—price and income stability and the development of indigenous resources. Among the potential benefits accruing to LDC's from futures markets are (*a*) increased integration of developing countries' pricing systems into world markets (to the extent that this integration effects greater substitution between commodities, one might expect a rise in the price elasticities of exchange-traded commodities); (*b*) a broadening of competition and a reduction of monopsonistic power; (*c*) a dissipation of the domestic risk load to the broader world economy; and (*d*) a strengthening of the financial infrastructure, with changes in the savings and investment functions, in developing countries that establish commodity exchanges.

If, as suggested above, futures markets offer positive externalities to LDC's, one might expect to observe an increase in LDC's participation in existing futures markets located in industrialized countries and the development of "regional" futures markets on the fringes of major LDC areas. Such efforts are already under way in Hong Kong, Brazil, and Malaysia-Singapore.

Foreign access to the U.S. futures exchanges should be kept as open as possible in order to avoid discouraging LDC's participation in futures markets and to further the competitiveness of U.S. markets. Consistent with this policy of openness would be an expanded informational effort by the CFTC to ascertain the extent of foreign participation in the U.S. markets. Such data should be aggregated to the extent necessary to protect the identity and size of individual holdings.

Lastly, complex theoretical and empirical issues are involved in substituting official intervention in futures markets for intervention in spot markets to moderate price fluctuations. These issues include the nature and strength of the transmission mechanism between spot and futures prices; the effect of extensive intervention in futures markets on private participation in such markets; and whether private hedging in futures markets, and the possible concomitant encouragement of private inventory building, may go a considerable way toward reaching the price and income stability currently sought by developing countries.

Commodity Options for Agriculture

Bruce L. Gardner

This paper considers the potential benefits of trading in options for farm commodities in three areas: risk management by individuals, the functioning of commodity markets, and the management of public policy with respect to farm products.[1]

Individual Risk Management Using Options

To review the terminology used, a "commodity option" is a contract to buy or sell a given quantity at an exercise price stated in the contract at the option of the purchaser of the contract. A contract conveying the right to buy is a "call" option. A contract conveying the right to sell is a "put" option. While an option confers the right to buy or sell, there is no obligation to do so. The right is not a free lunch, however, because the option must be paid for, whether it is exercised or not.

The person who receives payment, the other party to the contract, is said to "write" the option. He has a responsibility but no rights, for which he is paid. For a call (put) option, if the commodity price rises above (falls below) the exercise price by more than the "premium" paid (number of bushels in the contract divided by amount paid for the contract), the buyer of the option comes out ahead. If market prices does not rise this high (fall this low), the option writer gains. The gains of one party equal the losses of the other.[2]

There are four roles an individual may play in options contracting: one can buy a call option, write a call option, buy a put option, or write a put option. Any of these actions may either increase or decrease an individual's exposure to price risk depending on his position in the underlying commodity, in futures, or in other options.

Hedging using futures contracts provides a standard with which risk management by means of commodity options may be compared. The essential difference is that, while futures ideally determine price in advance for a hedger, an option fixes price over a range of market outcomes while confronting the individual with the market price over a different range. The results of a put option hedge by a producer are shown in figure 1. An option to sell at price P^*, for which the premium paid is V per bushel, guarantees returns of $P^* - V$ per bushel for market price below P^* but permits revenues to increase at higher prices. Numerical examples are presented below.

Whether hedging with put options is preferred to a forward sale would depend on the producer's utility function. The option would have appeal, for example, to a farmer having a utility function of the form suggested by Friedman and Savage to account for simultaneous insurance and gambling—risk aversion in the face of large losses but risk preference in choice between average and unusually large gains.

Even if a producer is uniformly averse to risk, options are promising in risk management when one moves away from the idealized circumstances in which a futures sale determines returns per bushel in advance. In more realistic cases in which output is stochastic, or when basis risk exists, futures are less effective in reducing risk. The variance of receipts in some such cases has been analyzed by McKinnon and by Peck. In the circumstances that McKinnon analyzes,

Bruce L. Gardner is a professor in the Department of Agricultural Economics, Texas A&M University.

The author wishes to thank Peter Barry, Tom Lenard, John Penson, Mark Powers, Gary Seevers, and Paula Tosini for helpful comments, and especially Paul Westcott for his valuable assistance. Texas Agricultural Experiment Station Technical Article No. 13597.

[1] Trading in commodity option for most domestic farm products (notable exceptions being sugar and tobacco) is currently prohibited by the Commodity Exchange Act. The occasion is appropriate to consider the economics of options because of the Commodity Futures Trading Commission's proposed pilot program in options trading for some nonprohibited commodities, which could open the door to a general relaxation of restrictions on options.

[2] Brokerage or other transactions costs are for the most part ignored in this paper, so that the premium paid by an option buyer equals the receipts of the option writer. The analysis also is oversimplified in not considering the distinctions between "American" and "European" options (defined below) or between options written on a commodity and options written on a futures contract. The basic economics of options is not affected by these complications, although they involve important practical issues.

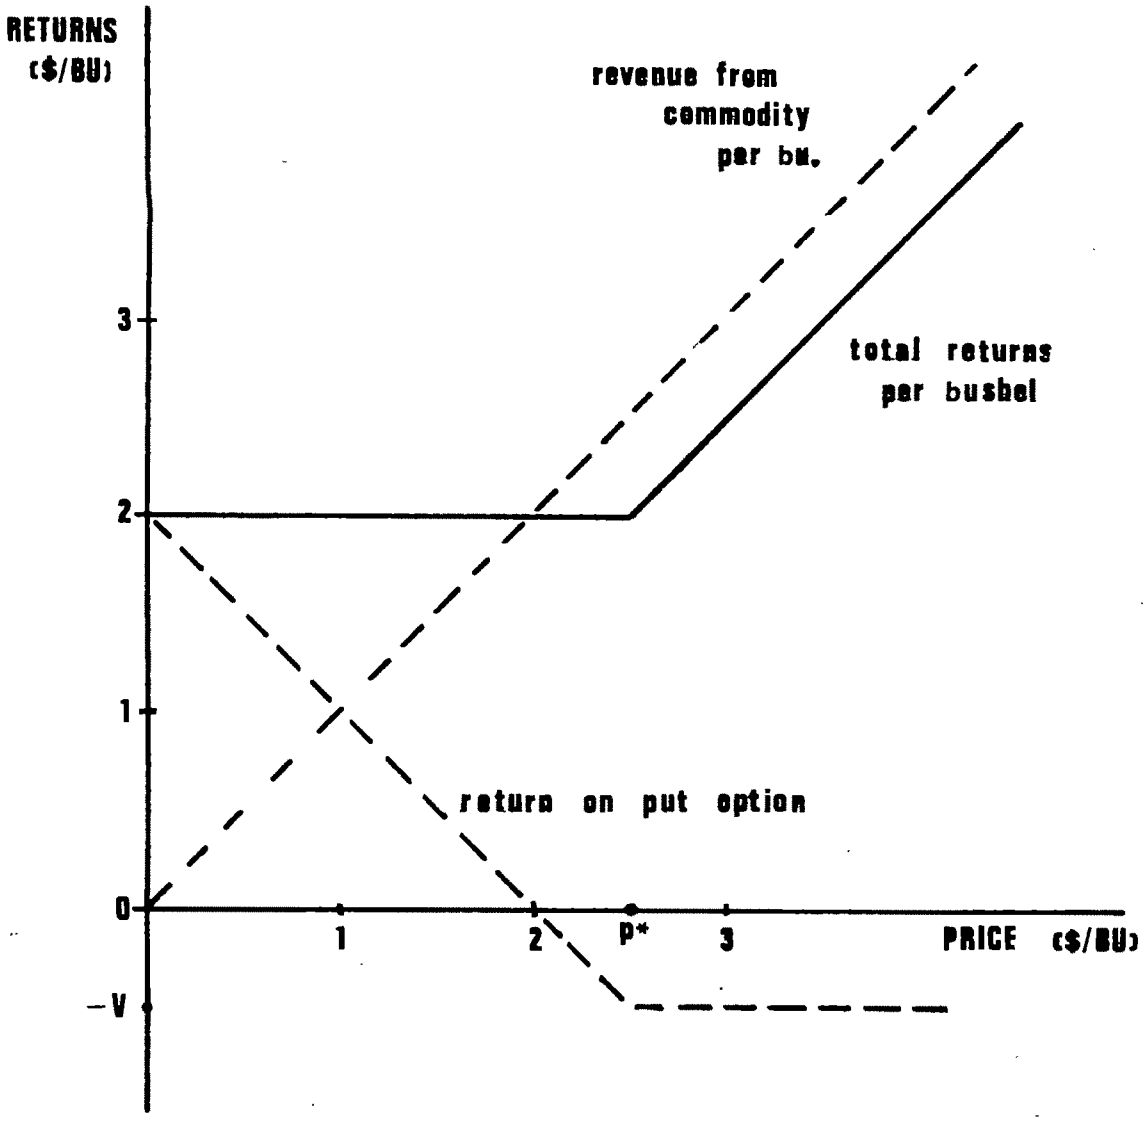

Figure 1. Returns per bushel for a hedging purchaser of a put option

where a farmer's output is negatively correlated with price, options can duplicate and even improve upon the stabilization of receipts attained by a forward sale.

To illustrate, suppose a producer faces the following situation: expected crop price is $3.00 per bushel, at which price it pays to commit $20,000 in contractually paid inputs together with owned resources normally sufficient to produce 9,000 bushels. Let there be five possibilities for market demand and the individual's yield, each with a probability of one-fifth, as shown in table 1.

There are only three quantity outcomes, but price may vary for a given crop size because of demand shifts and because other farmers sometimes have good crops when a particular farmer has a poor crop. Nonetheless, when poor weather reduces yields and increases prices for the market, it tends to do so also for a representative producer. Thus, a typical producer tends to observe negative correlation between yields and prices.

If the producer sells forward his entire normal crop of 9,000 bushels, he does poorly in outcomes (*a*) and (*b*) because he must buy to cover part of the forward sale at increased prices. The income results are shown in the sixth line of table 1.

McKinnon's formula for the optimal for-

Table 1. Producer Outcomes under Futures and Option Hedging

	(a)	(b)	(c)	(d)	(e)	Mean	Standard Deviation
Market situation							
Probability	0.2	0.2	0.2	0.2	0.2		
Quantity (1,000 bu.)	8	8	9	10	10	9	
Price ($/bu.)	4.00	3.50	3.00	2.50	2.00	3.00	
	----------	----------	----------	$1,000	----------	----------	----------

Income	7.4	5.4	6.4	6.4	6.4	6.4	0.63

* Revenue minus contractual costs of $20,000.

ward sale as a fraction of expected production works out in this example to about two-thirds, implying a forward sale of 6,000 bushels.[3] With a futures sale of 6,000 bushels, receipts are $18,000 from the forward sale plus the market value of additional production. The income results are presented in the seventh row of table 1. This strategy yields the same average income as selling forward the entire average crop of 9,000 bushels, but it gives more stability in returns.

Consider the use of options. In the optimally hedged position, income is lower in the high price outcomes. Therefore, an option stabilizes returns if it makes money when prices are high and loses money when prices are low. Let the farmer buy a call option for 1,000 bushels at $3.00. The expected value of the option when exercised is 0.2($4.00 − $3.00) + 0.2($3.50 − $3.00) = $0.30 per bushel. In a competitive options market, this is about what the farmer has to pay for the option.[4] The results are shown in lines eight through ten of table 1. The option transaction enables a reduction in income variability in addition to that attainable by the optimal futures sale. Mean income is the same in all cases because the expected return to options trading is zero. However, there is a real cost to the stabilization attained, namely, the brokerage fees that are left out of these calculations. The producer's choice is whether the stabilization of income attainable is worth these fees and other transaction costs that will be incurred.

Returning to the original unhedged position, it may be asked whether futures might not be dispensed with altogether. Since stabilization is achieved by reducing incomes in high price years, it is natural to consider writing a call as a substitute for the futures sale. Indeed, in this example simply writing a call option for 6,000 bushels at $2.00 duplicates the income results of the optimal futures sale of 6,000 bushels.

Finally, consider the following example in which futures transactions are replaced by two option hedges—writing a call option on 4,000 bushels at $2.50 (to reduce income under high prices) and simultaneously buying a put option to sell 10,000 bushels at $2.50. The payment to the farmer for writing the call option is 0.2(2.50 − $2.00) + 0.2($3.50 − $2.50) + 0.2($3.00 − $2.50) = $0.60 per bushel, and the cost of the put is 0.2($2.50 − $2.00) = $0.10 per bushel. The income results are shown in lines eleven through fourteen of table 1. This strategy yields a standard deviation of income lower than any yet considered.

Generally, a strategy of writing calls and

[3] The formula is forward sale/expected output = $[\rho\sigma_x/x]/[\sigma_p/p] + 1$, where ρ is the correlation coefficient between price and output (about −0.8 in the example, which is much greater than one would typically expect), and σ_x/x and σ_p/p are the coefficients of variation of output and price, respectively (McKinnon, p. 848).

[4] Not including brokerage fees. This assertion depends on there being no risk premium to speculators or else that speculators (individuals who increase their risk as a result of the transaction) are equally prevalent on the buying and selling side.

buying puts would be expected to compare favorably with an optimal forward sale. However, it is much more difficult to use options when the set of possible outcomes is unknown or is more complicated than in this simple example. Generally applicable optimal strategies for using options in hedging have not yet been developed. The point here is to show that options have promise for limiting price risk with more flexibility than futures allow.[5]

Options and Commodity Markets

The effect of options on the market for the underlying commodity should be similar to the effect of an improved form of insurance in any risky activity. More risk-averse participants should be drawn into the activity and should require smaller risk premia in their noncontractual returns. The introduction of commodity options should therefore tend to increase output and reduce prices. It might be expected, however, that any reduction in price would be quite small because fairly good substitutes as instruments for reducing risk already exist.

Baumol argues, as an instance of the general argument that speculative activity tends to be stabilizing, that options tend to reduce instability in the price of the underlying commodity because they increase the supply of speculative services. Apart from this effect, there is no a priori reason to expect an options market to affect price fluctuations in the underlying commodity, even though market participants can use options to control the risk they face as a result of these fluctuations.

A possibly more important result of options trading is the public information that can be inferred from the selling price of an option. Just as futures prices generate information about expectations of commodity prices, an option's price generates information about expectations of the variability of commodity prices.

The present value of a call option to be exercised at time t, is[6]

$$(1) \qquad V = e^{-rt}\int_{P^*}^{\infty} Pr(P_t)\cdot(P_t - P^*)\mathrm{d}P_t,$$

where P^* is the exercise price, $Pr(P)$ represents the probability density function of price at t, and r is the appropriate interest rate. If the probability distribution of price takes a form that can be represented by the mean ($\bar{P}_t$) and variance (σ^2), an estimate of $\bar{P}_t$ is consistent with only one value of σ^2, given the values of r and V. An estimate of $\bar{P}_t$ is available for some commodities from the appropriate futures price. An estimate of V is available from observation of the premium in the options market. Therefore, σ^2 can be estimated if an options market exists. The following discussion shows how.

Under log-normality,[7] equation (1) becomes

$$(2) \qquad V = \frac{e^{-rt}}{\sigma\sqrt{2\pi}}\int_{P^*}^{\infty}\frac{1}{P_t}\exp\left[-\left(\frac{\ln P - \overline{\ln P}}{\sigma}\right)^2/2\right](P_t - P^*)\mathrm{d}P.$$

Let $z = (\ln P_t - \overline{\ln P})/\sigma$, where σ is the standard deviation of the log of price. Then expanding to a P_t and P^* term, completing the square on $w = z - \sigma$ to integrate the P_t term, and using the fact that $\ln\bar{P} = \overline{\ln P} + \sigma^2/2$, where $\ln\bar{P}$ is the log of the mean and $\overline{\ln P}$ is the mean of the logs, the result is

$$(3) \qquad V = e^{-rt}\left\{\bar{P}_t N\left(\sigma + \frac{\overline{\ln P} - \ln P^*}{\sigma}\right) - P^* N\left(\frac{\overline{\ln P} - \ln P^*}{\sigma}\right)\right\},$$

where N is the cumulative normal distribution.

Since $\ln\bar{P} - \ln P^* = \ln(\bar{P}/P^*)$, dividing through by $\bar{P}$ yields

$$(4) \qquad V/\bar{P}_t = e^{-rt}\left\{N\left[\frac{\sigma}{2} - \frac{\ln(P^*/\bar{P}_t)}{\sigma}\right] - (P^*/\bar{P}_t)N\left[-\frac{\sigma}{2} - \frac{\ln(P^*/\bar{P}_t)}{\sigma}\right]\right\}.$$

[5] Although this discussion has dealt with producers who want to reduce risk, it should be noted that options also provide more flexibility for commodity purchasers and for speculators.

[6] This discussion considers only "European" options (exercised at the expiration date). Merton's discussion of options on securities indicates that it would typically pay to hold an "American" option (which may be exercised at any date until the expiration date) until expiration so that the two types would have roughly equal values. Black derives an equation equivalent to equation (4) under a time series of random changes in the commodity price, with changes distributed log-normally. However, the time series of agricultural commodity prices is not random in the same way as security prices because of seasonal factors. For example, an American call option for November soybeans, purchased in May, should be worth more than the corresponding European option because one would often wish to exercise the American option at the seasonal price peak in August. Therefore, hedging producers who are concerned with the November price would find European more efficient than American commodity options. However, an option to buy or sell a futures contract does not involve these problems, since there should be no seasonal in a particular futures contract's price.

[7] The log-normal distribution probably gives the best simple representation of the distribution of expected price. It is preferable to the normal distribution because negative prices are ruled out and equal percentage moves up and down, e.g., doubling and halving are equally likely.

Given the values of r and t, equation (4) contains three unknown quantities: $P^*/\bar{P}_t$, the exercise price relative to the expected price; $V/\bar{P}_t$, the value of the option relative to the expected price; and σ, the log standard deviation of expected price. With $\bar{P}_t$ from a futures market and an options market to generate P^* and V, we can calculate the implied σ.[8]

A test for the robustness of the estimated σ can be done easily if call options at different exercise prices are available. Each should yield the same estimate of σ. Even more useful as a check is the estimate of σ from the premium on a put option, which gives an estimate of σ based on the distribution of expected price in the low end of the price range.

Given the estimate of σ, it is possible to estimate the probability that price at t will be below or above any particular value. As with futures prices, it is unlikely that one will find any better estimate than the market's. This information could be helpful to a farmer in making production choices or to policy makers considering alternative price support levels. It would be a valuable byproduct of a market in farm commodity options. Since it would probably not pay for a producer to develop this information for himself, and since the information would be difficult to market by specialized firms owing to its public-good character, there may be reason actively to encourage and even subsidize options markets for their positive externalities.

Options and Farm Commodity Programs

The existence of an options market would clarify discussion of some aspects of farm policy and could facilitate the operation of some commodity programs.

Support prices as established by nonrecourse loans are equivalent to a put option. The producer has the right but not the responsibility to deliver the commodity to pay off the Commodity Credit Corporation (CCC) loan. The farmer has the same protection as if he had purchased a put option on a commodity market with an exercise price at the loan level. The difference is that the farmer does not pay for the CCC put option. Indeed, the economic value of the transfer from taxpayers to farmers each year is roughly the price that would have to be paid for put options to sell each year's crop at the loan level. This formulation makes clear that support prices have real economic value to farmers (and costs to taxpayers) even in years when market prices turn out to exceed support prices.

A major rationale for price support programs would disappear if a well-functioning market in put options existed. Each farmer could choose the degree of price insurance he wanted by purchase of a put option at the appropriate exercise price. Of course, the higher the insured price, the more the farmer would have to pay for his put option. If a farmer wanted a complete forward sale, he could sell futures or some other form of forward contract. The key feature of the put option is that it duplicates the kind of protection farm programs give—a price floor but no limit on profits from high prices—yet put options have neither the income redistribution nor resource allocation effects that price support programs do.[9]

Even if one believes that farm commodity programs should have income redistribution and resource allocation effects, options are potentially valuable in administering commodity policy. Although the existence of an options market may not have significant price effects, government intervention in this market can be used to change commodity prices just as intervention in futures or spot markets can. For example, call options could be a useful tool to government in management of grain reserves under an international agreement.

[8] Example: Suppose $\bar{P}_t$ = \$3.00 and an option to buy at P^* = \$3.30 sells for V = \$0.30 for a six-month option with r = 0.05. The value of σ that equation (4) implies is 0.36. If the option sold for less, say, \$0.15, then the implied σ is smaller, 0.22. When we observe the premium on an option whose exercise price equals the futures price, equation (4) is greatly simplified, and $V/\bar{P}$ depends only on σ. Also, observation of an option premium does not allow an estimate of expected price. If an option to buy at \$3.30 sells for \$0.30 per bushel, this does not imply a market expectation of a future price of \$3.60. However, observation of the market value of two options simultaneously allows inferences to be made about both the mean and standard deviation of expected price even without a futures market. The simplest case occurs when the exercise price P^* at which a put and call option have the same value is observed. Then, value of put = value of call:

$$\int_0^{P^*} Pr(P)\cdot(P - P^*)dP = \int_{P^*}^{\infty} Pr(P)\cdot(P^* - P)dP.$$

Rearranging terms,

$$\int_0^{\infty} Pr(P)\cdot P dP = \int_0^{\infty} Pr(P)\cdot P^* dP.$$

i.e., $E(P) = P^*$, expected price is the exercise price.

[9] There is an important difference in that a put option would probably expire within a year or so, while government programs ostensibly provide a price floor for longer periods. However, the permanence of government forward price guarantees should not be overstated. In the past when market prices have rested on support levels, support levels have tended subsequently to decline despite attempts to avoid this necessity by means of production controls, export subsidies, etc.

Such an agreement would probably require the United States to supply grain to the world market under some specific conditions. While most countries would meet such obligations by sales of government-owned stocks, the United States likely would prefer to rely on its well-developed private storage industry. Then delivery of grain under the international agreement could be guaranteed by acquiring call options from farmers or commercial sources.

An alternative to purchase of call options would be to extract a price from farmers for the CCC put option that current law establishes, the price taking the form of farmers giving the government a call option to buy grain at, say, twice the loan level in exchange for the farmer's option to sell at the loan level. The farmers, as owner of the put option and writer of the call, have effective control of the commodity at prices above the loan level but below twice the loan rate. The government, as owner of the call option and writer of the put, would have effective control of grain at prices below the loan and above twice the loan level. This seems a very natural arrangement for stabilization policy.

Some Objections to Options Markets

The objections to legalizing options trading seem to center on the difficulty of policing this activity and on alleged undesirable effects on competing financial markets, particularly futures markets.

The idea that any activity should be prohibited because of the difficulty of policing or regulating it seems to me a weak one. Options trading is a voluntary capitalist act between consenting adults, in Robert Nozick's phrase. People ought to have the right do these things unless it can be shown that serious external harm results. The regulatory view is that people ought to be forbidden from doing these things unless it can be shown that external good results. The regulatory view gains acceptance in the case of options because of the aura of disrepute about options trading. While options have the reputation of being inherently more purely speculative than futures trading, this reputation is undeserved. Options can be used either to increase or decrease risk of loss, just as futures or other wagers can. Options, however, are more flexible than futures, as illustrated above. Even for pure speculators, options can offer better controlled gambles than futures. In buying a call option the purchaser's maximum loss is limited by what is paid for the option. In futures trading or holding the commodity, losses are not so easily limited.

It is sometimes suggested that because the supply of speculative services is limited, the proliferation of options markets would reduce the viability of futures markets. This is an empirical issue that the Commodity Futures Trading Commission's proposed experimental program in options trading may help answer. Even if futures and options markets turned out to be such close substitutes that they could not coexist, can we be certain that the contest should be decided in advance in favor of futures?

It must be admitted, however, that there are many difficulties in establishing and facilitating trading in an options market and in keeping the public's trust in the integrity of such markets.

Summary and Conclusion

The effects of options trading in farm commodities cannot be established other than hypothetically since there is so little empirical evidence. Nonetheless, there are good reasons to expect that commodity options for farm products would be useful financial instruments. They can be used by producers and users of commodities for risk management purposes more flexibly than futures or other forward sales. They also present advantages to speculators. Their use could improve efficiency in the market for the underlying commodities. An organized options market would yield information about the distribution of expected market price that cannot be obtained from futures prices. This information would be useful for decision making in the private sector and for such purposes as setting support prices in the public sector. Finally, over the long term options could permit a further movement toward less reliance on the general taxpayer for farm income and greater market determination of prices and resource allocation in agriculture, while still permitting farmers to obtain a degree of insurance against the income consequences of low prices (without locking themselves out of the benefits of high prices as a forward sale does).

However, the private benefits of centralized

option trading could be insufficient to cover the costs of maintaining and transacting in such a market. If so, viable options markets will not develop. Nonetheless, there is no justification for stacking the deck against options by means of legislation. Indeed, the public good aspect of information generated by quoted option prices suggests that options trading on organized exchanges should be encouraged.

Discussion

Ben W. Gunn

In choosing to concentrate on Powers' paper, I am not in any way ignoring Gardner's important contribution on the potential use of options. I share the doubts Powers has about the feasibility of using futures trading to permit a governmental or international agency to stabilize price. There is probably scope for further research into the nature of price formation where cash and futures markets exist in parallel, but even more should be done to assess the impact of such stabilization operations on other participants in the market. Will they scare away hedgers or speculators? Will they attract speculation of the wrong sort: that designed to profit solely from the eventual exhaustion of the agency's resources, whether of cash at the bottom of the market or of commodity at the top?

My misgivings go beyond simply the capacity of officials to stabilize prices. I see a greater danger. It is widely recognized that the public sector has a role, however modest, in the regulation of commodity trading. This role must be exercised in cooperation with the exchanges themselves and with absolute impartiality towards all who trade on the markets concerned. Such regulation is quite incompatible with government operations on such markets designed to influence prices and by implication to favor one group of market participants against others. I would question whether this conflict can ever be solved by simply keeping the regulatory and the stabilization agencies at arms length since both derive their authority from the same source.

If the prospects for stabilization of prices through intervention in the futures markets look slight, prospects for primary producing nations to stabilize their incomes by using futures markets may offer more hope. We should, however, be aware of the background against which the primary producers see the marketing process as a whole. An item under this title has been on the agenda of the United Nations Conference on Trade and Development (UNCTAD) Committee on Commodities since the early 1970s, but progress generally has been slow. Although the intention was to study a fairly wide range of commodities by the time of UNCTAD IV in Nairobi last year, only three studies had been completed: cocoa, bananas, and hides and skins. Both the London and New York futures markets came under attack in the cocoa study for permitting excessive speculation to destabilize prices to the detriment of the primary producers. The developed countries have denied these charges, but they have failed to convince the primary producers. The same criticism of futures markets reappeared, and remained unresolved, as a sideline to the Conference on International Economic Cooperation North-South dialogue in Paris this year, and no doubt more will be heard of it.

Even if one does not accept the primary producers' mistrust of the futures market, one can perhaps understand their fear of the speculator's role. Speculation does involve the employment of wealth that is surplus to that necessarily set aside to ensure a comfortable and secure standard of living in societies where that standard is already very much higher than in many primary producing countries. The belief that such speculators are making vast profits at the expense of the impoverished producer—a view that has also been expressed from time to time in the legislatures of both the United States and Britain—has emotive overtones that simply cannot be ignored.

However, a role exists for further studies and education not only of the role of speculation but also how futures trading can help the primary producers. Before considering this, there is one more question to try to clarify, and here I am inclined to take issue with Gardner. I accept his proof that options trading can be used to stabilize a producer's income, but I believe that the producer really wants to maximize, not stabilize, his commodity income. Where the producer is largely or totally dependent on the income from that one source, however, he may recognize the need

Ben W. Gunn is with the Economic Intelligence Department, Bank of England, London.

to hedge, to sacrifice some of the potential profit in times of high prices to ensure a minimum subsistence income when prices are low. Even then he will not think in terms of stabilizing but in terms of the price he pays for the amount of security of income he needs.

Powers offers alternative strategies to the primary producers, either to operate on the existing markets in the developed world or to set up markets of their own. Both solutions present difficulties.

To turn to the possibility of new markets in the countries of origin, I find myself in substantial agreement with the six criteria Powers has laid down. I would add that it is not merely the need for adequate financial resources but the willingness to apply those resources to support futures exchanges in the face of competing and urgent priorities. The supply of speculation, too, may cause difficulty. If nonresident, it will demand free access to foreign exchange reserves, while if resident it may demand a distribution of wealth that is unacceptable socially in a relatively poor country.

My main doubts, however, stem from the fact that placing the futures market in the country of origin does nothing to stabilize that country's foreign exchange earnings, apart from the quite modest inflow of commissions that is generated. The flows associated with nonresident speculation and hedging by the overseas buyer are quite unpredictable. This places net foreign exchange earnings firmly in the hands of nonresidents. In a recent investigation into the United Kingdom's foreign exchange earnings from commodity trading published in the Bank of England *Bulletin* for March 1977, this was observed to be true for Britain also. The cash flow into or out of Britain depended entirely on the trading actions of nonresident users of U.K. futures markets and not upon the activities of U.K. traders. While not ruling out further study into establishing futures exchanges in primary producing nations (indeed, the producers themselves may well request it), I am not, at this stage, optimistic as to the outcome.

We have, therefore, to examine whether primary producers should operate on the existing markets. I think Powers has done us all a service in documenting the limited use the producers have made so far of markets in the United States. While we do not have the same statistical base from which to work, I am sure that the experience of the London markets is no different. The question now is whether we can—or should—encourage the producers to expand their use of existing futures markets. If I conclude by pointing to still further obstacles to be overcome, it is in the hope that prompt attention to the problem will arrive at solutions because it is in this field that I think that further research, study, and discussion can offer the most positive results.

From the primary producers we will be asking a fundamental change of attitude. The whole emphasis in international commodity negotiations has been toward the administration and suppression of the price mechanism in the interest of stabilization of incomes. The developing countries are not alone in this. Many countries in the world have done the same for their farming communities. In suggesting that many producing countries might benefit from more active use of futures markets, however, we are saying that they will have to learn to trade their commodities. This may require the transfer of responsibility for important segments of their economies from price administrators to commodity trading experts. Even if the latter are directly answerable to government, resistance to change and especially to change so controversial as this is only to be expected and will only be overcome if the advantages of an active trading policy can be clearly demonstrated.

Inviting the primary producers onto the markets will bring about change there, too. It is unlikely that such participation will come from individual producers within countries. In practice, such trading will have to be in the hands of governments or state trading agencies, who by their sheer size may carry considerable weight in the markets, even to the extent of being buyers or sellers of last resort. There is nothing to fear in this if the primary producers approach the market responsibly. We have seen such steady trading from London commercial firms with just as much potential to overwhelm the market, but a high degree of technical trading skill and sensitivity is called for. I should add that there is little the regulatory process can do to help. Any attempt to use the regulatory mechanism as a correction automatically raises international political issues between the two governments, which, if the regulation has the effect of restraining a rise in price, may also have overtones of exploitation.

To sum up, all this sounds rather negative, but my experience with commodity trading has convinced me that there are many prob-

lems to be resolved before we can be certain that existing markets can offer to the primary producers a workable and worthwhile alternative to the policies they are at present pursuing. Nevertheless, I believe that this is the line we should be following and the one that without excluding further study of alternatives should form the keynote of discussion today and the starting point for research that will spread far beyond the confines of this meeting.

Discussion

Allen B. Paul

These are two thoughtful papers. I have three comments on each.

Powers and Tosini show that Latin American traders' share of coffee futures recently had reached 25% of the total on the long side (shades of 1953?). A Federal Trade Commission (FTC) study found that in December 1953 a few Brazilian long accounts in N.Y. futures increased from 856 to 1,846 contracts, or one-half the open interest—largely accumulated in one week beginning 2 December when Brazil announced an increase in the loan rate from 1,200 to 1,500 cruzeiros per bag, after the hard July freeze. Such trading smacked of unfair advantage.

The FTC suggested imposing position limits. This advice was never followed, and it is just as well. It would not prevent anyone from making large forward cash commitments, which in turn could be laid off against futures. As Powers and Tosini argue, U.S. markets cannot readily be insulated from manipulative actions from abroad, whether by individuals, groups, or governments. But other people's information can probably be improved in order to reduce the power of some to manipulate or otherwise distort prices. More disclosure of changes in large cash and futures positions is needed if the game is to be competitive.

The relation of financial institutions to development is one of the grand themes of economics. Does financial development lead or follow growth of output? Goldsmith concludes that there is evidence on both sides. Powers and Tosini show the route to capital accumulation via futures trading to promote local savings and investment, attract foreign capital, and develop banking services. They list conditions in less developed countries essential to successful functioning of futures. To test these ideas, one might study India's experience with many small inland commodity exchanges.

Hicks teaches a larger perspective. Over the centuries, man has bettered his lot through the rise of markets, which implies the rise of a class of people who specialize upon trade. The conditions for the rise of markets are best at certain geographic nodes (historically, the city-state at the water's edge); and when this happens, it sets in motion the mercantilization of more and more of economic life. Institutions first arise to create widely acceptable money and credit, then to create more tradable rights in commodities and finally more tradable rights in land and labor. This evolution of the ideas and instruments of property that can be readily bought and sold by anyone who has the means works its way back into the hinterland and ultimately brings about great changes. Mercantile institutions spread slowly, much more slowly than most technology, but spread they do. The Powers and Tosini paper suggests that there are large educational opportunities to guide policy into fruitful channels not only in respect to futures trading but in respect to all institutions of trade if we were only equal to the task.

On buffer stocks, Powers and Tosini suggest that governmental programs, however handled, are largely incompatible with futures trading. I agree. Thus, it is an illusion to think that, in practice, the government can enter into futures trading to influence the carrying of stocks without also sapping its usefulness in allocating resources.

Futures trading is but one entity in the conflict between state and private decision making. We are a long way from settling such issues on a scientific basis. We need solid empirical studies of program alternatives, including the benefits of preserving the institutions of trade, e.g., what would be the effect on the world economy if there were no Chicago Board of Trade, or its equivalent, with which to price grain dealings within and between countries, state-planned or otherwise?

This is a fitting place to turn to Gardner's paper on commodity options. Such trading now is banned for major farm products. He makes a plausible case for their use to stabilize net income from a given crop whenever its

Allen B. Paul is an economist with the Economic Research Service, U.S. Department of Agriculture.

prices and yields are uncertain and negatively correlated.

This gets to the heart of a farmer's problem in using futures. Gardner shows how options could be used to supplement forward sales of a safe part of his expected crop; he also shows how options might replace futures altogether. But, conceptually, the same problem could be met by strategic use of futures—e.g., sell the normal output forward and then buy in one-third of this quantity if the futures price were to rise by the cost of an option; later, sell this quantity forward if the futures price were to drop to the original level. Option trading may cost less if the specialized intermediaries deal in volume, and they may offer less lumpy units. Also, market orders are uncertain of execution at a selected price. But currently the costs of eight-month options in London trading in coffee and sugar futures are about 20% of the price of futures, and options are thinly traded.

Options pose some social problems. While historically they have arisen in response to a genuine business need, like that shown by active trading in call options in the seventeenth century on the Amsterdam bourse for herring and other commodities that were to arrive by ship in uncertain quantities, option trading also has been outlawed from time to time. Undoubtedly reasons were not always well grounded in theorems of economic welfare. Genuine problems arise because in modern times option trading has been conducted in conjunction with highly organized futures machinery, and it has been used to cover increases or decreases in large futures positions. Mehl seems to suggest that the big option writers had manipulated futures prices in their favor when the exercise date had arrived. An important question at issue is whether regulation of option trading could be effective in preventing such manipulation and at what cost.

Gardner's analysis of government price supports as a put option freely given to farmers is apt. His suggestion that a government commodity reserve could be operated by granting such a put option, conditional on the farmer's granting the government a call option at twice the loan (put) price, is intriguing. But there might be nonperformance by some farmers because of low yields. A problem would arise only where there are not "safe" levels to create a call option against.

Discussion

Anne E. Peck

From the figures on foreign participation in futures markets, especially those for the less developed countries (LDC's), provided by Powers and Tosini, it appears that foreign traders rank only marginally above farmers in their direct interest in futures markets. The comparison is apt, for most foreign participation, and again especially for the LDC's, would be as producers, presumably, rather than as consumers or processors. Thus, there is a strong link between the papers presented today. The link lies in the producer and his seeming lack of interest in forward pricing.

Futures markets provide a market mechanism to deal with price level risk in a roughly symmetric fashion. This may not be their most important function,[1] but it is clearly one of their functions. By symmetric, I mean that, once a position has been taken, price changes in either direction affect profits or losses in an equal way. Profits or losses from an options position, on the other hand, are distributed asymmetrically with respect to the underlying instrument's (commodity or futures contract) price movements.

In this context, Gardner has developed a case in favor of options markets using the producer as his example. One reason that producers do not use futures markets or forward contracting to forward price their output may well be that their price risks are distributed asymmetrically. For example, suppose that at planting time, the market is somewhere near equilibrium, and the farmer plants accordingly. He expects normal yields, though realizes that he may get somewhat better or worse than normal results depending on rains and growing season temperatures. He also realizes that there is a possibility for disaster, for example, a corn blight or a drought. In this view, then, his basic production risks are not symmetric. Additionally, assuming a price inelastic demand, his income will be significantly higher in the high price years than in the normal-type years.

Perhaps, then, the reason farmers do not forward price with futures (or forward cash contracts) is that they would thereby not be able to take advantage of those bad yield/good price years. An options market, however, would permit the farmer to deal more effectively with exactly this type of risk, as Gardner's illustrations make clear. However, basically equivalent results can be obtained with the combination of a short futures position with an appropriately placed stop-loss order.[2] Since this is a possible trading strategy, why are farmers not trading? Or, more pointedly perhaps, if producers do not participate in options trading (assuming it is permitted on an experimental basis), is that grounds for deciding it is serving no economic purpose?

The other producer group of interest in this session are the foreign producers. I can only agree with Powers and Tosini that there are a variety of special legal reasons why futures trading by these groups (especially if it would be by state-owned marketing boards) in domestic markets should be carefully monitored. However, their presence or absence in the market seems to me not to matter when considering their fundamental influence on the market. For example, a freeze that damages the coffee crop in Brazil will have price effects in New York futures whether or not the Brazilians are trading there. Alternatively, a severe shortfall in Russian wheat production influences prices only if the Russian decide to enter the world market to make up the deficit. Whether they make that intention known directly through cash transactions or "indi-

Anne E. Peck is an assistant professor, Food Research Institute, Stanford University.

[1] The evidence suggests that the most important function of futures markets is in facilitating the intertemporal storage of commodities. The largest users of these markets are inventory holders, and they hedge to earn a profit from basis changes, not to avoid risks. On this point, see Working and Gray.

[2] A cheaper alternative would be to forward contract with the local elevator, simultaneously placing an order to buy futures at a specified price above the current futures price. In either case, the producer would benefit from the occasional large changes upwards in the underlying price level during any specific growing season. Determining the optimal prices to place the stop-loss order or the buy order is roughly equivalent to determining the value of an option.

rectly" through futures purchases does not really matter in the ultimate price effect.

Given the market statistics on foreign use of U.S. futures markets, one might wonder if there is any chance that new, "local" futures exchanges would survive, even if established. The statistics are not encouraging. It is likely, however, that U.S.-based futures markets are of little use to large segments of potential hedgers because of very unpredictable basis patterns. Thus, extensive commercial inventory hedging is simply not feasible in U.S. markets for foreign merchants. Regional exchanges would alleviate this problem to a great extent. Interexchange arbitrage would be another source of potential monetary benefits to the countries establishing the exchanges.[3]

Finally, both papers consider the price and income stabilization potentials with these forms of markets. Gardner states that "A major rationale for price support programs would disappear if a well-functioning market in put options existed." In any one year, farmers' purchase of a put option clearly would be equivalent to the effect of a loan program. However, exercise prices of options would likely vary as much as the underlying commodity prices from year to year.[4] Income and/or price stabilization similar to that provided by the loan program with its relatively constant (from year to year) loan prices would be impossible. Alternatively, suppose a constant year-to-year exercise price is established. In this case, the farmer would pay substantially for his put option in the low price years, and the net price for his production would be no different than if he had simply marketed it at the lower cash prices. Income (price) stabilization similar to the loan program is not possible in either case.

Powers and Tosini, on the other hand, focus their discussion on the proposals to stabilize cash prices with a futures fund rather than a buffer stock fund. In particular, they note it is likely that a futures fund, generally net long, would need to stand for delivery of commodities, thereby not in fact being able to avoid the accumulation of the commodity. In fact, it is more than just "likely" that these deliveries would have to occur. The basic proposal to trade futures instead of the cash commodity relies upon there being a close relationship between cash and futures prices. Indeed, for most major markets there is a close relationship. This relationship, however, exists only because of the threat and/or possibility of delivery. If a government fund, trading large quantities of futures, did not stand for delivery on its positions, the connection between cash and futures prices would dissolve, and the presumed price effects of government futures trading would not be transmitted to the cash prices.[5] Therefore, the purchase of futures could only be a temporary substitute for the accumulation of cash stocks, not an alternative method of stabilizing price.

[4] It makes no difference whether the option is on futures contracts or on the cash commodity, since futures prices are generally as variable as cash prices (Tomek and Gray). Since these prices do vary between years, it is likely that the exercise prices would also vary.

[5] An analysis of this and other effects of the government's trading of futures contracts is available in Peck's study of the Federal Farm Board's experiences.

Assessing Public Policies and Programs: Equity Considerations
(Kenneth L. Deavers, Economic Research Service, USDA, Chairperson)

Sociopsychological Measures of Quality of Rural Life: A Proxy for Measuring the Marginal Utility of Income

Wilmer M. Harper and Luther G. Tweeten

Economics has been defined as the science of allocating scarce means among competing ends. Ultimate ends to be achieved may be defined as well-being, satisfaction, utility, or quality of life. It has become fashionable to divaricate economics into dimensions of efficiency and equity. Defined as increasing the size of the "pie" of goods and services, efficiency has received the lion's share of attention by economists; its study has been viewed as objective, precise, and respectable.

Economists have relied heavily on perfect competition as a norm of efficiency, but perfect competition results only in a Pareto optimum. Using the Edgeworth Box as an example, two individuals or groups can be at a Pareto optimum on a contract curve, yet one individual or group can be in misery from starvation while the other individual or group can be satiated with goods and services. To move along the contract curve to a point of global welfare maximization requires knowledge of the marginal utility of additional goods and services (income). Utility is maximized at the point where marginal utility of income is equalized. Suggestions for such movement have been eschewed by positive economists in part because subjective, normative, interpersonal comparisons of utility were required and in part because, even if accurate estimates of marginal utility were unavailable, a normative judgment is implied that such movement is appropriate.

It is time to begin merging equity and efficiency in economic science, the nexus being the marginal utility of income. Given that economics is concerned with increasing well-being of people, the study of conventional measures of efficiency is neither objective nor precise because it conveniently assumes away too much by employing the premise that the marginal utility of income is equal for all income levels and all people. Neither is it appropriate to label the study of equity as unsuitably subjective and imprecise in view of advances in methodology that can provide useful comparisons of quality of life among populations defined by income, age, education, etc. Although methods for estimating marginal utility may yet be too imprecise to make interpersonal comparisons of the marginal utility of income, the methodology appears to be sufficiently advanced to make useful intergroup comparisons of utility for formulating public policies that impact unevenly on different groups.

If the marginal utility of income is less for gainers than for losers, it is possible that some public programs implemented on the basis of favorable conventional benefit-cost (B-C) ratios may in fact reduce well-being. To promote a nexus between equity and efficiency, an efficacious start is to replace the concept of economic efficiency implicit in benefit per unit of cost (B-C ratio) with the concept of social efficiency defined as satisfaction per unit of sacrifice. Social efficiency is similar in concept to economic efficiency except that dollar benefits are weighted by marginal utilities among gainers to indicate satisfaction, and dollar costs are weighted by marginal utilities among those paying the cost to arrive at total sacrifice.

Wilmer M. Harper is with the Department of Agricultural Economics, New Mexico State University, Las Cruces, and Luther G. Tweeten is Regents professor, Department of Agricultural Economics, Oklahoma State University.

Journal Article J-3357 of the Oklahoma Agricultural Experiment Station.

One goal of public policy is to fund projects with greatest social efficiency. Provision of satisfaction-sacrifice (S-S) ratios by no means rids the policy maker of the need to make judgments. The S-S ratio (or, alternatively, net social benefit defined as satisfaction minus sacrifice) from a project is but one of several positivistic pieces of information. The decision to allocate funds requires that the policy maker balance the S-S ratio against other information such as the outcome variation, the ethical soundness, and the political feasibility of increased well-being for society as a whole but requiring sacrifice by some members of society.

An advantage of the S-S ratio over the B-C ratio is its ability to measure the social efficiency of a wide range of programs including transfer payments. If the marginal utility of income is sufficiently great for low versus high income groups, greater social efficiency gains (based on the S-S ratio) may be obtained by redistribution of income than by some investment projects with conventional B-C ratios greater than 1.0.

If economics is indeed the science of allocating scarce resources among competing ends to improve well-being of society, social efficiency measures seem appropriate. This study shows one method of developing weights for benefits and costs among income groups for use in S-S analysis. The perceived quality of life index (QLI) is put forth as a measure of individual satisfaction and a proxy measure for utility.

Given knowledge of income flow over a period of time, economic theory holds that the rational consumption unit will choose that combination of goods and services that maximizes the satisfaction derived from the income stream. Well-being is assumed to be enhanced by having more options—greater income increases the options for purchasing goods and services or accumulating wealth that contributes to power and prestige. Given the basic economic assumption that more is preferred to less and the fact that income of the individual is finite, perceived quality of life is constrained by income. It follows that the quality of life that the individual perceives is, at least in part, a function of income.

Since Srole's development of a social indicator scale for anomie, social scientists have attempted to measure the relationship between social indicators and income. An inverse or negative relationship has been demonstrated between anomie and level of income (McDill, Mier and Bell, Bell, Bullough). A positive relationship between income and self-esteem has been established (Crain and Weisman; Heiss and Owens; Yancy, Rigsby and McCarthy), but the aggregation of income into too few segments (e.g., high and low) precludes determination of the rate of change in self-esteem as income varies. Scales measuring "level of happiness" or "life satisfaction" perceived by the individual have been found to have a positive relationship with income (Easterlin, Bradburn and Caplovitz).

The Rural Income Maintenance Experiment (RIME) conducted in Iowa and North Carolina during 1969–72 was a major effort "to test the behavioral consequences of a universal income-conditioned cash transfer program" (Bawden and Harrar, p. 1). The extensive sociopsychological data collected as part of the experiment included items that were modifications and adaptations of established social indicator scales. These items and the accompanying income and demographic items form the data base for this analysis. Data on attitudes were complete only for quarters 2 and 10 of RIME (Bawden and Harrar).

The objective of this paper is to construct a measure of individual perceived quality of life and to relate this measure, using ordinary least squares, to income, age, education, and other explanatory variables. Data were available for both household head and spouse, but taken as separate data sets, each group produced statistical results less satisfactory than those from the pooled data set reported herein. The coefficient for a dummy variable for spouse inserted into the general model was not significant at the 0.05 probability level. The family was taken as the relevant data set for QLI development and analysis. When logically consistent, independent variables were aggregated into family units and related to attitudes of the head and spouse.

QLI Construction and Analytic Framework

The quality of life index (QLI) is conceptualized as the weighted summation of three sociopsychological subindices: alienation (A), worry (W), and self-esteem (SE). The subindices were constructed from established social indicator scales. To verify the a priori conceptual grouping of the scale components into the subindices, principal axis factor analysis was

performed on the entire set of scale items with the number of factors restricted to three—the number of subindices. The resulting loadings of individual items upon the three factors substantiated the grouping of the scales into the proposed subindices.

Factor analysis was also used to identify factors (hypothetical constructs) that explain the variation observed within the individual scales. The following criteria were used to determine the maximum number of factors incorporated into each scale: the factors retained had eigenvalues greater than or equal to one, and/or the addition of another factor would result in the grouping of the scale items into a less plausible configuration of the scale items. To assure internal consistency and a QLI directly related to positive and negative perceptions, the factor loadings for negative construct factors within each scale were "reflected" by changing the algebraic signs. Individual responses to each item were standardized by dividing deviations from the mean item score by the standard deviation. Individual scale values were then calculated by the following functional relationship:

$$M_i = \sum_{k=1}^{m} E_k\left(\sum_{j=1}^{n} f_{kj}R_{ij}\right),$$

where M_i is the scale value for the ith individual, m is the number of factors extracted for the scale, n is the number of items in the jth scale, E_k is the eigenvalue for the kth factor, f_{kj} is the factor loading for the jth item on the kth factor, and R_{ij} is the standardized response of the ith individual to the jth item on the scale. The subindices of the QLI were calculated as

$$A_i = An_i + P_i + NA_i$$

and

$$SE_i = SS_i + LS_i + PA_i,$$

where An is anomie scale ($m = 1$), P is powerlessness scale ($m = 1$), NA is negative affect scale ($m = 2$), SS is self-satisfaction scale ($m = 2$), LS is life satisfaction scale ($m = 2$), PA is positive affect scale ($m = 1$), all for the ith individual. The worry subindex (W) consisted of only one scale with $m = 1$.

The final step in the QLI construction was the weighted summation of the three subindices. In the verification of the a priori subindex composition, each of the three factors received the loadings of the majority of the items of one of the subindices. The results of this analysis were used for the final weighting, and QLI_i was calculated as

$$QLI_i = E_aA_i + E_wW_i + E_{se}SE_i,$$

where E_a, E_w, and E_{se} are, respectively, the eigenvalues of the factor containing the majority of the items making up that subindex.

Theoretical QLI Model

The nuclear model for the QLI analysis was judged a priori to be of the following form:

$$QLI_i = f(Y^*_i, ED_i, AGE_i, N_i, L_i, R_i, S_i, PERFARMY_i, NW_i, QTR, T_i, E_i),$$

where QLI is the quality of life index. The independent variables are: Y^* is the expected net income in current quarter, including transfer payments, of the family unit; ED is the educational level (last grade completed) (Katona, Yuchtman); AGE is the age (Katona); N is the number of individuals (Smith and Haythorn); L is the geographical location of the residence of the family unit ($L = 1$ if Iowa; $L = 0$ if North Carolina); R is the race (Yancy, Rigsby, and McCarthy; Heiss and Owens; Tweeten and Lu); S is the sex; $PERFARMY$ is the farm income/total income ratio for the family unit (Tweeten and Lu); NW is the net worth of the family unit (Ackley); QTR is the time variable ($QTR = 0$ for quarter 2; $QTR = 1$ for quarter 10); T is the negative income tax treatment of the family unit; E is the error term, and i subscript represents the ith individual or unit. Interaction among the independent variables was also considered theoretically germane to the model. Four algebraic forms were initially considered: logarithm, square root, quadratic, and cubic.

Empirical QLI Model

Criteria for selecting a functional form were R^2, coefficient signs, and size of t-ratios. The quadratic form of the QLI model was selected, and certain of the theoretically admissible variables were rejected from the model on the basis of statistically insignificant coefficients (see table 1). The nine independent variables account for 82% of the variation in QLI, and each coefficient is significant at the 0.04 probability level or better.

In the empirical model, education (ED^2) is positively related to the individual QLI, but for any given level of education, increasing

Table 1. Ordinary Least Squares Estimates Relating QLI to Selected Variables

Variable	Coefficient	*t*-Ratio	Standardized Coefficient

N = 2,014 R^2 = 0.82
$\overline{QLI}$ = 330.35[a] s = 134.5683
$\overline{Y^*}$ = $2,193.41 per quarter $\overline{PERFARMY}$ = 0.02 (proportion)
$\overline{ED}$ = 9.62 years $\overline{AGE}$ = 43.21 years

[a] The coefficients of the independent variables are invariant to addition of a constant to the scale. Negative predicted values may be avoided by an arbitrary addition to the scale; adding a constant would affect only the intercept.

age diminishes the contribution of education. *AGE* initially exhibits a positive contribution to QLI, reaches a maximum, and declines thereafter. Based upon average level of education (see table 1), the contribution of *AGE* to QLI reaches a maximum at 39.43 years and becomes 0 at 78.87 years. The marginal contribution of *AGE* to QLI is linear and declines throughout. Interaction of age with education (*AGEED*) causes a change in the responses of QLI to age with each level of education. The positive relationship of location (*L*) to the QLI may arise from superior public services and other "environmental" factors in Iowa. The possibility that income contributes to the variation explained by *L* is discussed later with the income specific analysis.

A preference within the study group for farm derived income is shown by *PERFARMY*. The data do not permit a determination of the reason for this preference, but two potential sources are immediately apparent. Individuals may experience a positive influence from farming as a way of life; underreporting farm income may also make a dollar of reported farm income preferable to a dollar of nonfarm income. The time trend variable (*QTR*) accounts for considerable observed variation in QLI, but without additional observations for the QLI scale items, the data are not sufficient for an evaluation of the source of the variation explained by *QTR*. The "washing out" of an experimental payments effect over time, a decline in a "Hawthorne" or participation effect, or changes in the social environment and national mood of the United States are all potential sources of the observed *QTR* variation.

The failure of the theoretically admissible *NW* variable to enter the model may be due to inadequate data on net worth coupled with the fact that a large portion of the sample consists of low income individuals with little net worth.

Based upon an analysis of the general model containing Y_t and Y_{t-1} (t is quarter) as separate variables, income was aggregated into expected income (Y^*). Coefficients for the linear terms Y_t and Y_{t-1} were significant at the 0.05 probability level, but the coefficient for Y_{t-1} was much smaller. Y^* was calculated as

$$Y^* = \frac{b_{yt}}{b_{yt} + b_{yt-1}} Y_t + \frac{b_{yt-1}}{b_{yt} + b_{yt-1}} Y_{t-1}.$$

The decline in the size of the coefficients from Y_t (0.002298) to Y_{t-1} (0.001236) indicates that Y^* should not be seriously biased by the lack of additional lagged income periods. QLI reaches a maximum (marginal QLI reaches zero) at $40,942 of expected income Y^* per year, which is outside the range of the data; the point must, therefore, be interpreted with caution. The marginal contribution of Y^* is linear and declines throughout.

Income Related Hypotheses

Having established a general QLI model in which Y^* is one of the variables, we now appraise in more detail the specific impact of income on the QLI.

The relative versus absolute hypothesis tests the proposition that the variation observed in the QLI depends upon the relative as well as the absolute level of income. A dummy variable *PI* ($PI = 1$ if $Y^* > \bar{Y}^*$) was used to separate the regional data sets into subsets, where Y^* is above the mean ($\bar{Y}^*$) or less than or equal to the mean of the respective state sample. The relevant test statistics for *PI* are coefficient, 5.8514, and *t*-ratio, 0.585.

Given the small *t* for the coefficient of *PI*, the Chow test was used to test the structural stability of two equations estimated with data for individuals respectively above and below the mean of Y^*. The *F*-statistic (2.20) rejects at the 0.05 probability level the null hypothesis that the regression coefficients estimated by the respective subsets belong to the same structure, and the two structures are inferred to be different at the chosen level of significance. The difference need not arise from different responses to income, however. The regression coefficients 0.0165 (Y^*) and -0.0000008 (Y^{*2}) for data set $Y^* > \bar{Y}^*$ and 0.00226 (Y^*) and -0.0000011 (Y^{*2}) for data set $Y^* \leq \bar{Y}^*$ suggest that the marginal response of QLI with respect to Y^* is greater for the subset $Y^* \leq \bar{Y}^*$ than for the subset $Y^* > \bar{Y}^*$ over all relevant ranges of Y^*. A crude test for difference between the paired coefficients is $t = (\hat{b} - c)/s_b$, where *c* is the coefficient of the linear (squared) income variable and *b* is the corresponding coefficient of the linear (squared) variable in the equation of income above (below) the mean. The difference is significant at the 0.10 probability level for only the coefficient *c* of linear term Y^* of the subset $Y^* > \bar{Y}^*$.

The coefficient of the variable *L* is highly significant. *L* may also measure a part of the variation in QLI arising from a relative income phenomenon. If persons in North Carolina and Iowa judge their relative position based on a national rather than local perspective, the coefficient of *L* could indicate a lower QLI experienced by persons in North Carolina as they perceive their relative deprivation. The place of relative versus absolute income in determining the quality of life needs further consideration when more comprehensive data become available.

The income irreversibility hypothesis is that the marginal response of QLI is greater for falling income than for rising income. Two methods were used to test this hypothesis. First, the income variable was segmented into rising and falling components. No evidence was found to support the hypothesis that the marginal response of QLI with respect to Y^* is greater for falling than for rising income. Second, the Chow test was used to evaluate the structural stability of the QLI model with the data set subdivided into observations for respondents whose income increased and for respondents whose income decreased during the past quarter. The *F*-statistic (1.28) failed to reject at the 0.05 probability level the null hypothesis that the regression coefficients estimated by the respective subsets belong to the same structure. In estimating the impact of income on the quality of life, differentiating between rising and falling income does not appear to be necessary—the QLI index appears to be reversible.

The earned-unearned income hypothesis tests the proposition that earned income (Y^*_e) and unearned income (Y^*_{tr}) have different influences on QLI. The income variable (Y^*) was segmented (other variables the same as in table 1) with the results given in table 2. The coefficients indicate that the marginal QLI response to Y^*_{tr} is initially greater than to Y^*_e, but it falls more rapidly for Y^*_{tr} and reaches zero at a much lower level than for Y^*_e.

Separate regressions taking the model with Y^*_e and Y^*_{tr} as the unrestricted model and the model with Y^* as the restricted model failed to yield an *F*-statistic (1.25) significant at the 0.10 probability level.

In a test of the equality of the paired coefficients; (H_0: $B_{ye} = B_{ytr}$), the analysis failed to reject H_0 at the 0.05 probability level for both pairs of coefficients, but the analysis rejected H_0 at the 0.10 probability level for the squared terms. In short, the results provide modest and mixed support for the proposition that QLI responds differently to earned than to unearned income.

Implications and Potential Uses

The QLI function and the accompanying hypotheses of this analysis apply to some of the central issues of economic policy. These results, if substantiated by further experimentation, have profound implications for equity issues and suggest substantial welfare gains from a more nearly even distribution of income. Supplemented by findings extended to other geographic, temporal, and income conditions, results such as those shown above

Table 2. Estimates for Earned and Unearned Income

Variable	Coefficient	*t*-Ratio
Y^*_e	0.01647140	4.105
Y^{*2}_e	−0.00000095	−2.978
Y^*_{tr}	0.02452665	3.507
Y^{*2}_{tr}	−0.00000396	−2.242

would allow the computation of a more nearly optimal distribution of income. These results can provide a foundation for revision of income tax scheduled to provide equal marginal sacrifice or to redistribute income (see Harper). Benefit-cost ratios for public projects could be constructed by weighting benefits and costs among income groups according to the marginal impact on quality of life. The QLI results could enable the determination of an appropriate mix of transfer payments versus earnings-generating programs to maximize QLI. Findings can also be used to compute welfare losses from an unstable economy as well as benefits from programs to reduce instability. Given the declining marginal response of QLI to income, a greater quality of life may be derived from a given stable income than from the same income received on the average but with variability. Education appears to have an impact on quality of life independent of income; this finding could alter the procedures for computing returns to schooling. Amplification of the data base to additional geographic areas, income levels, sectors, and time periods should be accompanied by a reconsideration of the variables rejected from the general model.

The QLI model of this analysis reflects the environmental aspects of quality of life only as they influence individual responses. It would a priori appear that a more adequate explanation of quality of life would entail a larger set of independent variables including the institutional structure of the environment.

Distributional Equity of the Food Stamp Program

Philip L. Martin and Sylvia Lane

Under the current Food Stamp Program, participating low income households obtain stamps usable for the purchase of any food in cooperating retail outlets (USDA 1976b).[1] The program was made available to counties wishing to adopt it under the Food Stamp Act of 1964 (U.S. Congress, Senate 1976b). Food stamp and food distribution programs operated simultaneously as state-administered programs throughout the 1960s. By 1970, Food Stamp Program outlays amounted to $550 million (USDA 1976a). But between 1970 and 1976, standards of eligibility became nationally uniform and benefits were liberalized (1971); the Food Distribution Program was almost entirely phased out; the Food Stamp Program expanded to encompass participation by every county in the nation and by its territories (USDA 1975b); the number of Food Stamp Program participants quadrupled, and Food Stamp Program outlays increased over 950% to $5.9 billion (U.S. Congress, Senate 1976b; USDA 1976a; U.S. Congress, Senate 1976a). This expansion has been characterized as the single most important welfare change in America since the passage of the Social Security Act of 1935 (Nathan). Nonetheless, the Food and Nutrition Service of the U.S. Department of Agriculture estimates only about 60% of those eligible in the period of a month and 76% of those eligible in the course of a year elect to participate in the program (USDA 1975b, U.S. General Accounting Office).

Past studies indicate that those eligible may not participate because of ignorance, program costs to recipients, lack of income to purchase stamps, or the problem of earmarking income for food or because local attitudes discourage participation (U.S. Congress, Senate 1975a; U.S. General Accounting Office; Lane). Food Stamp Program participation varies across defined geographic and demographic cohorts, with urban eligibles more likely to participate than those in rural areas, younger persons more likely to participate than older persons, whites more than nonwhites, and larger families more than smaller families (USDA 1975a).

The Food Stamp Program is an "entitlement" program, i.e., the program promulgates eligibility criteria and a formula for calculating benefits but not a fixed expenditure level. Therefore, total program outlays accruing to different geographic areas depend on the level of benefits (uniform under the Food Stamp Program, depending only on family income and family size), the distribution of eligible beneficiaries, and the extent to which eligible persons elect to participate in the program.

In this paper determinants of county-level Food Stamp Program outlays per capita and per poor person in 1975 are assessed in light of county characteristics. The term "distributional equity," as used in this paper, implies that the Food Stamp Program should operate to assure that per capita county-level benefits vary only with those characteristics affecting program eligibility, viz., family size, income, and unemployment indicators, and that per poor person outlays should fall within a narrow range across classes of counties aligned along an urban-rural spectrum. The 3,097 U.S. counties are arrayed along a nine-category rural-urban continuum, and county-level outlay data are regressed against county characteristics data for 1970. County characteristics data are available on a national basis only in census years, forcing the use of 1968 and 1970 independent variable data to explain more recent outlay patterns. Although differential changes between and within rural and urban

Giannini Publication No. 479.

[1] A Food Stamp Program was operative from 1939 through 1943. Pilot programs were in existence in 1959 and federally mandated in 1961. Presently, food stamps may also be used to pay for meals furnished by some nonprofit meal delivery services, meals at communal dining facilities for the elderly, plants and seeds to grow food for the household's own use, and hunting and fishing equipment for qualifying Indians and Eskimos.

areas could limit the model's reliability, the relative position of counties with respect to the variables considered appears relatively stable.

In the following sections, salient features of the Food Stamp Program will be reviewed and the regression model and data sources described. The results of the regression analysis and their implications are reviewed. The summary, conclusions, and recommendations are in the final section.

The Food Stamp Program

To be eligible for benefits under the Food Stamp Program, a household must have cooking facilities, be unable to buy a "nutritionally adequate diet" (as specified in the USDA's thrifty food plan) with approximately 30% of its monthly net income, have less than $1,500 in liquid assets ($3,000 if a household member is over 60), and all able-bodied household members must register for and accept suitable employment. Public assistance and supplemental security income recipients (except in Massachusetts) are automatically eligible. Eligibility standards are uniform across the nation (USDA 1976b).

Food stamps cost recipients from 0 to 86% of their face value, the cost of the stamps being determined by family size and the recipient's income after allowable deductions. Deductions averaged $56.50 per household in 1975 (USDA 1975b). The purchase requirement varies between 0 and 30% of income. On average, Food Stamp Program recipients pay between 40¢ and 45¢ for each dollar's worth of food stamps (Madden and Yoder, Lane). All families of the same size receive the same dollar value of stamps, enough to purchase the components of the thrifty food plan. The difference between what a recipient pays for the stamps and their face value is termed "bonus stamps."

In January 1976, some 19.1 million persons (9% of the population of the United States and its territories) participated in the Food Stamp Program (U.S. Congress, Senate 1976b). Federal Food Stamp Program benefits were 18% of federal government expenditures on public aid in 1975 (U.S. Dep. Commerce 1976). Throughout the country, the Food Stamp Program is the only program available to the working poor and others in need of income supplementation who are not eligible for categorial welfare or other transfer programs.

The Model

The model used in estimating values of coefficients for determining Food Stamp Program outlays across counties was

$$Y_i = a + bP + cPA + dA + eT + fB + gI + hCG + iCR + jCC + kN + lLF_n + mV + nRV + oX + pU \quad (i = 1, 2),$$

where Y_1 is 1975 dollar outlays for bonus stamps divided by county population (equation (1)), Y_2 is 1975 dollars outlays divided by the county population below the low income or poverty threshold (equation (2)), a through p are constants, P is the percentage of persons in the county in poverty in 1970, PA is the number of persons in the county on public assistance, A is the percentage of persons in the county over 65 years of age and poor, T is the percentage of persons in county under 18 years of age, B is the percentage of population in the county that was Black, I is the percentage of population in the county that was Indian, CG is the characterization of the county as more or less urban or rural on a 0 to 8 scale (USDA 1975a) (a binary variable was used for each of the eight classes; fringe counties were omitted), CR is the census region, CC is whether a core county (1) or not (0), N is whether a new standard metropolitan statistical area, LF_N is the labor force participation rate (male), V is how population voted in 1968 (1 = Democratic, 0 = not Democratic), RV is the percentage of registered voters who voted in the 1968 election, X is the expenditure on another public program (in this case, CETA I),[2] and U is the unemployment rate in the county.

The model was estimated using ordinary least squares and cross-section data. We realize the "real world" may dictate use of a more complex model. Concentrations of poor persons may lead to increasing awareness of and participation in the program. Similarly, one could assume a variety of interactions and simultaneities between, for example, partici-

[2] CETA Title I funds, the largest expenditure component of the Comprehensive Employment and Training Act (1973), support manpower services provided in local areas. Such programs include outreach efforts, testing and assessment programs, orientation and counseling services, training programs, transitional public service employment, and labor market information programs. (U.S. Dep. Labor).

pation in a voluntary social welfare program and the percentage of those who voted or a simultaneity between outlays per poor person and the poverty population. However, this work is exploratory, our justification for using a model incapable of reflecting all real world conditions.

Data on 1975 dollar outlays for Food Stamp Programs bonus stamps and expenditures on the Comprehensive Employment Training Administration Title I Program were obtained from Federal Information Exchange System tapes. Data for the Food Stamp Program were originally compiled by the Food and Nutrition Service, USDA. Data used directly or for the construction of variables *a* through LF_N and variable *U* were obtained from the county characteristic profile tapes prepared by David Brown and Fred Hines of the Economic Development Division, Economic Research Service, USDA. Data on how the population voted in the 1968 election and on the percentage of voters who voted in the 1968 election were obtained from *County and City Data Book 1972* (U.S. Dep. Commerce 1973).

The dependent variable used in the equation—bonus stamp outlays per person—provides one indicator of the geographic distribution of bonus payments. Since the Food Stamp Program is oriented primarily toward poor persons, a second dependent variable, bonus outlays per poor person, was employed. Neither indicator is a perfect measure of local benefits, but both are useful in estimating the extent to which food stamp benefits are diffused across counties. The bonus stamp value per poor person focuses on only one subset of the eligibility group, the poor, and the census definition of poverty is not coterminous with the Food Stamp Program definition. The bonus stamp value per capita measure is more inclusive, accounting for the temporarily unemployed needing food.

The explanatory variables reflect the demographic composition of the county, the socioeconomic status of both the poor and nonpoor populations, and county attitudes as expressed by participation in a human resources program, political tendency, and the extent of voting. The variable *PA*, the percentage of a county's population receiving public assistance, indicates the importance of the poverty population in each county and/or the extent to which poor persons obtain public assistance. "Percentage poor" is an indicator of county need, while "percentage obtaining public assistance" reflects variance in eligibility criteria as well as the propensity or ability of those in need to receive cash support.

A second set of independent variables focuses on the demographic composition of the county's population. Economic and demographic variables have been recognized as important determinants of participation in the Food Stamp Program (USDA 1975a), although their effects on outlays per capita have not been studied. Two age variables, the percentage of a county's poor population over 65 and the percentage of a county's population under 18, are indicative of the relative importance of populations frequently in need of food stamps (U.S. Dep. Commerce 1976). Since minority populations suffer a disproportionate incidence of poverty, the percentage of a county's population that is Black or Indian provides yet another dimension of likely need for food assistance.

Labor force variables are used to indicate relative economic needs arising from a lack of income-earning opportunities. The male labor force participation rate (LFPR) is indicative of longer term economic conditions reflecting both the propensity of the male adult population to seek employment and the extent to which attractive types of work are available in the area, while the unemployment rate indicates the probability of finding employment. Unemployed persons are an important subset of those eligible to receive food stamps.

A unique set of variables was introduced to explore local attitudes toward social programs in general, local willingness to expend federal funds, and "public mindedness." The percentage of a county's population that voted in 1968 and a dummy variable to distinguish counties with Democratic congressional representation are employed as crude indicators of county attitudes. A better indication of county attitudes toward social programs is provided by a county's willingness to adopt a voluntary social program designed to assist low income persons. In this analysis, counties that elected to participate in CETA Title I programs were distinguished from those that did not. One other variable, census region (*CR*), with the Northeast omitted, was included to explore the possibility of regional differences.

One objective of this study was to assess the distributional equity of outlays across geographic areas. Since neither the value of stamps to which eligible households of equal

size and income are entitled nor purchase requirements vary across geographic regions, the only geographic differences that should arise are those associated with systematic variation in family size, net family income, or rates of participation.

Findings

The models used to explore the determinants of bonus stamp outlays per person and per poor person across county classes generally indicate: (*a*) that rurality does decrease bonus stamp outlays per capita and per poor person; (*b*) that variables that measure the extent of poverty and public assistance participation are the most important determinants of bonus stamp outlays; (*c*) that local attitudes, as expressed by partisan political choices and, more importantly, county participation in a voluntary human resources program, are significant determinants of per capita bonus stamp outlays; and (*d*) that economic and demographic variables have their expected effects on bonus food stamp outlays. The significance of both geographic and attitudinal variables suggests factors not envisaged in the authorizing legislation are, in fact, partially determining per capita food stamp outlays across counties.

The urban bias of the Food Stamp Program is evident from the coefficients (table 1). Movement from urban to rural settings along the urban-rural spectrum lowers per capita bonus outlays at an increasing rate. The urban county groupings had small and insignificant coefficients, while the rural groupings had coefficients that were significant and highest in the most rural county class. Per capita outlays were reduced by \$7.26 in the most rural county grouping. Outlays per poor person behaved in a similar fashion. Core and urban county benefits were higher and rural counties' benefits lower by up to \$50.44 per poor person. The pattern and significance of the rurality variable provides solid evidence of an urban bias in the Food Stamp Program.[3]

Compared with other regions, counties in the North Central region obtained lower food stamp benefits per capita and per poor person. Being in the South was positively associated with outlays per capita but negatively associated with outlays per poor person. Being in the West was not significant for outlays per capita, but outlays per poor person were significantly higher. Being a new SMSA was insignificant.

The most important determinants of food stamp bonus outlays were those variables indicating the size of the eligible population, i.e., poverty and unemployment measures. Per capita outlays increased by \$176 with each 1% increase in the percentage of the county's population below the poverty line and a further \$93 for a 1% increase in those on public assistance.[4] Combined with an unemployment rate coefficient of \$120 per capita, these results suggest concentrations of poor persons tend to fare better than the dispersed poor. But food stamp outlays per poor person are insensitive to the percentage of poor persons. This regression indicates those eligible must first be entered in public assistance rolls before outlays are significantly increased. Interestingly, a 1% increase in the unemployment rate increases bonus outlays per poor person by \$662, the most powerful impact on outlays.[5] Male labor force participation rates were insignificant.

The significance of public assistance and unemployment indicates poverty alone is insufficient to assure access to the Food Stamp Program benefits. Those on public assistance are automatically eligible for food stamp benefits, and the unemployed may be made aware of benefits by an employer, union, or friends. The rest of the eligible population may have to rely on local "outreach" efforts. If local attitudes hinder such efforts, participation and hence benefits may be lowered.

Variables used to assess local attitudes reinforce the hypothesis that local efforts significantly affect the distribution of food stamp benefits. Counties that participated in CETA Title I programs also "reward" poor persons with an additional \$14 in food stamp benefits. Similarly, voting and, in particular, voting Democratic tends to increase both per capita and per poor person outlays.

---

[3] Rural families tend to be larger and have lower incomes, on average, than urban families. Therefore, Food Stamp Program outlays should be higher per capita or per poor person in rural areas than in urban areas.

[4] Before 1974, public assistance households comprised a relatively stable 61% of all food stamp participants. In 1975 nonpublic assistance participating households first outnumbered public assistance households, and the trend has been projected to continue (U.S. Congress, Senate 1975a, b).

[5] The ratio of the coefficient to its standard error is largest for the unemployment variable. Of course, a 1% increase in unemployment is a relatively large change, and this should be kept in mind in interpreting the coefficient.

Table 1. Regression Results for Variations in 1975 Federal Food Stamp Program Dollar Outlays, 3,097 Counties

Variable	Program Outlays per Capita (1)	Program Outlays per Person in Poverty (2)
Constant	−26.39	22.33
Percentage "poor"	176.43	−15.89
	(7.05)[a]	(34.03)

	(1.14)	(5.48)
County group 7	−3.18	−39.58
	(1.13)	(5.42)
County group 8	−3.31	−34.64
	(1.32)	(6.38)
County group 9	−7.26	−50.44
	(1.19)	(5.77)
R^2	65.4	28.1

[a] Standard errors in parentheses.

Demographic variables had their expected impacts. Concentrations of minority populations tend to reduce outlays per person and per poor person, while the presence of more children increases outlays. The impact of the elderly poor and of the male labor force participation rate were insignificant.

Coefficients of determination were 65.4 for the per capita outlay model and 28.1 for the per poor person equation, the difference most likely attributable to variation in the percentage in poverty across counties. In part, R^2's are not higher because these models explore the determinants of per capita outlays across

counties, reflecting variance in participation as well as differences in family size and income. Although attitudes are known to affect participation, our simple indicators of attitudes presumably do not capture all local variations across county groups in such factors affecting participation (U.S. Congress, Senate 1975a, b), and some unmeasurable variables have been omitted.

Conclusions and Policy Implications

Federal efforts to assist low income persons are moving to embrace the concepts of income supplementation and universality. The Food Stamp Program is one of the major income supplement and income redistribution programs in the United States. As the only federal assistance program that permits the "working poor" to participate, it demonstrates that assistance programs can be inclusive rather than categorical. Its 19 million participants rival those of the Social Security Program, permitting food assistance and retirement assistance to be the bulwarks of the federal social welfare effort.

How well does the Food Stamp Program distribute funds to those of equal "need"? The record is mixed. Outlays per capita under the program are greater where there are higher percentages of poor people, higher percentages receiving public assistance, or unemployed people. On the basis of these indicators the program appears to be meeting income supplementation needs and may be termed an efficient program. However, where there are higher percentages of Black or Indian people, outlays per person and outlays per poor person are lower. There are regional differences, and, in more rural county groups, both per capita and per poor person outlays are lower. Higher outlays per person and per poor person accrue to core counties, the most metropolitan of all.

Despite the tendency of outlays to increase with poverty, the program does not appear to be uniformly equitable. Since federal income supplemention programs are national in scope, they generally abstract from known differences between urban and rural areas. Our findings support the hypothesis that there are structural differences between rural and urban areas that make for an implicit bias against rural areas in the distribution of program benefits. Distributional inequity may also be due to the attitudes of the county population as reflected by program administrators on the county level. Counties that participated in CETA Title I also had higher Food Stamp Program outlays per person and per poor person, a possible reflection of need as well as program administration. Outlays were higher in counties with a higher percentage of the eligible population that voted, and per capita outlays were higher in counties that voted Democratic.

What recommendation may be made on the basis of these findings? If the program is to meet existing needs as currently defined, participation rates should be increased. This would imply the encouragement of outreach efforts directed in large part at minorities. This recommendation is obviously contentious, since it would increase program expenditures. But it must be judged in the light of what the program is trying to achieve as an income supplement program, which raises the question of whether it is the best program for that purpose. However, the Food Stamp Program is politically palatable, and presently a comprehensive cash income supplement program is not.

Using Federal Outlays Data to Measure Program Equity: Opportunities and Limitations

Fred K. Hines and J. Norman Reid

Since the late 1960s, annual reports on federal spending in small areas have been available. This effort was initiated in the Community Services Administration (CSA) (formerly the Office of Economic Opportunity) in 1966 to monitor poverty program funds and was soon expanded to include most federal activities. Currently, the CSA has working annual files and published volumes for fiscal years 1968 through 1976. Published reports known as the *Federal Outlays* series are issued separately for each state and list the amounts of individual program funds spent by federal agencies in each county and in each city with a population of 25,000 or more. In total, over 1,300 program entries are reported for each county unit in the United States. The *Federal Outlays* is the only comprehensive series of county-level data on the federal government's spending.

Earlier editions of the reports suffer from serious problems of completeness, accuracy, program identification, and definition, many of which have been resolved in recent issues. Beginning with the 1975 issue, program identification was greatly improved by labeling programs with the program numbers given in the *Catalog of Federal Domestic Assistance* (U.S. Office of Management and Budget). This matching provides the user of the Outlays files easy access to the program descriptions in the *Catalog*.

The purpose of this paper is two-fold: to provide illustrations of how the *Federal Outlays* data series can be used to address equity issues at the substate level and to give a brief overview of the current limitations of this data series. In exploring equity issues, the Outlays data are used in conjunction with data from the census of population, census of governments, Internal Revenue Service, and selected state departments of taxation. The equity analysis uses data from 1972, the latest year for which comparable data from all sources were available. The simple equity analyses that follow are illustrations of possible uses of the Outlays files and are not meant to provide firm answers to equity issues in federal spending.

Fred K. Hines is an economist and J. Norman Reid is a social science analyst with the Economic Research Service, U.S. Department of Agriculture.

An extended version of this paper is available from the authors.

Using the Federal Outlays Data in Equity Analyses

The definition of equity is not well settled among either scholars or politicians, and various conceptions may be found in both analyses and grant-in-aid formulas. Aside from definitional differences, equity analyses can be conducted on several levels. The appropriateness of individual equity criteria in part depends on the analytic level at which one focuses. Many analyses have focused on federal aid programs, principally grants, often treating groups of related programs comprising a functional area. Other studies have evaluated the distribution of funds under individual programs (U.S. President 1977, National Science Foundation, De Leon and Le Gates). Finally, there has been some interest, heightened by attention to the "sunbelt" issue, in the analysis of total federal spending (e.g., macrolevel equity) and its relationship to the strength and growth of state and regional economies (Havemann, Stanfield, and Peirce; Jusenius and Ledebur).

The following sections focus on equity questions from different levels of program aggregation and by using alternative measures of equity. First, a micro approach is taken by relating selected individual program funds to proxies for target populations from the Census of Population (U.S. Dep. Commerce 1972).

Second, for selected states, differences in per capita outlays for community development and urban renewal are compared with differences in fiscal capacity and fiscal effort at the local and state level. Finally, a macro approach is taken to assess equity in total federal spending among metropolitan and nonmetropolitan areas and regions under three equity criteria.

Microlevel Equity Analyses

Perhaps the most common method of evaluating equity is to weigh expenditures for a function against variables indicating need; for example, variables indicating the size of the poverty population might be used to weigh the distribution of poverty funds, just as measures of the quality or quantity of available housing might be used to evaluate housing funds. Such need measures are frequently used in grant allocation formulas—poverty level population, percentage unemployed, age of housing stock, and population aged 65 and over are examples.

As one illustration, the *Fourth Annual Report on Government Services to Rural America* (U.S. President 1974) compares the distribution of fiscal year (FY) 1972 outlays for social security benefits and grants to states for public assistance (welfare) payments with selected target variables. Social security old-age and survivors benefits were distributed among metropolitan and nonmetropolitan county groups in approximately the same proportions as the aged population. However, relative to the distribution of the poverty population, the distribution of public assistance grants strongly favored metropolitan counties. Nonmetropolitan counties contained 39.8% of the poverty population but received only 26% of federal outlays for welfare programs. The difference is almost entirely attributable to the Aid to Families with Dependent Children program (AFDC). While some states have elected to provide benefits to intact families, the AFDC program is geared primarily to poverty families with female heads. Since relatively fewer nonmetropolitan poverty families are headed by females (23.2% versus 39.8% for metropolitan families), a smaller share of the nonmetropolitan poor are eligible for welfare payments. In addition, only 19.6% of AFDC outlays accrued to nonmetropolitan counties, despite the fact that 27% of the population under 18 in female-headed poverty families resided in nonmetropolitan counties. Further, almost 40% of the total poverty population under 18 years of age were nonmetropolitan residents. This disparity reflects the fact that the rural states have generally set lower benefit levels than their more urbanized counterparts.

Another equity measure that commonly appears both in program analyses and grant-in-aid formulas is fiscal capacity—the ability of the area to finance its public services from its own revenue sources. This criterion assumes that areas with the lowest capacity are least able to provide adequate services from their own resources. Although there are various means of measuring local fiscal capacity and differing views as to which is the most appropriate, the most frequently used measure is average per capita personal income (Nathan, Manvel, and Calkins).

The highest per capita community development funding was directed toward metropolitan counties, with core counties in the largest standard metropolitan statistical areas (SMSA's) receiving an average of $23 per capita, nearly twice the average for the four states used in the analysis (table 1). Counties in both medium and small metropolitan areas had higher outlays than most nonmetropolitan counties, and only the fringe counties in larger SMSA's received less than the nonmetropolitan average. As measured by per capita adjusted gross income,[1] the pattern of fiscal capacity is just the reverse; average incomes in the metropolitan counties were well above the four-state average, while nonmetropolitan counties ranged from roughly 60% to 85% of that figure. Although one might conclude from these figures that community development and urban renewal grants were distributed inequitably among metropolitan and nonmetropolitan counties, the four sample states were selected because of the availability of state tax data and the same conclusion might not hold for the entire nation.

A related equity measure is tax effort, which argues that areas that tax themselves at a higher percentage of their capacity deserve larger shares of federal aid. This criterion is one element in the general revenue sharing formula. State and local government taxes as a

[1] Adjusted gross income is the result of reducing gross income from all sources subject to the federal tax by adjustments for business expenses, moving expenses, depreciation, sick pay, losses from sales of capital assets, carryover of "net operating loss" to businesses, and contributions by the self-employed to retirement funds.

Table 1. Community Development and Urban Renewal Grants Compared with Fiscal Capacity and Tax Effort Levels, Selected States, 1972

Item	Number of Counties	Per Capita Community Development and Urban Renewal Grants	Adjusted Gross Income per Capita		State-Local Taxes as Percentage of Income	
			Dollars	Percentage of Four State Average	Tax Effort Factor[b]	Percentage of Four State Average
Total, four states[a]	282	13	3,431	100.0	12.4	100.0
Metropolitan total	87	15	3,635	105.9	12.0	97.6

Adjacent to an SMSA	25	4	2,109	61.5	18.9	153.2
Not adjacent to an SMSA	34	12	2,541	74.1	15.4	125.0

Sources: Outlays data: U.S. Community Services Administration; income data: U.S. Treasury Dep.; state-local tax data: U.S. Dep. Commerce, and various state sources as described below.

[a] The four states included in this analysis are Colorado, Florida, Louisiana, and Ohio.

[b] The tax effort factor is total state and local government tax collections in each county as a percentage of adjusted gross income. Total state tax collections by county were estimated. Figures were obtained from the 1972 annual report of the Colorado Dep. Revenue for income tax liability, motor vehicle registration, and net sales tax by county; these taxes, which equaled 60.4% of total state taxes in 1972, were inflated to equal total state tax collections. Florida tax collections by county were obtained from the Florida Comptroller's 1972 *County Finances and Fee Officers Report*, which reported data for major state taxes comprising 73.8% of the total; the county totals for these taxes were inflated to equal the state total. Michael and Jones estimated total 1969 Louisiana state tax burdens by parish, which were inflated to equal 1972 total state tax levels. Data for fiscal 1972 sales, personal income, motor fuel, and cigarette tax collections in Ohio counties were provided by the Ohio Dep. Taxation. Total tax collections in each county were estimated by inflating these taxes, which comprised 60.4% of the total, to 100%.

percentage of adjusted gross income are compared with per capita outlays for community development and urban renewal programs in table 1. In general, this criterion suggests an inequitable distribution of community development and urban renewal grants, though the pattern is not entirely consistent. Tax effort is higher in nonmetropolitan counties than in metropolitan counties, while per capita outlays for community development were higher in SMSA's than outside them. However, within metropolitan counties, the highest outlays go to the core counties, which have the highest tax effort, while the lowest tax effort, in the fringe counties of larger SMSA's, is rewarded with the smallest level of federal community development spending.

Macrolevel Equity Analyses

The recent "sunbelt-frostbelt" debates have focused attention on yet another level of equity analysis—the effect of total federal spending on state and regional economies. In this section, three measures of equity in total spending are illustrated: total outlays relative to income level, total outlays relative to federal personal income tax liability, and federal effort (federal tax liability as a percentage of income) relative to outlays.

Comparisons of the levels of per capita outlays in nonmetropolitan and metropolitan areas and census regions with their average per capita incomes are made in table 2. The figures suggest that nonmetropolitan areas gain less than equitable shares of outlays—both per capita incomes and outlays are lower in nonmetropolitan counties—and that the West gains more than equitable portions of outlays.

A second way of evaluating whether spending is equitably distributed is to compare spill-ins of spending with spill-outs of federal taxes. The analysis here compares per capita outlays

Table 2. Equity Measures for Studying Federal Outlays among Metropolitan and Nonmetropolitan Counties by Regions, 1972

Item	Federal Outlays	Federal Personal Income Tax Liability	Per Capita Adjusted Gross Income		Ratio of Federal Outlays to Tax Liability		Federal Personal Income Tax Liability as a Percentage of Adjusted Gross Income

Metropolitan	1,272	479	3,857	108.2	2.66	115.2	12.4	96.1
Nonmetropolitan	1,221	340	2,946	82.6	3.59	154.4	11.5	89.1

Sources: Outlays data: U.S. Community Services Administration; income tax liability and adjusted gross income: U.S. Treasury Dep.

with personal income tax liability.[2] By this measure, nonmetropolitan areas as a whole receive a net benefit at the expense of metropolitan counties with the least populous nonmetropolitan counties receiving the highest net inflow of federal dollars. The primary losers are the fringe counties in the nation's largest SMSA's, which both pay high taxes and receive back comparatively little federal expenditure. Similarly, the southern and western regions are significant net beneficiaries, both in their metropolitan and nonmetropolitan areas.

A third way of looking at equity in the distribution of total outlays is to consider them in relation to the federal tax burdens borne by the residents of each area. Here, we measure federal tax burden as federal personal income tax liability as a percentage of adjusted gross income. While there is some relationship between the average federal tax effort and outlays to metropolitan and nonmetropolitan counties, that relationship is hardly a consistent one (table 2). The metropolitan counties as a whole bear higher than average tax burdens and receive in return higher than average outlays per capita. Within the metropolitan

[2] Although federal income taxes comprised only 45% of all federal revenues in fiscal year 1972, they are used here to compare with outlays because data on other sources of revenue, such as corporate income taxes and employment taxes, are unavailable at the county level.

and nonmetropolitan groups, however, there is little apparent relationship. The figures for the four regions support this conclusion; the two regions with the highest average tax effort rank second and fourth, respectively, in per capita outlays.

Limitations of the Federal Outlays Data Series

The major limitations of the current Outlays files relate to the methods used to estimate and report county level outlays, matching individual programs with their descriptions in the *Catalog of Federal Domestic Assistance,* and year-to-year changes in the Outlays data and in federal programs themselves, which result in problems in using the data in time-series analyses.

Allocation Methods

For fiscal year 1976, only 27.6% of all outlays reported to the county level represented actual outlays rather than estimated amounts.[3] Over two-thirds (71.6%) of the funds were allocated to the county level by a variety of proration techniques. These allocation methods were used because of the difficulty of accounting for federal spending at such levels of geographic detail and of coordinating the reporting effort across all federal agencies.

The proration methods differ widely in sophistication and, as a result, in their probable effects on research conclusions. A majority of the programs, with nearly half of total outlays, involve proration methods that are reliable enough that the data can be used with some confidence. Of these programs, those involving the largest amounts of money are primarily benefit payments to individuals whose county level expenditures are estimated on the basis of target population size (the number of recipients) by assuming an equal benefit payment per case.

There are a number of programs, involving nearly a quarter of total outlays, for which the county level detail is not reliable enough to support valid research conclusions. Of these, the most important group includes both grant and contractual spending programs for which the county level spending is either unknown or unmeasurable and for which no attempt at proration was made. Included in this group are federal payments to prime contractors and formula grants to state governments, for which the Outlays data report only the initial payment and not the final expenditure of the money by the intermediaries. In addition, spending under some thirteen programs is estimated on the basis of each county's population, clearly too crude a method to support valid research conclusions.

Matching the Outlays Series with the Catalog

One of the major improvements in the *Federal Outlays* data in recent years resulted from identifying many Outlays program categories with program numbers appearing in the *Catalog of Federal Domestic Assistance.* The descriptive detail in the *Catalog* helps to flesh out the cryptic program titles in the Outlays publications and is of great benefit to the researcher, who might otherwise have to struggle to identify the content of programs.

Despite its value, the *Catalog,* which contains descriptions of the main characteristics of over 1,000 federal aid programs, including most grants-in-aid and a number of other forms of assistance, was intended to help state and local governments and other applicants to identify their potential eligibility for federal assistance. Thus, it is often inadequate as a comprehensive and reliable classification of the programs and activities reported in the *Federal Outlays* files. While the *Catalog* does not include all federal programs, it does purport to contain most discretionary federal assistance programs such as grants, loans, and technical assistance. As a result, the *Catalog's* lack of comprehensiveness may have less serious effects on equity analyses taking a micro approach (viewing equity for individual or selected groups of programs) than on those taking a more macrolevel view (as measured by total federal outlays).

The *Catalog's* value is further limited by occasional changes in its program classifications from one issue to the next, by alterations in the identification numbers that apply to a particular program, and by a lack of full coordination between the *Catalog* and the Outlays. The need for better coordination be-

[3] Federal outlays include all spending by the federal government's executive branch agencies, including such items as grants-in-aid to state and local governments, salaries and administrative expenses, military procurement and research contracts, and transfer payments to individuals (such as social security and civil service retirement benefits). The outlays amounts are not budget outlays as displayed in the annual budget documents but primarily represent funding obligations and new loan commitments. The method used to report outlays varies: some programs report on a cash basis, while others report on an obligations basis (e.g., the amounts of new awards of funds) or some other basis.

tween the two series is illustrated by comparing the *Catalog* identification numbers used in the 1976 Outlays publication with the most recent year they were listed in the *Catalog*. Of the 645 *Catalog* numbers referenced in the 1976 Outlays files, 92.5% (597) were described in the 1976 *Catalog*. However, the Outlays files used 24 catalog numbers that were not described in the current *Catalog* (though they were listed in earlier issues); an additional 24 program numbers have never been listed in any issue of the *Catalog*. While such discrepancies between the two sources remain irritating to the researcher, the *Catalog* remains the most useful available tool for identifying individual programs found in the Outlays files.

Using Outlays Data in Time-Series Analyses

One benefit of an annual data series is its potential for use in time-series analyses. The researcher who attempts to use the *Federal Outlays* data in this fashion faces several obstacles, of which the most significant is the difficulty of identifying equivalent component programs in each of several years. The constant change in federal policy, as new programs are created and old ones consolidated or eliminated outright, is a major source of frustration in such time-series efforts. The difficulties are magnified when the study involves a period of major transition in federal policy from one set of programs to another. An improved *Catalog of Federal Domestic Assistance* could support time-series analyses by helping researchers to identify and trace changes in federal policies and programs over time.

Summary and Conclusions

The illustrations in this paper point out the potential value of the Outlays series and the usefulness of the data when used in conjunction with other statistical series. The analysis demonstrates the measurement of equity at several different levels and uses various criteria for equity. The results indicate clearly that the choices of both level of analysis and evaluative standards are important ones that can be expected to have a significant impact on research findings.

The paper also considers the limitations of the *Federal Outlays* data series. The major advantage of the Outlays data is its high level of detail, both geographically and programmatically, which makes it amenable to the pursuit of hypotheses that could not otherwise be addressed. Its primary limitation centers around the fact that much of the county-level detail are estimates, rather than actual figures. Approximately 27% of the programs, involving 72% of total outlays on the 1976 file, employed some allocation technique to arrive at county-level figures. However, about two-thirds of these outlays used allocation methods that were judged to be acceptable for most research purposes. Many of the allocation techniques could be improved or eliminated entirely by incorporating other existing statistical series into the Outlays data reporting activity.

Assessing Public Policies and Programs: Equity Considerations: Discussion

Glenn L. Nelson

Harper and Tweeten present results that should stimulate interesting and useful hypotheses. They manipulate a rich source of data with a logical sequence of statistical routines. The limitations of factor analysis (Armstrong) and the problems of pretest bias in a succession of regressions (Debertin) warrant additional emphasis. But the authors are more careful in recognizing the value of prior information than many of their colleagues and are also aware their hypotheses need confirmation before application.

The failure of Harper and Tweeten to recognize explicitly the larger dynamic and macroeconomic setting is an important shortcoming. A major issue in the current debate of income redistribution is the trade-off between equality and efficiency (e.g., Campbell). Efficiency in the context of this debate includes encouraging the innovation and investment that maximizes future production as well as insuring incentives exist for appropriate allocations in the current period. The underlying premise is that redistribution of income discourages both the contributor and recipient from putting their resources into the most productive uses. This very hypothesis was a prime motivation for the experiment whose results are being analyzed by Harper and Tweeten. Once this trade-off is recognized and accepted, knowledge of the marginal utility of income among groups at a point in time, while useful, is clearly an inadequate base for policy formation.

Harper and Tweeten are overly anxious to have this type of study influence policy formation. A one-dimensional measure of the quality of life, a few explanatory variables possessing the usual problems of measurement and correspondence to theoretical constructs, and a regression equation are inadequate for the complex problems that confront us. The analysts who make an important contribution to equity issues in public policy in the near term will be those who explain "who gains, who loses, and why" along several socioeconomic dimensions and leave the weighting of the dimensions and the fixing of marginal utilities to the political process. The research reported by Harper and Tweeten is valuable but not as an immediate input to policy.

The paper by Hines and Reid contains a good, concise description of the *Federal Outlays* data and other closely related series. The illustrations of comparisons of outlays with other demographic and economic variables are useful demonstrations of descriptive studies. Such studies address the issue of "who gains and who loses" from a variety of perspectives, which, as noted earlier, is information much sought after and needed in political discussions. This account by two experienced analysts is a useful reference for those who wish to pursue studies with these data.

The major problem with the Hines and Reid paper is their failure to go beyond description in either illustrations or general discussion. The impacts on equity that they address are limited to initial impacts defined in narrow terms of who directly receives funds from or forfeits funds to the public treasury. The missing element is an analytic framework that would facilitate identification and measurement of causal factors and indirect impacts. Indirect impacts on regions, industries, occupations, and other variables may either reinforce or counter the initial impacts of programs (e.g., see Golladay and Haveman).

The description of the allocation procedures raises the question of whether analysts would be better advised in many cases to limit their analysis to rates of participation, i.e., recipients of outlays relative to members of the target population. When federal outlays are allocated to counties based upon their propor-

Glenn L. Nelson is an associate professor in the Department of Agricultural and Applied Economics, University of Minnesota, St. Paul.

Journal article 9981 of the Minnesota Agricultural Experiment Station.

tion of program participants, a comparison of estimated outlays and estimated target population is fundamentally one of comparing participant and target populations. A direct analysis of the participation rate would be more straightforward and less likely to be misinterpreted.

The paper by Martin and Lane possesses problems of conceptualization and interpretation. Part of the problem is the lack of a clear statement at the outset of how equity is to be measured. The authors cite numerous studies showing socioeconomic variables, such as location and race, that affect food stamp utilization. Martin and Lane apparently regard an equitable situation as one in which families of equal size and equal net income receive equal bonus stamps regardless of other socioeconomic factors. If this interpretation is accepted, the relevant objective is to quantify the impact of socioeconomic factors associated with different levels of bonus stamps among the eligible people. Such a study is valuable.

People of middle and higher socioeconomic status receive no, or extremely few, bonus stamps. This is easily explained by the income limitations of the program and is consistent with equity as defined above. An econometric analysis is not required. The equation explaining food stamp outlays per capita serves little or no useful purpose.

In conclusion, the definition of the concept of equity being investigated should be clearly stated in policy analysis. Distinctions between nominal and real goals are especially important in rural-urban comparisons. Should people receive more public assistance if they choose to live in high cost areas? How does this relate to our goals of the appropriate spatial distribution of people and economic activity? Which equity goals, if any, are best accomplished at regional, state, and local levels rather than nationally?

Research on equity issues should be conducted with an awareness of an integrated conceptual framework that includes indirect impacts and other macro considerations. Economic theory is at least as relevant in equity as efficient issues.

Personalizing Learning Processes in Agricultural Economics

Dayton Young Roberts and Hong Yong Lee

The past two decades have witnessed a resurging emphasis on the study of self as a concern of American education, a concern that had almost disappeared in the wake of the behavioristic tide generated by Watson and his followers in the 1920s. Today, numerous theorists and practitioners contend that self-concept theory and self-concept activities are vital ingredients in the educative process. Maslow, Rogers, Combs, and Purkey, among others, have related well the dynamics of self to motivation and behavior. Combs (1962, 1965) suggested that teacher preparation be based on a perceptual, self-concept approach, and at the University of Florida in 1969 he spearheaded an experimental program emphasizing the development of sensitivity, empathy, and capacity for effective interaction in teacher trainees.

The scarcity of such efforts, however, led Purkey to observe that "little has been done to equip teachers . . . with simple clinical techniques and instruments which would enable them to be more sensitive to their students" (pp. 57–58). What little has been done consists almost exclusively of preservice preparatory programs for teachers at the elementary and secondary levels.

A distinct departure, perhaps the first of its kind in preservice and in-service preparatory programs for teachers at the junior and senior college level, was the "Humanistic Approach to Learning" model and program, introduced and implemented at the University of Florida in 1971 and continuing from Texas Tech University under the title "Personalizing the Learning Climate."

Since 1971, more than 2,100 preservice and in-service college teachers and administrators have participated in the seminars and workshops of the program. The participants have been introduced to current self-concept theories, have experienced clinical tecnhniques, and have responded to instruments designed to increase their sensitivity and awareness of themselves, putting them in a better position to help build positive and realistic self-concepts in their students.

The instruments administered to these participants are, for the most part, forced-rank-order instruments dealing with attitudes toward personal values and with key questions related to their roles as college teachers. An analysis of the rank-order a teacher assigns the various structured responses offered in a list of terms or statements provides insight into specific attitudes and values of the teacher; the instruments are similarly revealing when directed at and administered to students. The following rank-order question is administered first since it serves to demonstrate the validity of personality type study to the participants, and this is essential for the success of the program: As an instructor, what do you think students look for when they enter a class for the first time? Rank the following from 1 to 7: friends in the class, number of assignments, instructor's personality, specific learning objectives, instructor's grading system, course reading requirements, and types of tests given.

As reported by Park in his 1971 ERIC study and by Roberts (1973, 1974) in two more recent studies, college faculty and college students at all levels most frequently rank "instructor's personality" number one. This revelation accompanied by a renewed interest in the psychological theories of Jung led to the use of the Myers-Briggs Personality Type Indicator as the principal and most sophisticated

Dayton Young Roberts is a professor of higher education and Hong Yong Lee is an associate professor of agricultural economics, Texas Tech University.

self-concept instrument used in the personalized learning program.

The Myers-Briggs Type Indicator (MBTI) is a self-administered 166 item self-validating instrument published in 1962 by the Educational Testing Service (Myers 1962). The MBTI and the supporting research stemming from its development expanded and clarified Jung's theory that seemingly chance variation in human behavior is in fact not due to chance; it is the logical result of observable and measurable differences in mental functioning.

These basic differences concern the way people use their perceiving processes to become aware of people, things, occurrences, or ideas and the way they use their judging processes to come to conclusions about what has been perceived. Since the two together—perception and judgment—are central to a person's mental activity, they determine, to a great extent, that person's overt behavior.

Jung's theory states further that there are two ways of perceiving—by sensing and by intuition—and two ways of judging—by thinking and by feeling. In addition to whichever of these processes an individual prefers, there will be an accompanying preference for introversion or extraversion. Thus, the MBTI defines the following pairs of preferences from which sixteen different combinations of personality type may be derived:

(*a*) Extraversion (E)/introversion (I): the direction of interest. Does the subject's interest flow mainly to the outer world of actions, objects, and persons (E) or to the inner world of concepts and ideas (I)?

(*b*) Sensing (S)/intuition (N): how situations are perceived and experienced. Does the subject attach more importance to the immediate realities of direct experience (S) or to the inferred meanings, relationships, and possibilities of experience (N)?

(*c*) Thinking (T)/feeling (F): judgment preferences. In making judgments, does the subject rely more on logical order and cause and effect (T) or on priorities based on personal importance and values (F)?

(*d*) Judging (J)/perception (P): lifestyle. Does the subject prefer to live in the judging attitude, systematically planning, ordering, and organizing his world, deciding what needs to be done and attempting to control events (J) or in the perceptive attitude, spontaneously, curiously, awaiting events and adapting to them (P)?

The preferences in type processes result in sixteen combinations of personality types (table 1).

In spring 1977 two members of Texas Tech University agricultural economics faculty participated in the second annual series of faculty development workshops titled "Personalizing the Learning Climate at Texas Tech." Their involvement in this program led to the typing of agricultural economics faculty and students with the MBTI.

Seventy-seven upper division students majoring in agricultural economics at Texas Tech University were typed with MBTI. In addition, eleven agricultural economics faculty members were also typed with the MBTI. Typology distribution of students and teachers, as shown in table 2, reveal (*a*) a much higher percentage (78%) of students are sensing (S) versus intuitive (N) than teachers (55%), (*b*) an overwhelming majority (82%) of teachers are judging (J) versus perceptive (P), whereas less than one-half of the students are judging (42%), and (*c*) a much higher proportion (82%) of teachers are thinking (T) versus feeling (F) than students (64%).

In spite of a rather small sample of teachers used in the study, disparities of the personality-type distributions found between faculty and students of agricultural economics at Texas Tech University is quite typical in higher education throughout the nation. The disparities point to the fact that a preponderance of sensing (S) types are being taught by teachers who are more apt to be intuitive (N) type than students. Sensing types do not see, hear, and/or experience things in the same manner as intuitive types. The higher the sensing score or the intuitive score, the more pronounced become these differences in perceiving things. Because of these differences, sensing types do not prefer the same teaching and learning staples as intuitive types. While intuitive types like to read, sensing types tend to favor other methods for learning.

Further analyses of the typology distribution indicate (*a*) nearly one-third of students are sensing-feeling (SF) type compared with none for teachers, (*b*) close to one-half of the students (45%) and teachers (55%) are sensing-thinking (ST) type, (*c*) only 4% of students, compared with 18% of teachers, are intuitive-feeling (NF) type, and (*d*) 18% of students and 27% of teachers are intuitive-thinking (NT) type. In her *Introduction to Type* Myers (1976) states that sensing-thinking types focus their attention on facts and handle

Table 1. MBTI-Type Distribution

	Sensing		Intuitive		
	Thinking	Feeling	Feeling	Thinking	
Judging	ISTJ	ISFJ	INFJ	INTJ	Introversion
Perceptive	ISTP	ISFP	INFP	INTP	Introversion
Perceptive	ESTP	ESFP	ENFP	ENTP	Extraversion
Judging	ESTJ	ESFJ	ENFJ	ENTJ	Extraversion

these with impersonal analysis. Thus, they tend to be practical and matter of fact and find scope for their abilities in such occupations as production, construction, accounting, business, economics, law, etc. Sensing-feeling types tend to be sociable and friendly. They are more likely to find occupations in sales, service, customer relations, welfare work, general practice, etc. Intuitive-feeling types find scope for their abilities in research, teaching, counseling, preaching, writing, psychology, etc., while intuitive-thinking types are more apt to be happy in such fields as research, science, invention, securities analysis, management, pathology, etc.

Students majoring in agricultural economics at Texas Tech University are predominantly (78%) possessors of personalities that tend to favor occupations in production, accounting, business, economics, sales, law, service, customer relations, etc. In view of the fact that employment opportunities for graduates with degrees in agricultural economics are most abundant in those fields mentioned above, it should be considered as a very healthy situation.

Interestingly, of the three students whose MBTI showed ENTJ type, two of the students are planning to pursue advanced studies in agricultural economics with full intention to become researchers.

Analysis of academic performances of the 77 students based on their work completed at Texas Tech University revealed that only two categories of MBTI-types showed statistically significant deviations in the distributions of students within each MBTI-type (table 3). Of the 77 students, 18 students (23.4%) had a grade point average (GPA) of less than 2.0 on a 4.0 point (for A) scale, 35 students (45.4%) had a GPA between 2.0 and 2.74, and 19 students (24.7%) had a GPA between 2.75 and

2.75–3.49	19	19						
>3.49	5	5						

[a] Based on grade point average on work completed at Texas Tech University on a 4.0 point for A scale.
[b] Same distribution for each MBTI-type is assumed as the distribution for the total.
[c] Statistically significant χ^2 values are 7.81 and 11.3 at 5% and 1% levels, respectively, for 3 degrees of freedom.

3.49, while 5 students (6.5%) had a GPA of more than 3.5. Of the 11 ESTP-type students, 6 students had a GPA of lower than 2.0 (compared with an expected number of 2.6), 1 had a GPA between 2.0 and 2.74 (compared with an expected number of 5), and 4 students had a GPA between 2.75 and 3.49 (compared with 2.7 expected). All three ENTJ-type students had a GPA between 2.75 and 3.49, which resulted in a significant χ^2 value. Even though two categories of MBTI-types showed a statistically significant χ^2 test, the MBTI-type is hardly an indicator of students' academic performances based on the sample of 77 students.

It appears that the greatest value of information of MBTI of students lies in aiding teachers in their counseling activities and in their teaching. As an example, it might be a mistake for a teacher to urge a sensing-feeling type student to pursue a career in research. Assuming that the sample of 77 students at Texas Tech University is a fair representation of agricultural economics students throughout the nation, it would be advisable for teachers to use teaching techniques that rely less on intuition and reading and more on sensing and factual materials. The study also points out the necessity of teachers to be extremely patient whenever they are involved with teaching materials that require much abstraction and/or conceptualization. Teachers in agricultural economics should neither expect the majority of their students to grasp readily anything that requires much intuition nor lose patience

when students fail to conceptualize in abstract.

In the first issue of *Findings*, the Educational Testing Service quarterly devoted to research in postsecondary education, Warren states, "New means of accommodating student diversity are clearly needed, and one approach is to assess the personal preferences or learning styles of the students and adapt instructional procedures accordingly" (p. 4).

Teaching and learning styles and their relation to Jungian personality preferences are now being investigated in numerous studies around the country, particularly at Texas Tech University. Findings indicate clearly that sensing and judging types prefer to teach and learn in an orderly, systematic manner using primarily their five senses and that they respond positively to varied multimedia instructional approaches and do not respond as well to the written or the spoken word (e.g., textbooks and lectures) when used alone as instructional media. The intuitive and perceptive types, on the other hand, prefer to teach and learn in a flexible, unstructured manner. They are more apt to respond positively to the written and spoken word, providing that these stimulate interest and imagery. Responses to such stimuli may range from hunches to creative discoveries. It appears then that students exhibiting these contrasting personality preferences to any significant degree should not be taught or treated in the same manner nor should they be given the same types of assignments.

In his preface to Brawer's *Personality Characteristics of College and University Faculty*, Arthur Cohen wrote, "One must know who and what one is if he is to be successful in teaching, a most humane profession" (p. III). American higher education has not accepted completely the premise that teaching is a most humane profession, especially at the college level, but when it does, exploration of self-concept and personality theories and the matching of teaching and learning styles with personality preferences will play key roles in the humanizing process.

Increasing Conflicts over Land Use: Conceptual Issues and Practical Problems (Daniel W. Bromley, University of Wisconsin, Chairperson)

The Economics of Agricultural Land Preservation

B. Delworth Gardner

Several state legislatures are considering enactment of tight zoning laws to preserve high productivity land for agricultural use. In the vernacular of the day, this land is referred to as "prime" (Raup, pp. 2, 3). Apparently, the myriad of tax preferential policies and other planning devices designed to protect agricultural lands from conversion to other uses have not been very effective (Hansen and Schwartz). Some of our best agricultural land continues to be converted to expanding urbanization, transport, utility easements, and for a variety of public purposes. So it is argued by those who advocate zoning for agricultural land that more drastic measures are now needed to stop this avalanche before "serious" agricultural land shortages occur.

Of course, if social action is needed to retain prime land in agricultural use, the land market cannot efficiently allocate land resources among competing uses. The tax preference schemes were enacted to make it less costly to use land for agricultural purposes so that significant quantities of land would be kept in agricultural use that would otherwise shift. But use changes could still occur through the market if value differentials were great enough to offset the production cost advantage created by the tax preference. The crux of the proposed prime land preservation legislation is quite different; it removes the land allocation decisions from the market entirely by using productivity criteria to qualify land for preservation and by granting the power for exemptions and use changes to designated boards.

This paper is largely concerned with the economic implications of this drastic policy shift. There must be substantial political pressure for retaining prime agricultural land since proposals are numerous and are being made in all sections of the country. It is the thesis of this paper, however, that the economic costs and benefits of such proposals have not been adequately explored and that it is the obligation of agricultural economists to do so. Not even the philosophical rationale for removal of the market from land use decisions has been adequately considered (Ervin et al.). This paper is more of an exploration of this issue than it is an empirical demonstration of market efficiency.

The next section discusses the perceived benefits of prime land preservation; the third section discusses market failure and the alleged justification for social intervention; the fourth section treats the selection criteria that have been proposed to qualify prime land and how the program will be administered; and the final section highlights the major efficiency and equity implications of market removal from land allocation.

Before proceeding, it is significant that it is not only the states that are agitating for preservation of prime agricultural land. The U.S. Department of Agriculture (USDA) has clearly gone on record in supporting the notion also. There is no compelling evidence as to the need for preserving prime agricultural land found in the background papers presented at the Seminar on Retention of Prime Lands (Krause and Hair).[1] Despite this fact, those writing the summary volume, *Recommendations on Prime Lands,* said the following:

Discussants for this session were Paul W. Barkley of Washington State University, James C. Hite of Clemson University, and Phillip M. Raup of the University of Minnesota.

B. Delworth Gardner is the director of the Giannini Foundation of Agricultural Economics and a professor of agricultural economics, University of California, Davis.

Giannini Foundation Paper No. 470.

[1] Evidence presented at the seminar points to the opposite conclusion: there is likely to be ample agricultural land and forestland to meet food and fiber requirements until the turn of the century and after.

"USDA should take a major, defined, and well-promoted role in the national questions of utilization, enhancement, and retention of agricultural lands as an advocate of retaining the maximum possible base for the production of food, fiber, and timber products, and minimizing actions that will diminish the nation's capacity to produce these essential commodities" (USDA 1975, p. 17). This may be effective rhetoric in attempting to convince agricultural producers that the USDA is looking after their interests, but, taken literally, the statement cannot be taken seriously. Will anyone in the USDA really advocate retaining the maximum possible land base in agriculture? This would be essentially all land since at some cost nearly all land could be used for agricultural purposes. Or can anyone believe that actions that diminish the nation's capacity to produce food and fiber should be minimized, i.e., reduced to zero? To answer "yes" would require stopping all developments that compete with agriculture for resources and all environmental and safety regulations that impinge on agriculture.

On 21 June 1976, acting secretary of agriculture in the Ford Administration, John A. Knebel, issued Secretary's Memorandum No. 1827, Supplement I, "Statement on Prime Farmland, Range, and Forestland," which contained the following recommendations for USDA agencies in regard to prime land: (*a*) advocate the protection of prime lands from premature or unnecessary conversion to other land uses; (*b*) assure that environmental impact statement procedures and review processes thoroughly consider and evaluate the impact of major federal actions on prime farmland, range, and forestlands; (*c*) emphasize programs to inventory, assess, and evaluate the nation's farmland, range, and forestlands; (*d*) initiate cooperative efforts with states, local governments, and universities to assure that concerns for food, fiber, and wood production are recognized and emphasized in the identification of prime lands; (*e*) USDA agency actions and programs should give consideration to local, state, and national concerns for the retention of prime lands; and (*f*) programs of the agencies in the Department should be reviewed to insure consistency with the intent of this supplement.

President Carter's team in the USDA has espoused the cause with equal if not greater enthusiasm. Rupert M. Cutler, assistant secretary of agriculture for conservation, research, and education, said on 9 June of this year, "How far can we as a nation go in continuing to permit the kidnapping of prime farmland for housing and industrial use without gravely endangering our capacity to meet the food needs of our people and our food commitments to the disadvantaged people of the world? How far can we go before we upset irrevocably the environmental balance—if we have not already done so?" (Cutler, p. 3). Cutler goes on to indicate that he has reestablished the USDA Land Use Committee that "will be busy looking at an appropriate mix of tools for preserving prime farmland and other values, such as land use controls, land acquisition, easements, tax and other financial incentives." (p. 6).

The above makes it quite clear that this powerful federal agency is supporting fully the idea of retaining prime agricultural land by extramarket means. Since such legislative actions as have been proposed to date might involve "high" societal costs, a significant loss of freedom of landowners, and may even be inimical to the interests of most farm operators, this strong USDA advocacy is premature and may be regretted.

The Benefits from Prime Land Retention

Some of the issues incorporated in agricultural land retention are expressed in Assembly Bill No. 15 introduced in California during the 1975–76 legislative session:[2]

> The legislalure finds and declares that the preservation of agricultural land is of paramount interest to the welfare of the State of California in that the preservation of such land, especially prime agricultural land, is critically important in order to assure and to maximize the food, fiber, open space, and employment opportunities which are necessary for present and future generations of the state and the nation.

What society appears to get in the action of preserving agricultural land are at least four joint products (benefits)—three of which are referred to in the above quote: (*a*) "sufficient" food and fiber to meet the nutritional requirements of a growing national and world population; (*b*) local economic benefits that derive from a viable agricultural industry; (*c*) open space and other environmental amenities that

[2] This bill was passed by the Assembly but defeated by the Senate in 1975–76. Other very similar bills have been introduced in the 1976–77 and 1977–78 sessions. At the moment of this writing, all are help up in the Senate Committee on Agriculture and quite possibly will be tabled there.

accrue chiefly to urban residents; and (*d*) more efficient, orderly, and fiscally sound urban development.

Given that these are the joint benefits that will hopefully be achieved by retaining high productivity land in agriculture, what is the rationale for extramarket social action? To put the question another way, why won't the land market allocate socially optimum quantities to agricultural use? To move toward an answer, it is useful to relate the various joint benefits that derive from agricultural land use to the theory of market allocation of resources.

Market Failure and Prime Land Retention

So long as product and factor markets are perfectly competitive, goods are private as contrasted with collective, and no externalities exist, it is generally conceded by economists that the free market will allocate the socially optimal quantity of land to various competing uses. Thus, if the market is removed from the allocation task and is replaced by essentially nonmarket allocation criteria as is proposed by the prime land preservation legislation, some rationale should be offered. In addition, the consequences in terms of economic efficiency and equity should be carefully evaluated.

If some of the joint benefits from land discussed above are collective goods, it is granted that the free market will not allocate land among uses efficiently. Collective goods have two fundamental characteristics: the impossibility of excluding consumers who do not pay for the good in question and consumption by one consumer occurs without reducing the quantity of the good available for other consumers (Mishan 1969). Thus, if a good is a collective good, the marginal supply cost of extending its consumption is zero; therefore, the efficient supply price would be zero. At a zero price, obviously no private entrepreneur would be willing to invest in its supply, and no supply would be forthcoming. The market simply cannot handle the supply problem.

External effects may be defined as unpriced or improperly priced effects emanating from production or consumption activities that impinge on the welfare functions of third parties (Mishan 1976).[3] Establishing that externalities exist may not automatically mean a departure from Pareto optimality. It depends on the costs of negotiating mutually satisfactory arrangements to establish liability for the externality (Coase). In any case, the existence of unnegotiated and uncompensated external effects may be another example of market failure in land allocation among uses and a justification for social action.

Collective goods and externalities are the two most often cited examples of market failure but not the only ones. Two others are monopoly or monopsony in product or factor markets and so-called merit goods. There appear to be no advocates of prime land retention who have justified agricultural zoning on the basis that land markets have been monopolized or monopsonized, although speculation is an issue that is often raised. In the case of merit goods, there are some "food fundamentalists" that have argued that food is such a basic human need that the private land market should not be allowed to determine the acreage devoted to food production. Food and fiber should be provided to all as a "right" and should not be governed by market criteria.

Another member of the family of market failure is the distortions in prices caused by public policies of various kinds. There are a large number of these running the gamut from environmental and safety regulations to agricultural income and price policies. Two especially significant and vexing practices that affect land allocation and ownership are the taxation of real property by local government and provisions in the Internal Revenue Code that make agricultural land an attractive way of holding wealth.[4] The first practice discriminates against real property and may create cash flow problems for owners that wish to utilize land in low valued uses. It does not discriminate against agricultural use of land per se, however. The second practice may discriminate in favor of agricultural use of land if the Internal Revenue Service (IRS) regulations provide tax loopholes that make it especially profitable to own agricultural land. Clearly, IRS regulations have had a significant impact on who owns agricultural land if not on the aggregate acreage in agricultural use.

Let us now turn to the four joint products alleged to be significant in prime land retention and see if there are elements of market failure

[3] This definition rules out so-called "pecuniary" effects as qualifying as external effects since they are by definition price effects.

[4] William W. Wood, Jr., and L. T. Wallace called attention to these important factors in reviewing an earlier draft of this paper.

that justify the removal of the land market from allocation decisions.

Except for the merit good argument suggested above, it is difficult to see why the market will not allocate sufficient land to food and fiber production. The food and fiber sector of the economy is as competitive as any other, and food and fiber prices adjust rapidly to changing conditions in supply and demand. The enormous increases in agricultural land prices of the last five years have been due principally to expectations for higher food and fiber prices at the farm gate. If further increases are expected, there is nothing inherent in the land market that would prevent these expectations from yielding even higher land prices. The more productive the land, the higher the agricultural land price can be expected to be and the more competitive agriculture will be for land vis-à-vis other land uses. The greater the comparative advantage of American agriculture and the fewer the impediments to free world trade in agricultural commodities, the greater will be the demand facing our producers, the higher the profitability of producing food, and the stronger the competitive position of agricultural producers who compete for prime land.

The collective good and externality arguments do not seem very relevant when applied to food and fiber. These products meet all of the requirements of private goods, and significant external effects are not obvious in consumption. There may be external diseconomies in production of good and fiber (such as the use of chemicals), but this would suggest too much effort in production—not too little. Of course, if land and these chemicals were good substitutes rather than complements, more land and less chemicals may well be more efficient.

The merit-good argument is more difficult to deal with on rational grounds. If one believes that food and fiber are somehow special (like safety and education apparently are), this may suggest setting prices below marginal supply costs. Even such a cheap food policy ought to require that a given amount of food and fiber be produced at minimum factor opportunity cost to society. Some system will be required to establish land values within agricultural uses and between agricultural and other uses. It is not easy to see how this can be better accomplished by removing land allocation from the market and using noneconomic criteria instead.

Decision makers across the spectrum of agriculture—such as farm operators, processors, farm suppliers, transporters, financial firms, university professors in agricultural fields, and government agency personnel—have obvious stakes in a viable and stable industry. Landowners are directly affected in a unique way by the prime land retention issue. If land is immobilized in agricultural use, they forfeit the direct wealth gains in price appreciation that would have occurred with the possibility of changing use in a free market. This equity problem is discussed further below. The others listed above are affected more indirectly. The wealth impacts could be substantial for them also—positive or negative. Conceptually, these indirect impacts are identical to secondary benefits and costs in traditional benefit-cost analysis. In addition, these effects are primarily pecuniary as contrasted with technological. As such, they qualify neither as collective goods nor relevant externalities in justifying interference with the land market.

Some might argue that income and wealth differences among regions may justify prime land retention in order to prop up the dominant local industry—agriculture. The argument is thin as related to these secondary beneficiaries because they tend not to be low income people. It may apply to some immobile farmworkers who may benefit if local land is left in agriculture. Many of these same issues are applicable to producing a more efficient, orderly, and fiscally sound urban development by agricultural zoning. If prime agricultural land cannot be developed for urban purposes, demand shifts to parcels that are not so zoned, conferring wealth gains on the owners of these parcels. Whether the result is a more or less efficient urban development is far from clear, however. It depends on where these parcels are, how efficient they are in producing urban amenities, what the costs are of bringing public utilities and transport to these parcels, etc. It is not obvious in principle that urban "leapfrogging" will be reduced over what the free market would have produced. Much would depend on the criteria utilized to zone agricultural land, the number of zoning variances granted, and the availability of soil types and other land classification data. Much depends also on jurisdictional boundaries and the ability of local governments to tax the parcels affected and charge the average costs of supplying public services. In any case, most of

these impacts are also pecuniary and offer only a weak justification at best for interference with the land market.

Finally, there is the case where market failure is most apparent—the creation of open space and environmental amenities. These benefits obviously meet the criteria for collective goods, and there are elements of Pareto-relevant externalities as well. Since there are no market signals, there is little evidence available as to how much these amenities are worth; but it seems clear that their value would be much higher in Los Angeles County in California than in central Wyoming. In any case, in principle at least, the market will not provide the optimal quantity of these amenities; and there may be some justification for social action to remedy this market failure.

Before exploring the implications of the conclusions reached above for economic efficiency and equity, it will be useful to be more specific about how land allocation will be done under the proposed land retention legislation.

Land Allocation under Prime Land Retention Legislation

Two major issues that must be resolved in any retention program are the criteria utilized to qualify land parcels and the administrative apparatus that will apply the criteria, make exceptions, and arbitrate disputes. Although the laws proposed in various states are no doubt somewhat different in detail, the central thrusts are very similar. The proposed California legislation will serve as an example. Much of this material is taken directly from Assembly Bill No. 15 introduced in California Legislature, 1975–76 regular session (reintroduced in the 1977–78 session as Assembly Bill No. 222).

"Prime agricultural land" means an area of land whether a single parcel or contiguous parcels that is over 20 acres in size, on the date of enactment has not been developed for use other than agricultural use, and meets any of the following qualifications: land that qualifies for rating as class I or class II in the Soil Conservation Service (SCS) land use capability classification;[5] qualifies for rating 80 through 100 on the Storie Index rating; supports livestock grazing and has an annual carrying capacity equivalent of at least one animal unit per acre; is planted with fruit or nut-bearing trees, vines, bushes, or crops that have a nonbearing period of less than five years and produces an annual unprocessed gross crop value of not less than $200 per acre; and has returned an average annual gross income of $200 per year in unprocessed plant products.

The criteria set out above seem to rule out the forced retention of small parcels (under 20 acres) and land already put to a nonagricultural use at the time of enactment. Thus, the central issue focuses on the scope of qualification criteria and how much land currently in agricultural use may escape inclusion.

It is significant that the wording of the bill specifies that land that meets any of the above criteria qualifies. So long as gross crop income exceeds $200 per acre, land will qualify regardless of capability class and Storie Index rating. Some rough yield and price calculations reveal that there is not much commercial agricultural land in California that does not produce gross crop income of at least $200 per acre. At average yields and prices in 1976, of the hundreds of crops grown in the state, only oats and barley failed to yield $200 per acre. They are most often doublecropped with other cash crops like tomatoes and sugar beets. Thus, it is quite clear that not much land under cultivation in California will escape prime classification because of this feature of the law.

Nearly all land use bills introduced in California apply both the SCS classification system and the Storie Index to designate which land is prime agricultural land. Several of the bills require the land to rate I or II in the SCS system and between 80% and 100% on the Storie Index. Another bill (SB 1710) includes also land classed as III in SCS and drops the Storie Index from 60% to 100%. The two classification systems use approximately the same factors but combine and weight them differently. The result of using the two systems is that, occasionally, land classed as "prime" under the one may not be so under the other.

How do the two compare? The Storie Index is older and has been traditionally used in California but not in the rest of the country. The SCS system has been expanding in usage even in California. The SCS system has twelve categories of classification: effective soil depth, surface layer texture, permeability, drainage,

[5] Two bills introduced in California during the current legislative session vary slightly from Assembly Bill 15 in the land qualification criteria and in the administrative framework under which the law will be administered.

available water capacity, slope, erosion hazard, flooding hazard, salinity, alkali, toxic substances, and length of frost-free season (USDA 1973). In each category soil is rated I (best) through VIII (worst). The lowest rating in any one category pulls the entire classification of the land down to that level.

The Storie Index is based on four factors that parallel some of the SCS categories (Storie). The percentage ranks achieved in each factor are multiplied together. If less than 100% is attained in each, the Index declines multiplicatively (for example, 60% × 85% × 95% × 90% = 44%). Factor A is similar to the first classification under SCS. The rating is based on the profile of the soil, how hard the clay pack is, and how deep the topsoil cover. Factor B rates the surface texture. The rating is among three extremes—all clay, all sand, or all silt. The best combination of the three called loam would rate 100% in factor B. The rating declines as any of the three extremes is approached. Factor C rates the slope of the land from nearly level (0 to 2% slope) as 100% rating to very steep (45% slope and over) as from 5% to 30% rating. Factor X combines several of the SCS categories: drainage, alkali, nutrient level (fertility), acidity, erosion hazard, and microrelief (smooth through dunes). The percentages attained in any of the subcategories of factor X are multiplied together to give the percentage for factor X.

It is significant that both the land capability classification systems and the Storie Index are strictly oriented toward physical productivity. Location plays no role whatever. Because of the point made earlier that agricultural productivity may not be the only purpose for land retention in agriculture or even the major one, criteria that do not include location factors may be quite inefficient in producing desired results. After all, enhancing environmental amenities, removing competition for urban land parcels, and preventing urban sprawl are all tied up in the location of the land parcels affected. Urban people who want these joint products of land retention may well be frustrated and disappointed in the results of a land preservation scheme that retains land in agricultural use based only on agricultural productivity criteria.

With respect to the administrative issue, the proposed California legislation creates an agricultural resources council that would have the primary function "to delineate and map the location and boundaries of prime agricultural lands . . . to prescribe various land uses which may be permitted within areas designated as prime agricultural land; and upon certification, such land could only be used as so prescribed." The council would clearly "call the shots" in land use decisions.

The council would have twelve members as follows: (*a*) three representing counties (incumbent county supervisors), (*b*) three representing cities (incumbent city councilpersons), (*c*) three representing the public, and (*d*) the secretary of agriculture and services agency, the secretary of the resources agency, and the director of finance. Lest anyone conclude that the council would be dominated by local interests, vis-à-vis state interests, it need only be pointed out that the individuals in (*a*), (*b*), and (*c*) are to be appointed by the Governor, the Senate Rules Committee, and the Speaker of the Assembly (each gets to name one person in each group). Obviously, if one political party or one philosophy of government dominates the political scene in Sacramento, the decisions of the agricultural council would likely be dominated by the same party or philosophy.

The legislation provides that the council shall adopt regulations prescribing the various land uses that may be permitted within areas designated as prime agricultural land. Such regulations shall automatically apply to any activity of a local agency or to any authorization, lease, permit, license, or entitlement for use issued by a local agency of government. Cities, counties, special service districts, etc., may petition the council for exemptions, plan modifications, or remapping, but the legislation makes it clear that the council is the final arbiter.[6]

Efficiency and Equity Implications of Market Allocation versus Prime Land Retention

Efficiency Implications

As pointed out previously, the effect of the prime land retention proposals is to remove land allocation decisions from the market and

[6] Assembly Bills 437 and 1900 and Senate Bill 193, introduced in 1977, give much more responsibility to local government. Each city or county must adopt an agricultural plan that would contain four components: an agricultural land preservation plan, a plan to resolve conflicts between competing land uses, mapping all prime agricultural lands, and an agricultural inventory component. Even though many rural politicians favor these bills over Assembly Bill 15, it is unclear which, if any, will ultimately be adopted.

give them to local or state planning councils. There are many reasons for believing, a priori, that the efficiency costs of taking this step will not be inconsequential.

Consider a hypothetical example (Gardner and Zivnuska). Suppose that land parcel A yields an annual surplus (revenue minus non-land costs) of $100 per acre in the developed use and $50 in agricultural production (table 1). An alternative parcel B has an annual surplus of $150 in developed use and $90 in agriculture. If the relevant capitalization rate is 10%, parcel A would be worth $500 per acre to agricultural owners and $1,000 to developers. Developers must pay at least $500 to get $1,000 and would capture a potential maximum wealth gain of $500 per acre. In the case of parcel B, they are willing to pay the agricultural value of $900 in order to get a capitalized value of $1,500, a difference of $600 per acre. The competitive land market will allocate B for development if there is sufficient demand for only one of the competing parcels. This market solution is socially optimal, assuming no Pareto-relevant external effects, as society captures a larger rent in foregoing agricultural production on parcel B ($60 per annum) than it would have in the case of parcel A ($50 per annum).

Perhaps the above conclusion results from the numbers chosen rather than from any economic principle. To see that this is not so, consider a third parcel C that has comparable agricultural value with parcel B (annual surplus in agriculture of $90) but is only slightly better for developed purposes (say, $101 annual surplus) than the poorer agricultural land parcel A. Let us now compare parcels A and C as this comparison prompts the question usually asked by prime land advocates; namely, why allow good agricultural land to go to developed uses when poor agricultural land will do nearly as well? Will the market now take the better agricultural land (parcel C) when the poorer land (parcel A) would do nearly as well in the developed use? Clearly not! Developers would have to pay $900 to get parcel C, which would be worth $1,010 to them, and they stand to get a gain of $110. If they can get A, they would gain $500 as has been already demonstrated. As before, in the absence of externalities, the perfectly competitive market produces a socially efficient allocation of land.

Table 1. Hypothetical Surplus Values Yielded in Developed and Agricultural Uses

Use	Parcel A	Parcel B	Parcel C
Developed	100	150	101
Agricultural	50	90	90

The same can hardly be said for a land-planning council guided by agricultural productivity criteria as described above. Comparing parcels A and C, they would direct that A should be developed, which would be the efficient choice. But in choosing between A and B, they would select parcel B to remain in agriculture every time unless they succumb to the pressures (if not bribes) of the developers (Lewis and Kuttler). If they do, the prime land retention scheme is innocuous in its allocation effects anyway. But society would have to carry the burden of an administrative agency that is in the business of passing out windfall gains and/or wipe-out losses, most often with adverse equity consequences.

Because the point has been made so often, it seems almost trite to add that there is no good substitute for the market in providing signals in the form of prices that reflect relative scarcity of resources and relative values of these resources in alternative uses. A set of firm property rights is the institution that permits the market to serve this function efficiently. When property rights are altered, such as would be the case if land disposition is restricted, the signals are distorted, and the market does not work efficiently. If society really has a scarcity of agricultural land and food and fiber prices are not artificially controlled at lower than equilibrium levels, the land market serves perfectly well to reveal this scarcity. If this effective instrument for revealing scarcity is replaced by the prime land retention schemes proposed where inadequate economic or political criteria dictate resource allocation, there is no reliable way of knowing whether agricultural land is becoming scarcer or more plentiful.

None of this argues that there are not now encroachments on the free exercise of property rights. There are, as the discussion above on taxation points out. What is argued here is that existing encroachments do not clearly reduce the acreage in agricultural use below the social optimum and that, therefore, no new encroachment is needed to offset existing ones.

Another common allegation is that in investment decisions the market is shortsighted

compared with political processes. In fact, do the actors operating in the market have a bias toward the present that is socially inefficient? The land "speculator" is that bad guy who makes his living predicting the future more accurately than the rest of us. He has an incentive to do his job well, and market prices reflect his anticipations of future scarcity. What reasons can be advanced for believing that a part-time agricultural board member or even a career planner can do a better job of predicting the future?

This point has been succinctly stated by Gramm and Ekelund:

> A basic understanding of market decisions reveals that current land prices, and thus land use patterns, reflect both current valuations and expected future preferences. However, in a world of uncertainty, forecasts about the future are continuously being proven incorrect; and any viable system of allocating land to various uses must be capable of quickly and efficiently adjusting to these ever-changing forecasts. Those who are less adept at predicting future events will find themselves buying at high prices and selling at lower ones and eventually being forced into another occupation. Thus, the free market system provides both a payoff for accurate forecasting and a penalty for inaccurate forecasting.
>
> Planners have no direct signals to revise their initial plan until shortages have produced political pressures to alter the plan. Planners will be forced to handle pressure from private landowners who recognize the change in circumstances and seek permission to convert their lands to this use. It would be extremely naive to argue that land use planners will be able to maintain independence when no other government regulatory agency has succeeded in doing so (Gramm and Ekelund, pp. 133, 134).

Because the market is an institution where preferences can be freely expressed, although these preferences are constrained by limits on purchasing power, there is always some uncertainty associated with market allocation (Johnson). There may be less uncertainty with government allocation. By the same token, there will almost surely be more freedom of choice in the market and better information of foregone alternatives.

It is true that the market will not provide the optimal quantity of the collective good—open space. But neither will the prime land retention schemes. They preserve land on the basis of agricultural productivity and there may or may not be a good match between high productivity agricultural lands and open space for urban recreators. Given that open space is partially a joint product with agricultural use, it is an empirical question whether the land market or zoning based on agricultural productivity criteria will provide more socially optimal quantities of open space. If there is a critical shortage of open space, a sensible and efficient solution would seem to call for open space selection criteria and either zoning on that basis or public acquisition of the requisite lands in the market.

Equity Implications

Granted that there are public interests to be served in the supplying of open spaces and feeding the world's people by prime land retention, the equity issue boils down to creating these benefits by imposing a wealth loss on the owners of prime agricultural land by immobilizing the land in that use and thus preventing land use shifts at higher prices. Thus, unless compensation is given, these landowners absorb losses in order to provide the collective goods enjoyed by society as a whole.

Whether or not compensation is paid is the principal difference between the two most commonly utilized devices for social control of land resources—zoning and eminent domain. Zoning employs the police power of the state to regulate use without compensation, whereas eminent domain appropriates private property for social uses and "fair" compensation is paid. Both administrative practice and judicial decision have standardized the distinction (Pach). If the action requires an enlargement of the public's assets, as with highway building or park construction, it is normal for property rights to be acquired through eminent domain. On the other hand, if private use can be legitimately regulated in promoting public health, safety, and welfare, and there is little or no effect upon property rights, zoning through the exercise of the police power is the accepted technique.

At least one observer questions whether "open space zoning" can qualify for use of the police power of the state without the payment of compensation since "open space regulations are usually designed to protect scenic beauty, wildlife, and watersheds, rather than traditional objectives of protecting public health and preventing nuisances. When land values are severely depressed and the objectives tend toward the aesthetic, courts have leaned away from police power" (Pach, p. 25). If the arguments presented here are valid,

that agricultural zoning will severely reduce land values and that open space preservation is the primary justification for prime land retention by zoning, the conclusion stated in the quote above would seem to apply to agricultural zoning as well as to open space zoning.

Two much-discussed but little-utilized techniques designed to deal with the equity problem are zoning by eminent domain (ZED) and transfer of development rights (TDR). ZED combines eminent domain and zoning and permits the state to acquire by eminent domain the development rights for all purposes other than those permitted under the zoning plan. TDR is a system that permits property owners with restricted land to sell development rights to those whose property is zoned for nonrestricted uses. These techniques have been described and evaluated by Ervin et al. Their conclusion is that ZED is very costly to the state and is difficult to administer. They are less negative about TDR, although they do question its political feasibility. Those benefited by the system—the landowners—are likely to be far fewer in number than those who pay the compensation in the form of higher prices—the ultimate owners of new homes, offices, businesses, etc. The latter group would likely swamp the former group in an election or referendum.

Even though there do seem to be devices that can mitigate the equity problem, there has been no attempt to incorporate them in the proposed legislation, and there is even a conspicuous absence of any discussion of them. What is perhaps even more significant, there is not even any explicit recognition that an equity problem exists at all.

Summary

Perhaps the most apt way to sum up is that agricultural land retention legislation is the wrong thing at the wrong time and for the wrong reasons. The number of people clamoring for enactment and the power of the governmental agencies supporting the idea do not alter this basic conclusion.

It has not been adequately demonstrated that more American land than the market will make available will be needed to produce food and fiber in the decades ahead. Granted that the market will not provide optimal quantities of open space and that more can be justified, what sense does it make to use agricultural productivity criteria to select the land parcels desired? Additionally, even if urban growth needs to be better managed and agriculture needs to be more profitable to shore up rural economies and communities, why should immobilizing land in agricultural use be an efficient way of reaching these goals? Even if all these ends were achievable by employing the means of preserving agricultural land, what is more inequitable than requiring agricultural landowners to bear the costs in the form of foregone increases in land prices?

———. "The Relationship Between Joint Products, Col-

Land—The Far Horizon

Sterling Brubaker

The theme of this session is "Increasing Conflicts over Land Use." Perhaps that title is a bit myopic. There have always been intense conflicts over land use—Romans versus barbarians, Indians versus settlers, fences versus range, sheep versus cattle, to name a few. Indeed, conflict over land use is more basic and is found in nature in the form of "territory" and "niche."

While man overwhelms the territorial claims of other species, within human societies conflict also arises over territorial rights. In the United States our institutions are strong enough to regulate simple territorial claims without great conflict; thus, the law determines rights where like users seek to displace one another. But conflict also comes from a different source—from the pressures of increased use and from incompatible types of use. Greater intensity of use, whether with fixed or changing technology, implies more active competition for land, and some competing uses may be excluded for economic or technical reasons. The effects of land use change are rarely confined to the plot concerned, so nonowners have a stake in the outcome. That is what is happening in our society. Whether this means that the conflict has grown more acute in our time is problematical, but at least its changing character makes us think so, and our legal and economic institutions ensure that the conflict will be extended, litigious, and inconclusive.

Now, as before, the problem is how to accommodate changing demands on the land. If new demands have sufficient economic or political force behind them, they will prevail at the expense of less insistent uses. Yet often the result is conditioned as much by shortsightedness or intellectual rigidity as it is by irreconcilable interests. We should examine ways in which the finite land could be made to serve more of our diverse wants. This helps distinguish areas of necessary conflict from those that are unnecessary. We can say something about the strength of the forces for change and where they appear to be taking us. At the same time, we need not worship the apparent result; we also should stand back somewhat and look at requirements for the preservation of our land resource and whether the emerging pattern of use is consistent with those requirements. A land economics not informed by a land ethic carries the potential for disaster.

Sterling Brubaker is a senior fellow, Resources for the Future, Washington, D.C.

The Land Use Pattern and Its Changes

The pattern of land use needs only the briefest review. As of the last complete survey of land use in the United States, forests were the largest category (32%), followed by pasture and range (27%), and then by cropland (21%). A miscellaneous category of wastelands comprised 12% of the total, and special use areas such as urban land, roads, military installations, parks, and wild life areas made up the remaining 8%. Alaska, with about 16% of the total U.S. land area, had three-fourths of the miscellaneous category. For the coterminous states, cropland amounted to 25% of the total, pasture and range 32%, and miscellaneous lands 4%, while the share of forests and special use lands was essentially unchanged (USDA 1973).

This pattern has remained remarkably stable over a period of decades. The amount of forest has changed hardly at all since 1900. As one would expect, urban lands and parks have encroached a bit on other categories, but the intensive uses in urban areas and transportation facilities remain a tiny 2.7% of the nation's land (USDA 1973). Cropland increased mainly at the expense of grassland up to the 1930s but thereafter receded slightly until the early 1970s (USDA 1973). If we use the narrower measure of cropland harvested, the decline was considerably sharper and the recovery likewise. Since the upsurge in foreign demand for U.S. agricultural production in recent years, cropland harvested again has swelled at the expense of grass, and harvested

acreage has regained the level of a quarter century ago.

While aggregate land use shifts have not been very dramatic, the figures conceal the considerable amount of churning that has gone on. The principal oscillation is between cropland and grassland and pasture. There also has been considerable shifting between cropland and forests. Geographically, this reflects the reversion to forest of much land in the Northeast and in Appalachia, while other forest lands in the Delta and elsewhere were converted to crops. Meanwhile, other new lands have been brought under cultivation, especially in Montana, Washington, California, Kansas, Colorado, Texas, and Florida. The net result is that some of the older areas ill suited to modern large-scale farming have been abandoned in favor of better terrain or climate (USDA 1974). Another major national trend is the unidirectional shift of land to urban or infrastructural uses or its designation as parkland. There also has been a steady increase in irrigated acreage (USDA 1974).

Forces Determining Land Use

What forces have shaped our land use pattern, and what is their strength for the future? Will new ones assume importance not heretofore observed? Physical capability and economic demand have been the major influences at work, though preferences expressed through public policies may play a significant role in the future.

In its extensive uses, our land use pattern reflects the physical capabilities of the land to a major degree. (Mineralized lands are an exception in all categories.) Tundra is not readily converted to anything else. High elevations likewise have limited adaptability. Arid lands may be made productive with water, but the availability of water is too limited to change most of them. Steep slopes remain productive only in trees or permanent grass. Many grasslands lack moisture to support trees or crops. Most forest land is unsuited to crops and most range unsuited for forest or crops. But in areas of moderate relief where irrigation is possible, or in more amply watered terrain of the same sort, two or more of these extensive uses may be physically possible, for example, crops, pasture, or forest. At that point the configuration of demand and costs determines uses—demand not only for food, fiber, and wood but for the amenity products and site uses of the land as well. Costs include the investment costs of converting land to other uses. So, while physical capability is very important, potential competition for land between uses is significant and must be resolved by economics or by policy.

At this point, a hierarchy of economic demands on the land asserts itself. Land sought for use as urban sites or for transportation facilities rarely can withstand that claim; such uses ordinarily outbid all others in the market or may assert eminent domain. If land is suitable for crops, this use ordinarily takes precedence over all other nonurban uses. Range and forests are residual claimants, the balance between them determined by local conditions. Obviously, this array reflects long-standing price relationships. For example, not all potential cropland has been cultivated because, with existing technology and costs, demand was not strong enough to justify it. Likewise, one could imagine a price for wood that might make forest use competitive with crops or pasture where it is not at present. Finally, while economic demand is a powerful determinant of land use, it must be remembered that public policy intervenes in a thousand ways, direct and indirect, to influence the outcome; farm price policy, trade policy, environmental regulations, tax policies, and the exercise of eminent domain are examples.

The Demand for Cropland

The physical capabilities of the land are relatively permanent. After a long period of trial and error, most present land use is consistent with physical capabilities. Of course, there will be changes in the intensity of present use. Beyond this, economic and policy factors will dominate future marginal shifts in land use within its physical capability, so that higher uses will claim suitable land as needed from lower uses. Cropland is the preeminent user of rural land. Will there be enough of suitable quality? Will crops encroach seriously on other uses? Does cropland need extramarket defense against other uses, particularly more intensive ones? To get at these questions we must consider the prospective demand for U.S. agricultural products and the technologies, as constrained by economic and environmental developments, that will be used to produce them.

Overall demand for domestic agricultural output will increase only slowly if USDA baseline projections are realized (Crosson, table 1). This scenario reflects normal population and income growth. A high demand scenario occasioned by rapidly expanding foreign demand for U.S. agricultural output represents a significantly different possibility. The implications of these two demand possibilities for land requirements depend entirely on yields. The rate of yield increase gradually declined during the 1950s and 1960s. If this yield trend is maintained, Crosson figures that baseline demand can be met with little increase in harvested land. On the same yield assumptions, the high demand projections would require about 50 million additional acres.

However, in very recent years, yields of grain and soybeans have failed to improve in line with trend. Many speculate that this is a real shift caused by exhausting the potential of known yield-increasing technologies. Others blame adverse weather, input price rises, and conversion to crops of less productive land. Whatever the reason, if yields remain relatively flat, meeting even the baseline demand will require about 50 million additional acres. Thus, on the most favorable assumptions about yields, 1985 baseline demand could be met by 343 million harvested acres, while on the least favorable yield assumptions 447 million acres would be needed for the high demand scenario (Crosson, table 4).

Farmland Availability

It would not be all that easy to find an additional 50 to 100 million acres of harvestable cropland. The idle acres of yesteryear already are back in production. While it was once fashionable to refer to 264 million acres of uncropped land in classes I to III as an ample agricultural reserve, it is now recognized that most of that land is not truly available to modern farming. A more modest appraisal was made recently by the Soil Conservation Service, which found 78 million acres with a high potential for crops as of 1974, or 111 million acres if lands of medium potential are included (USDA 1976b, table 4). However, two things need to be said about those figures: being based on 1974 cost and price relationships they give an exceptionally favorable reading on the economic viability of land conversion, and the farm economy cannot harvest every cropland acre in a given year; much of the potential added cropland would go to the categories of fallow, failure, and cropland pasture.

Presumably a high demand scenario that calls for extension of cropped area would also imply the improved cost-price relationships necessary to bring potential cropland into production. While that would be a relief to farmers squeezed by deterioration of their cost-price relationships since 1974, it could mean substantially higher food prices for the American public and might therefore become politically chancy. Would our open export policy be able to survive the resulting pressure? Since expanded exports entailing more land would bring increased environmental pressure on U.S. lands, we might find consumer and environmental interests combining to restrict exports.

At present about 335 million acres are harvested annually in the United States. The Soil Conservation Service study of potential cropland identified 400 million cropland acres. Since some land (about 30 to 40 million acres) must be held fallow, crop failure will claim another 5 to 15 million acres per year, and some cropland must be used as pasture to support the farm operation or will be unavoidably idle, clearly at 335 million or so harvested acres existing cropland is fully utilized. Net conversions from other uses will be required if harvested acreage is to increase.

Where will it come from? Of the 78 million acres considered to have high potential for conversion, over 62 million acres are in pasture and range and 13 million acres in forest (USDA 1976b, table 4). Yet some of those pasture and range acres with high potential for crops already are integrated into farm operation and not readily spared from existing use. Moreover, while most of the high potential lands are in capability classes I to III (65 million acres), only about 39 million acres rate as prime land. Prime farmland meets specific physical criteria with respect to soil quality, moisture supply, temperature regime, erodability, water problems, and the like that make it best suited to crop production. Very little additional prime farmland seems to be available. Of 384 million acres classified as prime farmland, 250 million acres presently are cropland. That leaves 134 million acres of uncropped prime land, but 86 million acres of this are rated as having little or no potential for conversion under 1974 conditions; only 39 mil-

lion acres are accorded high potential and 9 million acres medium potential. When high and medium potential lands are classified according to the kind of problems that must be overcome if they are to be converted to crops, only 42 million acres are adjudged free of problems. The other 69 million acres have one or more problems; they require clearing, face high erosion hazards or costs, lack dependable water, are subject to flooding, or have other deficiencies (USDA 1976b, table 3). In brief, the environmental costs of converting much of that land will be high in terms of erosion, floodplain encroachment, loss of wetlands, or loss of other habitat.

We have a long record of conversion of other land to crops. Over the recent past it is estimated that about 1.3 million acres per year were converted, partially offsetting the loss of farmland to other uses (Cotner). As was noted, this entailed regional shifts and the substitution of land better suited to modern farming for land that no longer met requirements. In view of the above numbers, it is difficult to see where much good quality land could come from. High demand accompanied by slow growth in yields could produce a real pinch on farmland availability a decade hence. A reach for 50 to 100 million acres could compel use of a substantial amount of lesser quality land.

Forestlands and Their Potential

A word should be said about the availability of forest land for conversion to crops. Some 43 million forested acres have been designated as prime farmland, but only 10 million acres of this is judged to have high or medium potential for conversion to crops (USDA 1976b, table 6). Some additional forestland in the Delta and Southeast may be converted to cropland, but elsewhere reversion to forest will continue in agriculturally retrograde areas. There is no likelihood that forests will take productive cropland.

Some foresters worry about agriculture encroaching on forest lands, but that seems a needless worry. Not only is the amount of forest land suited to crops limited but it is increasingly likely that potential demand for wood products can be met from less land. It is widely believed that the forest industries are on the verge of a technical revolution much like that undergone by agriculture in post-World War II years. If that is true, it means that our expanding demand for wood and pulp can be met from constant or declining acreage. Much of our forest land is poorly managed at present. Sharply higher prices would induce management improvements on the best forest land. Under intensive management, it is estimated that only one-third of the forest acreage would be required to meet wood requirements to the end of the century (Clawson).

Urban Competition for Cropland

But that is not the whole story. Urban and other uses continue to encroach on cropland. We see all sorts of numbers on the amount of rural land lost annually to urban and other special uses. The *Potential Cropland Survey* (USDA 1976b) showed 16 million acres lost to urban use and 7 million acres to reservoirs over the eight-year period 1967–75, or an annual loss of 3 million acres of which 750,000 acres was cropland. Total special use areas comprising urban, transportation, recreation and wildlife, public facilities, and farmsteads increased 27 million acres during 1959–69, most of it in the recreational and wildlife categories (USDA 1973). In addition, it is alleged that up to 2 million acres of rural land becomes entangled in the development process each year and lost to other uses (Dideriksen and Sampson). Looking only at cropland, Cotner, Skold, and Krause find cropland abandonment for all reasons of 2.7 million acres per year partially offset by new cropland development of 1.3 million acres for a net annual loss of 1.4 million acres. Of those lands converted directly to urban use, somewhere between one-fourth and one-half are cropland. In standard metropolitan statistical areas where lands are especially vulnerable to development, 18% of the land is class I and II cropland and 15% other cropland on a national basis. Overall, the picture is one of a steady loss of cropland, not at a dramatic pace, but one that forces any needed expansion of crop acreage to move against the current.

However, one can question whether urban demands on the land will continue at the previous rate. As of 1969, only 61 million acres were devoted to the two most intensive uses—35 million acres in direct urban use and 26 million acres used for transportation facilities (USDA 1973). Between 1950 and 1969, direct urban land use doubled, growing by 17 million acres to the 35 million figure, while

transportation uses increased only 3 million acres. That represents a combined annual diversion of 1 million acres. I have no data on the quality of land presently in urban use, but given the history of settlement in valleys and in agricultural areas and the easy adaptability of farmland to development, probably half of it is land suited to crops. However, it does not seem likely that we will continue to convert rural to urban land at recent rates. Our population already is urbanized and the rate of total growth has slowed. A population stabilizing at 250 to 300 million and using urban land at past ratios would require no more than an additional 9 to 18 million acres plus modest amounts for transportation facilities. If half of this is cropland, some 2% or 3% of the present cropland total might be claimed for urban use. Recent growth in urban land use clearly has been disproportionately high, reflecting the drive of Americans to spread out in suburbia.

Some believe that this trend is reversing for a variety of reasons. Demographic trends are hard to predict. Nonmetropolitan areas clearly have enjoyed some favor over metropolitan areas during this decade, part of the desire to spread out. At the same time, some cities report a new interest in city living. Since some of our older city centers have been substantially depopulated, renewed preference for the city would not simply displace present residents. The result would be landsparing.

Other special use categories do not compete for cropland in a major way. A growing category is parks, game refuges, and wilderness preserves. While some wildlife refuges may compete for potential cropland, most of the other special uses do not. Nearly two-thirds of the wildlife refuge area is in Alaska (the Alaskan acreage stands to be greatly enlarged), and only a few million acres elsewhere preempt possible cropland. Likewise, most of the Department of Defense and park and wilderness lands are in the arid or mountain West and do not take potential cropland. Concern over the development of resource values on federal lands because of restricted entry is focused on potential mineral, timber, and grazing output rather than on crop potential, there being very little such potential.

Land Speculation

Rural land, both cropland and other, is serving another function at present that is not well recorded in the statistics; it has become the national security blanket. Until recently we have satisfied the urge to own property with home ownership, but recently rural land has become the focus of a great deal of this motivation.

The reasons are complicated. Farmland has proved a very good speculation, its value doubling between 1971 and 1976 (USDA 1976a). Of course, speculations are self-justifying as long as they last. Coming at a time when the stock market has been sluggish and other investments unspectacular, the land boom has drawn much mobile capital. But there is more to it than that. To many who seek something tangible and enduring in the face of endless inflation, land has seemed a secure hedge. Others, disturbed by the malaise of the cities and frightened by resource and environmental doomsayers, have sought asylum in rural land ownership. Even our more phlegmatic citizens may have a residual land mystique in which rural pursuits are seen as more stable and worthy, even though they cannot be immediately indulged; land ownership is a downpayment on the dream.

This flow of largely city money on what seems a rather large scale is certain to have effects on the rural economy. We know too little about this. Not only cropland but range, forest, and recreational lands are affected. If the remote owners put their holdings to active use, this trend may actually be invigorating; it could bring capital and initiative where both were lacking. Or, if they are able and willing to rent out their holdings to active managers, the impacts may be small. It is the idling of land as the toys of urban dwellers that seems the major threat. The fractured pattern in which land is passing into such ownership discourages active management and frustrates land planners. While the large holdings of absentee owners presumably are bid for in the rental market, the small acreages are less apt to be sought.

Another major impact is through the effect of this bidding on land values. Rural land values in many areas have ceased to be related to their productive potential in agriculture or forestry or to their development potential. Every holder becomes a speculator and has much of his capital unproductively tied up in land. How strong is his incentive to improve or protect the productive value of the land when its price is increasingly divorced from its

productivity? This could retard the development of new cropland, for in addition to the normal risks of conversion there is the large risk that the speculative value of the land will collapse—a risk that could easily swamp gains from conversion.

Land Use Criteria for the Future

While some of the interest in holding rural land is speculative and some is an inflation hedge, part of it is grounded in fear about where our technological society is taking us. That includes a concern about the land, that it is being stripped, clear-cut, eroded, poisoned, paved, drained, and developed but that no one is really watching over it and looking out for it. There is a sense that whether we use it or not, we still want to know that it is there in all its variety and still potentially productive. When we feel it is not being protected and that society has otherwise lost its way, one reaction is to clasp a bit of soil to oneself.

Much of the malaise about land use is related to an instinctual distrust of the concept of land as simply a commodity like any other. We feel a communal interest in the health of the land that derives from awareness of its enduring nurturing role—the mother earth syndrome. The idea of stewardship in which a present owner has obligations toward others and a present generation to future generations in the management of the land, while not frequently articulated, is widely held. Moreover, we are all accustomed to deriving certain unpaid benefits from the land if no more than the aesthetic pleasure from a landscape.

But we are ambivalent. The communal and stewardship attitudes compete with the aspirations of individual owners to maximize their returns from ownership. Private rights are deeply embedded in law and attitudes. Still, there is a growing sense that when the economic criterion is given primacy, many desired values from the land do not survive. Because land is a finite and potentially eternal resource on which other economic activity must rest, the community interest in its deployment and preservation seems paramount.

Although there has been much recent interest in land use controls, we have been slow to define the objectives of such controls or the public purposes they are to serve. Too often land use regulation assumes the character of benefiting some at the expense of others, with the public purpose barely discernible. If there is to be public intervention, the social rationale should be apparent and enjoy wide agreement. At present we have little agreement on the goals.

As a first step toward social consensus we might try to identify those physical or social imperatives to which land use must respond. These would include both some environmental and some resource parameters. Since truly long-range resource needs are not foreseeable, a prudent course would assume they will be no less than at present. Therefore, one aim would be to meet current demands for output consistent with current environmental standards in a way that does not irreparably damage future environment or productive capacity.

That aim is the essence of much conservationist thinking. For example, it is not antiproduction, but it seeks to preserve the productive base. It would support erosion control programs as essential to long-term productivity and to the maintenance of environmental standards, and it would be land sparing.

I am not convinced that agricultural land requirements and demographic trends are on an early collision course, but it still seems wise to give more serious attention to land-sparing urban forms. We may want to do that for other resource reasons. For example, the energy crunch is new and not yet fully reflected in behavior; ultimately it may favor more compact cities. Or preferences could change, favoring the city over suburban sprawl, even though present population growth probably does not compel this as a means of preserving agricultural land. Even so, urban planning could take greater account of the desirability of preserving prime land. Since many urban areas are surrounded by a variety of lands, and the nearby forest and pasture is seldom very productive in those uses, growth could be focused on those areas while saving farmland. Admittedly, the bypassed farm operation would face many problems (Otte), but preserving such land in large blocs could alleviate some of them. Cropland is in great demand for development because it is desirable—clear, well drained, and of moderate relief. It is not insatiable urban growth but simple economic demand (much cherished by farmers) that moves adjacent farmlands into urban use.

A land-sparing policy need not be confined to urban areas. All forms of human activity could be concentrated to a greater degree or lands best suited to them through improve

cultural or management practices. This was already discussed in the case of forest lands. For grazing lands, range improvements would greatly increase carrying capacity while sparing more fragile lands. It is quite likely that further attention to agricultural technology will permit us to maintain output and environmental standards while concentrating production as was done in the past. (Of course, at some level, foreign demand could swamp all other forces.) In general, a land-sparing approach should appeal to those who are interested in maximum preservation of wetlands and wild areas, since it would permit human needs to be met from the smallest acreage while keeping much of the natural system in the ecological bank. Such decisions should not be made on pure efficiency grounds, although they can be informed by economic and social analysis.

If we are to respond to physical or social imperatives, we will have to do so not by private actions alone but through public processes. These may include education, moral suasion, and regulation or acquisition.[6] In combination, they will greatly modify the old perception of land as a commodity. That concept was never held in pure form in any case, and historically it is a modern aberration. It was suited to the task of occupying an empty land in a situation where relatively homogeneous uses prevailed. But our denser pattern of use, more powerful technology, and growing diversity of aims is not compatible with unrestrained private use.

We now place numerous restrictions on private land use. The most obvious reason is to minimize the external consequences of such use. These consequences may be of the simple upstream-downstream variety, or they may involve remote and tenuous linkages. Or we may impose restrictions for planning convenience, especially in an effort to minimize the cost of public services. In other cases, restrictions are aimed at providing or defending public goods; air pollution regulations surrounding a national park would be an example. In all of these cases (except possibly the last) something identifiable in economic terms is being sought and the rationale would be made on those grounds.

Some land use decisions are irrevocable in character and require ethical judgments of the society, others are of less import. If we are to act responsibly, we will harken to the ethical imperative and thereby will be restricted in our range of choice. Public decisions will be required to defend the public purpose. Other decisions allow more latitude in outcome, but because of the prevalence of externalities they still require public choice. In this area of planning and regulation where there is room for the expression of preference, we need improved techniques of public choice. The aim is a model that is less arbitrary, more open to all participants, and more equitable in its results. There is no right answer. Welfare economics may be of some value by proposing reciprocal compensation between winners and losers in the process, or we might look to an ethical model as per Rawls or to a political trade-off model as sketched by Haefele.

It is important to know when to apply these decision models. We may have great latitude in deciding whether to favor private or common space in the city, but the time might come when there would be less latitude in deciding how much land of what kind can be spared for cities. The decision to preserve a major share of the natural system is essentially an ethical choice and should not be seen as simply a matter of arbitrating preferences (Leopold). For that decision we need a vision—a land ethic that allows space for ethical values because it properly organizes other human activity.

Emerging Issues in Agricultural Labor Relations

Philip L. Martin and Refugio Rochin

Labor relations in agriculture have been characterized by the absence of formal agreements negotiated by employer and labor representatives. Historically, labor law has assured agriculture a "special and exempt" status, a condition obviating any legal responsibility for employers to respond to employee demands, making organizing efforts more difficult. The hired farm work force found self-organization nearly impossible. Despite periodic resurgences of interest in the agricultural labor problem associated with the periodic "rediscovery" of migrant farm laborers, the extension of minimum wages and, more recently, unemployment insurance to farmworkers, and the proper role of alien labor in American agriculture, agricultural labor relations within a defined legal framework are a product of the mid-1970s.[1] The 1975 passage of the Agricultural Labor Relations Act (ALRA) in California, the state with the largest hired work force, marks a new era in agricultural labor relations.

A system of labor relations is usually defined by the actors or participants in the process (e.g., employers, workers, and government), a context or framework within which the participants interact, and a body of rules that govern participant behavior in the course of negotiating and interpreting labor agreements. The identification of participants, frameworks, and rules implies a sense of formality and continuity, attributes uncharacteristic of past labor-management interactions in agriculture. The fact that an orderly system of labor relations is just emerging forces an analysis of two related issues: factors giving rise to unionism and bargaining, i.e., the existence of unionism and the share of the agricultural labor force that is organized, and factors shaping the direction and content of labor relations, i.e., the type of labor-management relationship that evolves.

This paper explores salient aspects of current labor relations in agriculture and erects a framework for predicting the course of future labor-management interactions. After exploring the impacts of agricultural structure and labor force composition on the functioning of the agricultural labor market, the evolution of public policy that culminated in California's ALRA is described. Predictions about the existence and shape of agricultural labor relations are made within the framework of structural, composition, and public policy influences, and it is suggested that the ability of the competing employers and unions to secure favorable public intervention will be as important as raw economic power for achieving partisan goals. Although data are drawn from national sources, we conclude by noting that agricultural labor relations are most likely to be confined to the labor-intensive fruit and vegetable sectors in the South and West.

Labor Relations Systems

The study of labor relations encompasses the nexus between fundamental productive forces in society. It describes the intersection of entrepreneurial interests in production and profit, worker interests in economic welfare

[1] Hawaii's labor relations statutes have covered agricultural labor since 1945 and Wisconsin's labor legislation was construed to include agricultural laborers in 1967–68 (Martin). Four states, Idaho (1972), Arizona (1972), Kansas (1972), and California (1975), currently have agricultural labor relations statutes. For a comparative analysis of the legislation in these four states, see Kozlara.

and dignity, and the public interest in ensuring prosperity and stability. In the American context, labor relations have historically been confined to the resolution of competing interests in the private sector, with government existing primarily to determine the "rules of the game" or framework that bound permissible private actions. The recent evolution of labor relations in America has altered this two-factor model: government now intervenes to alter both the outcomes of the bargaining process (because of macroeconomic conditions) and the negotiation process itself (because of, e.g., civil rights concerns).

The system of labor relations that evolves in each industry or occupation depends on three (sets of) interdependent factors. The structure of the industry and the composition of the labor force govern the operation of the labor market, the institution for matching labor demands and supplies. Individuals and traditions in each sector influence the type of labor relationship that exists, from cooperation and renouncement of strikes in the steel industry to more persistent strife in longshoring. Finally, public policies influence labor relations both directly and indirectly. In addition to specifying duties and permissible activities within a defined legal framework, public policies affect labor markets through social welfare policies, immigration policies, and taxing and spending policies.

Agricultural labor relations are likely to be influenced by these same general factors. The structure of the agricultural industry influences the number, type, and concentration of employees, the extent to which agriculture is perceived as a sector deserving "special and exempt" status, and the degree of uniformity of interest among farmers. The composition of the farm labor force and the attitudes and beliefs of trade union leaders affect the ease or difficulty of achieving and maintaining union organization as well as determining the choice of instruments used to negotiate and enforce settlements, e.g., the choice of strikes versus boycotts. Agricultural structure, labor force composition, and union and public policies combine to determine the structure and functioning of the agricultural labor market. Public policy also exerts more direct influences on agricultural labor relations by specifying the legal framework and providing a forum for legal recourse.

Rather than experiencing the evolutionary growth of public intervention in the processes and outcomes of industrial relations, agricultural labor relations in California have been marked by a high degree of public input from the outset. Public intervention in agricultural labor relations reflects, in part, the increased acceptance of intervention in labor-management relations, but it also illustrates the need for guidance in a complex and diverse sector characterized by a variety of possible bargaining units, a fluid work force, and a need to define rights of access and property rights when residences and businesses merge. The degree of public input induced by this complexity means that competing farmer and worker interests will bargain in both public and private arenas, with success in the public rule-making process crucial for determining subsequent private bargaining outcomes.

The Agricultural Labor Market

Agricultural labor is performed by three distinct groups. Farm operators, numbering about 2.5 million in 1974, do most of the agricultural work. Farm operator labor is supplemented by nearly 0.5 million unpaid family workers and an estimated 2.7 million hired farmworkers (USDA).[2] Since labor relations are largely confined to the hired farm workforce, attention is directed to the number, characteristics, and distribution of such workers.

The hired farm work force, about 3% of the civilian labor force, is distributed unevenly across crops and, given their spatial concentration, across geographic areas. Although man-hour distributions may not indicate the allocation of farm laborers because of variance in hours worked, only man-hour labor breakdowns are available for crop groupings. In 1975, 2.9 billion man-hours of (self-employed and hired) labor were required for the production of crops in the United States, nearly 55% of all hours used in agriculture.[3] Three labor-intensive crop groupings, tobacco, vegetables, and fruits and nuts, accounted for 38.8% of all crop hours in 1975, even though their sales

[2] Four federal series on agricultural labor are available. For a discussion of the concepts and shortcomings of each, see Holt et al.

[3] In 1975, a total of 5.3 billion man-hours of labor were used in the production of crops and livestock. If every person in agriculture had worked "full-time" (40 hours per week for 50 weeks), a total of 2.6 million workers would have been required. The 2.7 and 2.9 million estimates reflect only hired workers; a further 2.2 million persons self-employed in agriculture were aided by 423,000 unpaid family workers in 1974 (U.S. Dep. Commerce).

value was only 12.4% of all crop sales (USDA). Since labor relations are defined by the interaction of groups of workers and management, most union activity occurs in those labor-intensive crops that bring together groups of workers for periods of peak labor demand, i.e., the harvest.[4]

The nature of agricultural production concentrates hired farm labor on particular types of farms at specific times of the year. The distribution of crops are in turn consolidated in particular geographic areas, permitting identification of potentials for labor relations merely by examining the spatial distribution of crop types. In the Pacific region, for example, 78.4% of all man-hours necessary for crop production in 1975 were used by growers of vegetables, fruits, and nuts. Thus, the nature of labor demands and the concentration of labor-intensive crops ensures that pressures for labor relations are limited geographically and that actual employer-employee interaction is of limited duration in any growing season.

The nature of labor-intensive crop production and the characteristics of agricultural products combine to define some well-known aspects of agricultural labor markets (Fisher). The temporal and spatial concentration of the demand for labor assures the need for a hired labor force, but the fact that labor demands peak for a harvest typically lasting less than two months forces either the availability of a reserve labor pool for agriculture, e.g., housewives or students not normally in the (agricultural) labor force, and/or a harvest labor force that can migrate from one crop harvest to another. The multiplicity of heterogeneous growers permits a variety of economic and institutional factors to influence labor demands and hiring practices, from individual recruitment efforts to reliance on public employment services or simply utilizing farm labor contractors or union hiring halls.

Although farmworkers find work in a variety of ways, agricultural wages are far more uniform. Traditionally, grower groups recommended piecework rates in their annual winter meetings, which became standard for a particular crop in the following year. Since a relatively large fraction of the seasonal work force is new each year, wage bonuses are not typically paid to returning harvest workers; veteran farmworkers are not even assured priority in hiring. The "impersonality and insecurity" inherent in the hiring-wage payment system were recognized as early as 1939 by witnesses before the La Follette Committee (U.S. Congress, Senate) and repeated in the report of the President's Commission on Migratory Labor. With piecework wage rates shifting the efficiency burden to harvest workers and because relatively little skill is necessary for most harvest jobs, employers had few incentives to foster the creation of a stable recruitment and hiring system.

The hired farm work force is a heterogeneous lot. Demographically, most hired farmworkers (1975) are white (72%), male (75%), have nonfarm residences (79%), and are nonmigratory (93%). Until Spanish-surnamed persons were separated from whites, the hired farm work force was becoming whiter, as black laborers exited agriculture in the South. Males with nonfarm residences have long comprised more than 70% of the labor force, but the importance of youth has been increasing; today, nearly two of every three hired farm workers is under 25.

The hired farm work force exhibits both demographic and participation heterogeneity. Most hired farmworkers (65%) work less than three months in agriculture, while fewer than one in six work "full-time," i.e., more than 250 days per year. Agricultural labor relations are largely confined to the seasonal hired farm work force, working at least three months each year. Regular or full-time workers are spatially dispersed (even a large farm rarely has more than three or four full-time workers), while the extremely casual labor force, in farmwork less than 25 days per year, has few incentives to pay union initiation and membership fees. If seasonal farmworkers are defined as those working between 25 and 150 days in agriculture, this seasonal component comprised 34% (911,880) of the 1973–75 average work force (Rowe and Smith).

California's hired farm work force is assumed to differ from the national farm work force in several important respects.[5] Seasonal farmworkers have long been more important in California, since specialty crops require preharvest, harvest, and postharvest attention. Ever larger farms and increased mechanization seem to have altered the compo-

[4] Although tobacco harvesting results in concentrations of hired farm labor, formal labor relations in agriculture are unlikely to result in tobacco production because of its location in the Southeast, the practice of exchanging labor among small growers, the dominance of youth in the labor force, and the availability of a mechanical tobacco leaf harvester.

[5] The last detailed profile of California's farm labor force was done with 1966 data (California Assembly).

sition of this labor force, increasing the relative importance of housewives and youth, but peak labor demands are still met by the longer term seasonal labor force. This longer term seasonal component of the labor force has been successful in initiating unionism and bargaining and has succeeded in establishing a public policy toward farm labor in California.

The Emergence of Agricultural Labor Policy

Agriculture, the dominant sector in every society during initial stages of economic development, has always experienced government intervention. In the 1920s and 1930s, public intervention in output markets and nonlabor input markets occurred, the former setting target or minimum prices and the latter assuring credit, electricity, and cooperative opportunities. The special status conferred on and imposed by farmworkers that the hired laborer position was only a transitory way station to farm ownership permitted employer interests to exclude agricultural labor from much of the social welfare legislation initiated at the same time (Morin). Despite public intervention at other junctures, agricultural labor was excluded from legislation because of its "peculiar features," including the seasonality of employment, labor migrancy, the perishability of agricultural crops, and the competitive output markets faced by farmers.

Efforts to promote the integration of agricultural labor into the larger social fabric were not absent. Several studies demonstrated the extent to which (California) agriculture was more like industry than merely a collection of family farms. McWilliams documented the extent to which California farms were merely "factories in the field," while Jamieson identified numerous attempts to organize the hired farm work. These organizing efforts, often spearheaded by nonfarm groups, failed to secure stable agricultural labor relations.

The early 1960s witnessed the rise of ethnic-based unionism among Filipino and Mexican farmworkers in California. Cesar Chavez was able to combine the AFL-CIO's Agricultural Workers Organizing Committee with his own National Farmworkers Association to form the United Farm Workers Organizing Committee (UFWOC) in 1967. The events surrounding the passage of civil rights legislation in 1964 heightened awareness of ethnicity and equality, permitting the UFWOC to integrate both economic and sociopolitical concerns into its organizing drives.

California's agricultural labor relations during the 1965–75 decade were marked by the instability characteristic of the past. This time, the farmworkers succeeded in securing enough outside assistance to assure a permanent organization. Continued pressures forced legislative hearings on agricultural labor problems, with the growing realization that some type of farm labor legislation was inevitable. Initially, employer antagonism and a lack of legal redress were primary union concerns; later, interunion rivalry between the (renamed) United Farm Workers Union (UFW) and the Teamsters, who secured fieldworkers contracts to complement their cannery and transportation membership, increased public awareness of the farm labor issue. The UFW engaged strategies and tactics common in pre-1935 industrial relations, including secondary boycotts of businesses selling nonunion and rival union products, the elicitation of public sympathy, and attempts to channel demands through political channels.

In 1975, California passed its Agricultural Labor Relations Act (ALRA). Prior to the ALRA, Fuller noted:

> farmworkers were being forced into one union or the other without the exercise of self-determination; farm employers were being forced to choose one of three options: to resist unionization, to capitulate to coercion, to engage in collusion. None of these choices brought tranquility to the parties involved or to the community at large. To the contrary, the numerous frictions involved were regularly disruptive and occasionally bloody (p. 72).

The ALRA was viewed as necessary to restore tranquility and ensure agricultural production.

The ALRA, modeled after the National Labor Relations Act, created an Agricultural Labor Relations Board (ALRB) to supervise and certify farmworker elections. Certification petitions, normally filed by employees or labor organizations, are the basis for ALRB ordered elections. To maximize the participation of seasonal and migratory workers, elections can be held within 48 hours, although the ALRB is allowed up to seven days between petition and election. To ensure participation, petitions must be filed when the number of employees is at least one-half the employer's peak agricultural employment in the current calendar year.

Under national labor statutes, the National

Labor Relations Board (NLRB) is given some license in determining appropriate bargaining units. A labor organization selected by the majority of employees in the defined bargaining unit is entitled to exclusive recognition as the unit's labor representative. The ALRA defines the appropriate bargaining unit to include "all agricultural employees of an employer,"[6] precluding the formation of separate units based on craft or departmental community-of-interest considerations or distinctions between seasonal, migrant, and full-time workers.

Determining eligibility to vote is a major issue in the face of the casual labor force that dominates agriculture. Since a majority of all hired workers do less than 25 days of farmwork each year, an equal weighting of votes would give those with only a casual attachment to farmwork the same voice as those most dependent on farmwork. The ALRA declares that "all agricultural employees of the employer whose names appear on the payroll applicable to the payroll period immediately preceding the filing of the petition . . . for an election should be eligible to vote" (*California Labor Code*, sec. 1157). Problems arise because of (*a*) differing modes of payment, e.g., daily, weekly, and biweekly payrolls, (*b*) the eligibility of strikers, especially when the striker is only a casual worker, (*c*) the eligibility of workers in second or runoff elections after they have, e.g., already moved on to a new employer, and (*d*) the eligibility of those on temporary layoff, because of, e.g., bad weather or slow crop ripening. Those issues, illustrating the administrative complexity inherent in any agricultural labor relations statute, have yet to be resolved in California (Grodin).

When disputes arise, the ALRA has attempted to limit the range of recognition and impasse resolution instruments. The UFW successfully used the boycott to gain recognition and force settlements at its inception, and the ALRA is cognizant of the importance of boycotts, permitting the union to picket and discourage purchases from those handling nonunion products if the union has been certified as bargaining representative for the primary employer's labor force. If a union is attempting to organize a group of unorganized workers, the union may distribute information to (but not picket) a secondary employer. If bargaining fails to produce a settlement, conciliation is available but not required. Harvest strikes, always a contentious issue, are not restricted by statute.

The ALRA had an uneven beginning. After only six months, funds were exhausted, and ALRA opponents succeeded in denying funding from February 1976 until July 1976. After the defeat of proposition 14 on the November ballot, which would have made funding for the ALRB a constitutional mandate and given organizers easier access to farmworkers on grower property, the ALRB began "normal" operations with the opening of field offices in December 1976. In February 1977, the Teamsters agreed to halt their fieldworker organization drives, leaving harvest labor's representation to the UFW (Rochin).

Contemporary Issues

Formal labor relations in agriculture are a result of the erection of a labor relations framework that provides a forum for dispute settlement and a mechanism for redress. In light of the severe contractions in UFW membership in the period prior to the ALRA, the union's survival has been remarkable. As the dominant union active among agricultural fieldworkers, UFW strategies and successes will shape the future of agricultural labor relations in both California and in other states.

Several sets of issues remain unresolved. The immediate problem is the formulation of specific labor policies in a heterogeneous agriculture, including the definition of bargaining units, the determination of voter eligibility, the timing of elections, the rights of union organizers, and the timely resolution of objections. Until precedents are established, adversaries will have incentives to litigate, since the outcome before the ALRB remains in doubt. The ALRB itself, hampered by personnel turnover as well as a need to hire and train personnel, requires time to gain consistency and self-confidence.

Longer term issues center on the impacts of a changing agricultural structure and social welfare policies on the structure and functioning of the agricultural labor market. The structure of labor-intensive agriculture in the West could be quickly altered if persistent water shortages led to "full pricing" of state and

[6] The ALRB is permitted to exercise its discretion in defining bargaining units when "the agricultural employees of the employer are employed in two or more noncontiguous geographic areas" (*California Labor Code*, sec. 1156.2).

federal irrigation waters, since fruits and vegetables are both water intensive and time intensive, requiring labor to nurture and harvest. Enforcement of the 160 acre limitation on farms receiving federal water could encourage a shift toward labor-intensive fruits and vegetables, since large acreages capable of using capital-intensive equipment would no longer be as profitable.

Trade and immigration policies affect the agricultural labor market by altering demands for labor. As Mexican irrigation systems expand and as the real cost of transporting agricultural commodities between the United States and Mexico and the Orient declines, the production of labor-intensive products may shift to countries with lower labor costs. Such moves are accentuated or impaired by tariff and quota policies with respect to agricultural products. If barriers to importing agricultural products are erected and farm wages rise, the incentive to (illegally) enter the United States increases, making immigration and trade policies mutually dependent and imparting another source of instability to agricultural labor relations.

Just as trade and immigration can affect the number and focus on farm labor jobs, so do continued prospects for mechanization and labor displacement in agriculture. Agricultural mechanization efforts, concentrated in labor-intensive sectors, are less predictable than changes in trade or immigration policies, allowing growers to use mechanization as a threat in bargaining. Unless unions extract negotiation or compensation rights to govern the introduction of labor-saving technology (Martin and Johnson), possible mechanization will inject another element of uncertainty into the agricultural relations system.

Trade and immigration policies, water prices and acreage limitations, and innovation development and diffusion are directly or indirectly influenced by public policies, affecting the structure and processes within agriculture and thus the operation of agricultural labor markets and labor relations. Labor and manpower policies directly affect the size and composition of the labor force as well as the mode of labor relations. In addition to the labor relations law, public policies toward minimum wages in agriculture, workmen's compensation, and the extension of unemployment insurance to farm labor affect the type of worker likely to be hired and the need for union-management bargaining over these labor issues. To the extent that agricultural labor is treated as industrial labor and record-keeping burdens are increased, employers may have incentives to hire more native males and fewer aliens, youth, and females. As income security programs expand, the size of the hired farm labor force may decrease, leaving fewer casual workers with low labor force and union attachments. Pesticide and environmental policies affect agricultural labor relations by transforming one aspect of bargaining from private to public forums, although this translation often produces employer-union solidarity, as in the automobile industry. Thus, labor and social policies will affect future agricultural labor relations by directly erecting and altering the bargaining framework and by indirectly affecting the issues to be negotiated as well as the size and composition of the labor force to be bargained for.

Labor relations in any industry are a product of both general trends and policies and the unique characteristics and individuals in each industry. Agriculture is a complex, heterogeneous industry imbued with antilabor traditions. The "lateness" of the advent of labor relations in agriculture has reserved a much larger role for public policy in the formation and direction of labor-management interaction. Public policy, of course, results from the resolution of conflicting claims in public rather than private forums. Farmworkers, experiencing only limited successes privately, have now secured legal frameworks for initiating labor relations in several states. As in most situations where a dominant party must yield to one traditionally excluded, initial experiences have lacked stability and predictability. But, after the resolution of short-term initiation problems, agricultural labor relations promise to achieve a degree of stability at least congruent with the stability of agriculture.

Emerging Issues in Agricultural Labor Relations: Discussion

Collette Moser

The paper by Martin and Rochin is a combination of an historical account of the development of labor-management collective bargaining in agriculture in the United States, the current status of collective bargaining in California agriculture, and predictions about changes in labor supply and labor demand in agriculture. Sometimes the predictions refer to labor supply and demand changes in response to collective bargaining; sometimes collective bargaining is itself a response to labor supply or demand changes; sometimes the connection between the predictions and collective bargaining is unclear.

My discussion is organized around four models that one often sees in the literature of labor economics and labor relations. These models are as follows: (*a*) a comparison of the situation of the unionization of workers in relevant industry (agriculture) with unionization of workers in another industry; (*b*) analysis and predictions of the outcome of unionization of workers in an industry based on information on changes in another policy area (for example, it is not unreasonable to predict what will happen to agriculture workers with changes in labor-management relations laws in view of changes in protective labor laws that affect agriculture); (*c*) a comparison of unionized workers in an industry, sector, or geographic area with nonunionized workers in that same industry but in a different sector or different area (for example, one might compare unionized agricultural workers in California with nonunionized workers in the Midwest); (*d*) economic theory used to predict various effects of unionization of agricultural workers.

The paper contains observations on the development of collective bargaining in agriculture that point out some special characteristics of unionization of agriculture that appear to differentiate agriculture from other industries. Most notable of these is the lateness with which legislation for effective systems of collective bargaining has come to this industry. However, legislation for collective bargaining for hospital workers and state and local employees has also been late, and there are groups of workers such as household domestics that are less unionized than agriculture. It is not clear whether the authors accept the concept that agriculture's features of seasonality, labor migrancy, perishability of crops, and competitive output markets are "peculiar." In any event there are other industries such as construction and longshoring that have comparable characteristics.

Martin and Rochin discuss in detail certain features of collective bargaining as it is emerging in California agriculture that appear to differentiate it in "the formulation of specific labor policies . . . , including the definition of bargaining units, the determination of voter eligibility, the timing of elections, the rights of union organizers, and the timely resolution of objections." However, these problems have been confronted and resolved in other industries and, here again, comparisons with longshoring and construction are relevant. In fact, in some construction cases the problems of tracking down workers for a runoff election may be even more difficult since the worker may not expect to work for that employer again. In any event these are organizational problems that the union faces and if the union is sufficiently strong it will overcome them.

Moreover, the national legislation governing the holding of representation elections outside of agriculture is also being questioned. Recent proposals by President Carter and Secretary of Labor Marshall to amend the National Labor-Management Relations Act speak to problems faced by some unions, particularly textile workers in the South, in their organizational efforts (*Nation's Business*). The anti-labor traditions in agriculture are probably no worse than those in some other industries that have had much larger corporate finances for "union busting."

Collette Moser is an assistant professor in the Department of Agricultural Economics, Michigan State University.

The authors suggest that the role of part-time workers in farm union elections is a unique and negative one. Other unions also have a predominance of part-time workers and are able to survive. In fact, this feature, as well as the youthfulness and turnover of the agriculture labor force and the availability of a reserve pool of workers such as housewives or students, are also features of much retail employment that is unionized.

While Martin and Rochin appear to be arguing for removal of part-time workers from representation elections, protective labor legislation, as it is being applied to agriculture, appears to be going in the opposite direction. Instead of narrowing the concept of a "worker," public policy is making workers in more industries and employed by smaller employers eligible for unemployment compensation, worker's compensation, and minimum wages.

Moreover, the effects of the extension of protective labor laws to agriculture on employer preferences as to "native male, aliens, youth, and females" are not necessarily homogeneous. For example, unemployment insurance extension may actually increase the demand for youths because since they return to school they are ineligible for benefits.

In fact, proposed increases in minimum wage laws, particularly those that tie automatic increases in the minimum wage to increases in the average hourly wage in manufacturing, may actually be more significant than collective bargaining in determining labor supply-demand adjustments. These proposals are not discussed in this paper.

Based on economic theory, the authors predict an increase in mechanization in response to unionization. In the Midwest, great mechanization has taken place without the threat of unionization. Mechanization is used to lower unit costs, labor being only one of these. In order to determine that unionization "causes" mechanization, one must assume that the union will have a strong effect on wages, that is, that wages will increase by a greater amount than they would in the absence of the union. However, as Marshall carefully concludes, it is unlikely that a union of unskilled agriculture workers will have such an effect on wages (p. 162).

On the other hand, the authors assert that "enforcement of the 160 acre limitation on farms receiving federal water could encourage a shift toward labor-intensive fruits and vegetables. . . ." Based on experiences in the Midwest with its smaller farms, such a shift from capital to labor-intensive production seems unlikely. In many cases farmers would custom-hire equipment.

Martin and Rochin also predict a shift toward "more native males and fewer aliens, youth, and females" as a result of increased costs of record keeping. I assume that the prediction is based on an expected greater productivity of native males relative to aliens, youth, and women and the assumption that the wage rates for all groups would be the same. While the latter condition is unlikely, the former condition may also not be so. Aliens who are often worried about keeping their jobs may actually work harder and women according to a recent report may actually cost less because "men are most likely to cause . . . discipline problems, especially those arising from drug and alcohol abuse" (as stated in the *Chicago Tribune*, p. 1).

In conclusion, Martin and Rochin have tried to distinguish between private and public labor relations in agriculture. The passage of farm labor relations laws in California and a few other states represents the "public policy era." To me situations outside of agriculture comparable with this model would be pre- and post-1935 Wagner Act periods. Before collective bargaining had the legitimacy of the Wagner Act, it was a public activity and there were public policies toward it. I submit the same is true of agriculture. For instance, whether injunctions are or are not used against strikers, picketers, etc., represents the implementation of public policy even in the absence of direct labor legislation.

What we are witnessing then is not a shift from the private to the public arenas but a movement along a continuum of public policies. If the movement parallels events in other industries, it will evolve into full coverage of agriculture workers under all protective labor laws and under the National Labor Relations Act.

Interactions Between Farm and Nonfarm Labor Markets

Wallace E. Huffman

During the past 25 years, rural areas in the United States have undergone some dramatic changes. The most fundamental and pervasive forces behind these changes have been technological advancements in agriculture and economic growth (i.e., growth in real income per capita). This paper is concerned with the interaction of farm and nonfarm labor markets. The time horizon is the past 25 years, roughly since 1950. I shall highlight some of the significant long-term changes that have occurred in these labor markets and then discuss policy implications.[1]

A Framework for Viewing Interactions

During the past 25 years, the most fundamental and pervasive factors affecting the interaction of farm and nonfarm labor markets have been economic growth and technological change. The per capita income elasticity of demand for farm products is (and has been) positive but less than one, so the income elasticity of demand for nonfarm products is larger than one. Thus, domestic growth of real per capita income has caused a more rapid rate of growth of domestic demand for nonfarm products than for farm products. Furthermore, differences in rates of growth of domestic demand have increased as the rate of population growth has slowed. If the supply curve for domestic farm products shifts at least as fast as the supply for nonfarm products, the farm output share of national income and the relative farm output price must fall, provided that foreign demand growth for U.S. products is not offsetting.[2] Even if technical change was so favorable to agricultural labor as being factor neutral and at equal rates in both sectors, the income elasticity differences imply that growth of labor demand in the nonfarm sector exceeds the farm sector. If both sectors initially have equal rates of population and labor supply growth, the relative farm-labor wage rate must fall.

For labor to be fully employed and farm labor to earn its opportunity return under these conditions, a net transfer of labor to the nonfarm sector must occur. Wage rates become more equal, and they may approach equality when allowance is made for living cost differences and an opportunity return on moving costs. The geographical dispersion of agriculture as an industry and its rural location away from most, but not all, other industries increases the costs of obtaining information about nonfarm jobs and the probability of household mobility for persons to switch industries.

The transfer of labor occurs in three major ways. First, families may sever farm sector ties by quitting farm jobs, selling any farm capital they own, and taking a nonfarm job, perhaps moving to a city. Second, as children come of age, they may leave agriculture and take nonfarm jobs, but their parents remain in farming until retirement. Third, workers and their families may stay on farms, but some family members take full-time nonfarm jobs (e.g., wife) while others (e.g., husband) continue full-time work. Or some members may reduce their hours of farm work, take a nonfarm job, and become multiple jobholders. The relative attractiveness of these alternatives depends on the location of nonfarm job opportunities, the types of skills of the people, and the costs of commuting or of moving to nonfarm jobs. All have been important sources of adjustment.

Wallace E. Huffman is an assistant professor of economics, Iowa State University.

The author wishes to thank Ben French and John Miranowski for helpful comments on an earlier draft of this paper. Journal Paper No. J-8916 of the Agriculture and Home Economics Experiment Station, Ames, Iowa. Project 2078.

[1] Johnson also discusses some of these changes. Others may consider that some significant changes have been excluded.

[2] All (own price) demand elastitities are assumed to be negative, and all (own price) supply elasticities are assumed to be nonnegative. Production functions for both products are assumed to be homogeneous of the same degree.

If, with growth, the real wage rates rise in the nonfarm sector as they have in the past and enough labor moves out of the farm sector so the real wage rate rises there, too, new labor-saving technology may be induced for agriculture. This process is elaborated on by Binswanger. His results suggest that induced innovation has occured in U.S. agriculture and that it has been labor and land saving. Also the population and labor supply growth rates may initially be larger in the farm than in the nonfarm sector as a result of the higher birthrates of farm women. Both these changes increase the net transfer of labor services required to equalize earnings between sectors while maintaining full employment.

Economic growth has led to other changes that have enhanced the interaction of farm and nonfarm labor markets and eased the labor market adjustment. The expansion of communication systems (free mail delivery, telephone service, radio, and television) to rural areas greatly increased the access of rural and farm people to ideas and knowledge. The cost of rural transportation has fallen with the improved quality of rural and urban roads and improved quality and falling cost of automobile services. The rising education levels of farm and nonfarm populations have increased the supply of allocative ability and the ability to perceive and respond to changes in economic conditions (Schultz) and have increased general skill levels. But educational level differences between the farm and nonfarm population, whites and nonwhites, and the South and the rest of the United States are sizable and are narrowing slowly. The reduced cost of transportation and communications and increased education levels have decreased the transactions cost of resource adjustment and have enhanced the efficiency of resource allocation between rural and urban labor markets.

Long-Term Changes

Farm-Nonfarm Income and Population Changes

During the early 1950s, the income position of the farm population deteriorated relative to the nonfarm population; since then it has improved markedly. Average per capita disposable personal income of the farm relative to the nonfarm population was 55.1% in 1950, falling during the early 1950s to about 45.7% in 1956 (USDA 1976).[3] Since the mid-1950s, the relative income position of the farm population has steadily improved. In 1970, the ratio of farm to nonfarm real disposable personal income was up to 75.5%,[4] and in 1975 up to 87%. Thus, the income position of the farm relative to the nonfarm population has improved dramatically. This period of improving relative income position of the farm population coincided with a marked decline of the farm population size.

During 1950–70 there was a massive net movement of whites and nonwhites off farms and into the nonfarm population and labor market. The result has been a reduction of the farm share of the total population from 15% in 1950 to less than 5% today. For whites, the percentage reduction between 1950 and 1960 was 40% and between 1960 and 1970 was lower, 18%. For nonwhites, the movement off farms between 1950 and 1960 was more dramatic, exceeding 50%, and it was a slightly lower 47% between 1960 and 1970.

There were, however, large regional differences in the rates of population change. The West and the South have had the largest percentage increases in the nonfarm population (table 1). For the farm population, the South and Northeast registered the largest net declines between 1950 and 1960, roughly 50% for whites and nonwhites. The North Central region had the lowest rates of decline for whites (27%) and nonwhites (16%) for the early period. Between 1960 and 1970, the North Central region had the largest reduction in the white farm population (45.5%), and the South had the largest reduction (52%) in the nonwhite population. The net result of these changes has been a significantly greater concentration of the farm population in the North Central region (an 11.2 percentage point gain) and significantly less concentration in the South (a 13.9 percentage point decline).

The movement off farms during 1950–60 contributed to an equally rapid growth rate of urban and rural nonfarm populations. The de-

[3] Personal disposable income of the farm population refers to income received by all persons living on farms. It includes the families of hired farm workers who live on farms, but it excludes farm operators and their families who do not live on farms. Before making the relative income comparison, the per capita income of the farm population was deflated by the USDA index of prices paid by farmers for family living items (1967 = 100) and the per capita income of the nonfarm population was deflated by the consumer price index of all items (1967 = 100).

[4] The boom in farm prices and net farm income in 1973 actually pushed the ratio up to 109.4%.

Table 1. Farm and Nonfarm Population Change (Percentage) by Census Regions and Race, 1950–70

Region, Race	Total		Nonfarm		Farm

[a] Numbers in parentheses in the 1950–60 (1960–70) columns give the regional distribution of the population in 1950 (1970).
[b] Numbers in brackets in the 1950–60 (1960–70) columns give the percentage of the population in the region that is nonwhite in 1950 (1970).

cade of the 1960s, however, was the period of movement from rural to urban areas. During this period, the growth rate for the urban population was 2.5 times larger than for the rural nonfarm population. Since 1970, signs of at least a temporary reversal of the rural to urban population movement have occurred (Beale). The positive growth is in nonmetropolitan areas both adjacent to and more distant from large urbanized areas. Some of the reasons for this reversal seem to be decentralization of industry, growing population of retired and semiretired individuals, growing rural-oriented recreation industry, and increasing air pollution, crime, and congestion in urban areas.

The Rising Labor Force Participation Rate of Women

A major postwar change in the U.S. economy has been the rising labor force participation rate of women, especially of married women. Between 1950 and 1970, the labor force participation rate of women (married women, husband present) increased from 31% (24%) to 43% (41%), and the increase in number of women in the civilian labor force was a dramatic 85.6%, compared with 18.8% for men (see bottom of table 2). In both farm and nonfarm households, birthrates have fallen during the past 25 years, and households have purchased many new durable goods, some of which are labor saving. Both factors have contributed to a reduction in the demand for wives' household time, releasing time for work outside the household and/or for "leisure" time.[5]

The participation rate of farm resident wives in nonhousehold work also is rising. The level

[5] These factors have also contributed to the leveling out of the labor force participation of women by age; i.e., for recent years, there has not been such a drop in female participation rates during their twenties.

Table 2. Occupational Distributions by Farm Residents (≥ 14 Years of Age) in Civilian Labor Force

Occupational Categories	Percentage Change[a]			
	Males		Females	
	1950–60	1960–70	1950–60	1960–70
Farm residents

[a] The numbers in parentheses under 1950–60 (1960–70) column gives the distribution of the male (female) civilian labor force across occupations in 1950 (1970), except for the all occupations categories that give total workers in civilian labor force (thousands).

is lower but is rising similarly to the participation rate of other women. For example, in March 1959 the labor force participation rate of all married women was 31%. For farm wives it was 27%. By March 1971 the percentages had increased to 41% and 37%, respectively (U.S. Dep. Labor).

The Falling Number of Nonwhite Farmers

During the past 25 years, a dramatic fall has occurred in the number of nonwhite farmers, primarily in the South (see table 3).[6] Before the Civil War, many blacks were slaves on southern farms and plantations. Freeing the slaves, which was not accompanied by land reform, upset factor ownership proportions but left largely unchanged the number of blacks working in agriculture. The white landowners had few options for labor aside from former slaves, and the former slaves had few options outside southern agriculture. The sharecropper tenure system became a new and successful institutional arrangement for carrying out voluntary exchange between landowners and workers in the post-Civil War South. The shared incentives by tenants and landowners helped insure cooperation between them, diligence of work by tenants, and willingness of landowners to help tenants acquire cooperating farm inputs (Reid). But not all blacks were sharecroppers or even tenants, and not all sharecroppers were black. In 1920, 76% (36%) of southern nonwhite farm operators were tenants (sharecroppers). By 1950, their percentage had fallen to 65% (table 3).

Both nonwhite tenants and owners in the South have had a history of small farm sizes (Lewis). Most of these small, largely tenant-operated farms have been a casualty of labor-saving technological advances in agricultural production. Major technical ad-

[6] More than 95% of the U.S. nonwhite farm operators are in the South.

Table 3. Changing Distribution of Farms and Number of Farms by Race, South

Race	Distribution of Farms			Percentage Change in Number of Farms	
	1950	1959	1969	1950–59	1959–69

vances have been the switch from animal to mechanical power in seedbed preparation (1930s and 1940s), from hand weeding to flame cultivation and herbicides (late 1940s through 1960s), and from hand to mechanical harvesting of cotton and tobacco (1950s and 1970s, respectively). These advances brought a dramatic fall in the demand for unskilled labor in southern agriculture. Landowners with a few hired workers and modern technology have replaced thousands of tenants and other farmers in the South.

Because of the small size of nonwhite farms and larger share of tenant nonwhite than of white farmers, it is not surprising that during the past 25 years nonwhite farmers have quit farming and shifted to the nonfarm population and labor market at a faster rate than have white farmers (table 3).[7] Unfortunately, most rural farm nonwhites have been poorly prepared for nonfarm jobs. They have low education levels and few marketable skills. Those that move to the cities have become a growing welfare burden because they have had generally high unemployment rates and unskilled workers are among the first to be laid off in a business cycle downturn.

Increasing Importance of Nonfarm Income

The welfare of farmers, even large ones, is not determined solely by incomes from their farms. The farm population's share of personal income from nonfarm sources has increased steadily from 27% in 1950 to 50% in the 1970s, except for 1973 when net farm income rose dramatically.[8] Thus, a large and growing income share of the farm population is not from farming. This change has reduced the vulnerability of the farm population to wide swings in farm prices and net farm income.

Another development is the remarkable increase since 1960 of the relative and real incomes of farm families that operate small farms. This change also is tied to rising nonfarm incomes. Because the index of prices received by farmers was approximately unchanged between 1960 and 1965 but about doubled between 1965 and 1975, a constant dollar value definition of "small" farm size is used in the comparison. A farm is small in 1960 and 1965 if it had sales of less than $5,000 but in 1975 if it had sales of less than $10,000.[9] For these small farms, average constant dollar nonfarm income increased from $2,789 in 1960, to $4,652 in 1965 (by 68%), and to $7,862 in 1975 (by 69% over 1965).[10] Average constant dollar realized net farm income remained unchanged between 1960 and 1965, but it actually fell by $337 between 1965 and 1975.

This rising nonfarm income of small farmers has caused a dramatic increase in their family income positions relative to larger farmers. In 1960, average total (farm and nonfarm) income for small farmers was only half as large as for the larger farmers, but by 1975 it had improved to 66%.[11] Rising nonfarm incomes of families that operate small farms have been successful in improving the relative income position of these families even though most government programs have had little positive effect.

---

[7] Discrimination against nonwhites in obtaining education and extension information also placed nonwhite farmers at a disadvantage in competing against white farmers (Huffman 1977a).

[8] More than 70% of the income from nonfarm sources is wage and salary income of farm males and females from nonfarm employment. Income from nonfarm sources also includes nonfarm business and professional income, rents from nonfarm real estate, dividends, interest, unemployment compensation, and social security payments.

[9] The number of farms and amount of nonfarm income by sales class are USDA estimates (USDA 1976).

[10] Deflator is the index of prices paid by farmers for family living items, 1967 = 100.

[11] We do not know how many of the small farmers of 1960 were still around in 1975 or, if they were still farming, what size of farm they were operating.

Integration of Farm and Nonfarm Labor Markets

In early days travel was slow, and workers had to live close to their job sites. Improved rural (and urban) roads and cars and reduced time and money costs of transportation have made it possible for people to live a greater distance from their jobs. Decisions on residence are not so closely tied to job-site location. This reduction in commuting costs has enhanced integration of farm and nonfarm labor markets.[12]

During the past 25 years, striking changes have occurred in the integration of farm and nonfarm labor markets. The major changes are an increasing percentage of the farm population in the labor force has nonfarm jobs and an increasing percentage of those who work on farms reside elsewhere. First, the reported occupations of resident farm males and females show some of this change (table 2). In 1950 75% of the farm resident males and 41% of the farm females in the civilian labor force ≥ 14 years of age) reported their occupation as being one of the two farm occupations (farmers and farm managers or farm laborers and farm foremen).[13] In 1970 this frequency had fallen to 49% for farm males and to only 10% for farm females. Thus, the percentage point increase in reported nonfarm occupations was 25 for farm males and 31 for farm females.

Also, the increasing amount of off-farm work by farm family members shows another aspect of taking nonfarm jobs. Nationally, the percentage of farm operators reporting any off-farm work during the census year has risen steadily from 39% in 1950 to 54% in 1969.[14] Operators working 100 days or more per year off their farms increased from 23% to 40% during the same period. Perhaps surprisingly, all regions except for the Northeast showed a similar rise in the off-farm participation rate of farm operators (table 4). However, only in the North Central region did the absolute number of farmers participating in off-farm work actually increase. For farm wives, the nonfarm labor force participation rate increased from 16% in March 1959 to 26% in March 1971 (U.S. Dep. Labor).

[12] During 1948–72 the relative price of gasoline declined. But in 1973 there was an abrupt change in this trend when the price of petroleum products rose rapidly. A rising relative price of gasoline could reverse the trend toward greater integration of farm and nonfarm labor markets.

[13] Occupation is determined by where the individual spent the largest number of hours working during the census week. If he was unemployed, the occupation is the last one where the person was employed.

[14] Most of the off-farm work is at nonfarm jobs and very little is work on other farms for pay. For example, in 1964, 96% of the total off-farm work days of farm operators was spent in nonfarm work (U.S. Dep. Commerce 1968).

[a] Percentage change in number of farms in each class.

What do we know about farm households' decisions on off-farm work? First, the off-farm jobs pay much higher wage rates than the going wage rate for farm hired labor. For example, in 1964 the national average daily wage rate for off-farm work by farm operators was 2.33 times the average daily wage rate for hired farm labor. For other farm household members, the factor was 1.78.[15] Second, decisions on off-farm work are part of the relatively complex joint farm production and household consumption decisions. Inputs into farm production (and farm output) and inputs of goods and human time into household consumption are determined jointly. Third, results from fitting an off-farm labor supply function to county average per farm data for Iowa, North Carolina, and Oklahoma show that off-farm work by farmers responds positively to their own wage rate but negatively to the wage rate of other household members (Huffman 1977b). Imputed farm output (from an estimated production function) has an expected negative effect. The education of farmers affects the quantity of their off-farm work in three ways. It has a positive effect on farm output and on their wage rate, and each of these variables enters the off-farm labor supply function. Then education has a separate positive direct effect on off-farm work. The net effect of farmers' education on their off-farm labor supply is, however, positive.

Last, an increasing percentage of males and females who do farm work do not reside on farms. The percentage of males reporting occupations of farmers and farm managers and living off farms increased from 8% in 1950 to 20% in 1970. For males reporting occupations of farm laborers and farm foremen and living off farms, the increase for the same period was from 33% to 66% (see footnote 13). A similar change occurred for females who reported these two farm occupations. This integration has been facilitated by reduced transportation and communications costs in rural areas and is partly a consequence of rising labor force participation of married women. During the past 25 years, farm and nonfarm labor markets have become more integrated as an increasing proportion of the farm population that is in the labor force has taken nonfarm jobs and as an increasing percentage of those who work on farms reside elsewhere.

[15] The data on off-farm days worked and wage and salary income of farm households are taken from the 1964 *Census of Agriculture*. The wage data for hired farm labor are from the USDA (1965) publication *Farm Labor*.

Implications

Agricultural policy is currently up for review and revision. The dramatic long-term changes in the interaction between farm and nonfarm labor markets between 1950 and 1970 should be recognized in drafting new legislation. It will be easy to draft legislation that effectively attempts to protect agriculture from needed long-term resource adjustments, especially the reduction of labor in agriculture. To the extent that protection is successful, it only delays the time when resource adjustment must occur.

The increasing interaction between farm and nonfarm labor markets has increased the short-run elasticity of supply of labor in the farm labor market. When this fact is combined with the increasing share of farm output costs that are due to the purchased inputs that are highly elastic in supply, it is clear that small errors in setting farm commodity support prices too high will be very costly to U.S. taxpayers and consumers. Unfortunately, the costliness of such mistakes may become all too obvious in the near future.

The increasing share of farm family income from nonfarm sources and rising off-farm labor force participation rates of farm males and females have made the economic welfare of farm families less dependent on net farm income. These changes make even clearer that target prices for agricultural commodities are an inefficient method of transferring income to low income farm families. A general welfare reform that leads to some type of negative income tax or income maintenance program seems a better income transfer plan. Federal assistance would then be based upon being poor rather than being in some (other) special interest class.

Interactions Between Farm and Nonfarm Labor Markets: Discussion

Sigurd R. Nilsen

Huffman's paper is an excellent review of some of the primary factors contributing to the decline of the farm population during the past twenty-five years. The historical perspective provides valuable insight into the transfer of labor from the farm to the nonfarm sector. However, in terms of providing a useful perspective on rural labor markets, this approach suffers from problems introduced as a result of dealing with the farm sector in isolation from other economic activities in rural areas. Huffman notes that the farm population has declined from 15% to 5% of total population and that the primary source of support for small farmers in 1975 is from nonfarm income. Yet, he still deals with farm labor as if it were isolated from alternate employment opportunities.

The agricultural sector is an important factor in the economy of many rural areas. However, the recent growth of employment in manufacturing and the reversal in the trend of rural population loss indicates that rural areas are not totally dependent upon agriculture for an economic base. This implies that there may be much more interaction between the farm and nonfarm sectors than Huffman indicates.

According to Rowe and Smith's *Hired Farm Working Force of 1975*, 54% of those who did hired farm work were otherwise not in the labor force in 1975, being mostly students or housewives. This group accounted for over 25% of hired man-days worked in agriculture. This study also found that during 1973–75 an average of 77% of farmworkers were not farm residents. Thus, it appears that investigations of farm labor markets should not be executed in isolation from other sectors of the rural economy. This is further supported by Huffman's discussion of the relative farm and nonfarm wage rates. Huffman's reasoning seems to be somewhat contradictory when he implicitly assumes that agriculture is not only an economically isolated sector but is also physically isolated. If it were, how could small farmers earn an average of eight times their farm income from nonfarm employment?

Huffman's paper has thus provided an excellent starting point from which to reorient investigations of farm labor markets. We must investigate not only the off-farm employment of the farm population but also the farm employment of nonfarm residents and the alternative nonfarm employment opportunities available to rural residents. Huffman implicitly concedes this point when he notes, "The major changes [in the integration of farm and nonfarm labor markets during the past twenty-five years] are an increasing percentage of the farm population in the labor force has nonfarm jobs and an increasing percentage of those who work on farms reside elsewhere." He does not utilize the evidence cited to develop a more integrated conceptualization of rural labor markets where the farm is but one sector. Instead, he reverts back to the farm as the relevant unit of analysis. This perspective is most likely the result partially of his own biases and partially a result of the paucity of data that provide employment information on all sectors of the rural economy. The treatment of the farm as a quasi-business, quasi-household unit further confuses both data collection and analysis.

The conclusion that target prices are an inefficient method of transferring income to low income farm families is well taken. However, based upon his own observations of income from nonfarm sources, an income transfer plan for the rural poor should be only part of a broader based rural development program.

In my view, Huffman's premature conclusion that an alternative income transfer plan is the relevant approach to aiding needy farm families results again from the treatment of the

---

The views expressed here are those of the author and do not necessarily represent the position of the U.S. Department of Agriculture.

farm in isolation. Rural development is not synonymous with farm development. To constructively aid the rural population, we must first understand the structure and processes of rural labor markets. Then we may determine what action, if any, is necessary to promote relevant employment opportunities for rural residents and also what role an income transfer plan should play in the overall scheme.

In conclusion, I would like to make some remarks regarding my own views pertaining to rural labor market analysis. First, I believe I have made my feelings clear that agriculture, and the farm, should be viewed as a sector interrelated with others in the rural economy. Second, particularly with respect to labor supply analysis, we must build upon existing work, which is focused mainly upon urban or urban-biased national studies, to determine how the rural population behaves, what differences exist in the labor supply decisions of rural vis-à-vis urban residents, and how the mass, diversity, and access to employment opportunities affects labor supply in rural areas.

My final point concerns the definition of rural. Researchers and institutions have many conceptions of what is rural. For some it is areas characterized by open country, for others it is all nonmetropolitan counties, still others regard any political unit with a population less than 2,500 as rural. The definition adopted by a particular researcher or institution is of marginal importance, except of course when it affects the distribution of public funds. What is important is that all factors that differentiate one area from another be explicitly included in any analysis of rural labor markets. For example, a resident of a rural portion of a standard metropolitan statistical area will most likely face a different set of employment opportunities and have better access to them than a resident of a small town in a nonmetropolitan county. Thus, characteristics such as industrial and occupation structure and the transportation system of an area are important factors.

My comments on Huffman's paper may be viewed by some as straying far afield from my prescribed task. However, I submit that investigations of the interactions between farm and nonfarm labor markets merit a broader perspective than has heretofore been taken.

Farm Labor Markets: Discussion

John W. Mamer

These two papers come to the optimistic conclusions that the farm and nonfarm labor markets have become more integrated and are functioning so as to reduce the excess of labor in agriculture. Huffman expresses the hope that public policy will not shield agriculture from "needed long-term resource adjustments, especially the reduction of labor in agriculture."

Martin shares the good news. However, we have to extend his reasoning a little to make explicit the area of agreement. Martin reviews the recent past with respect to labor relations in agriculture. He, like Huffman, finds good news in the evolution of events. We are evolving in agriculture a stable system of labor relations—at least such an outcome is in prospect. This new style of labor relations most fully developed in California, where the enactment of the Agricultural Labor Relations Act of 1975 facilitates the development of unionization and collective bargaining. The initial period has been a little unstable, but Martin concludes "after the resolution of short-term initiation problems, agricultural labor relations promise to achieve a degree of stability at least congruent with the stability of agriculture."

Martin does not argue directly that a reduction of labor inputs in agriculture is an outcome likely to be associated with an expansion of labor relations carried on under a regimen of collective bargaining. But he expects the labor force mobilized to shrink in size as more employment per worker is achieved under collective bargaining. An effective union will tend to reserve employment for those members who have more seniority.

Both authors thus are favorably disposed toward a reduction of labor in agriculture. Although both union rationing of jobs among members and the market mechanism will tend to shift human resources out of agriculture, we should recognize these two systems work in quite different ways. Both are functioning simultaneously in the nonfarm economy currently. Economists could contribute to rational public decision making by discussion and analysis of the efficiency and equity of these two systems for allocating human resources among occupations.

The evidence offered to support the optimistic conclusions warrants some comment. The main bits of evidence are a reduction in per capita disposable income differentials, the increased tendency for those who work on the farm to reside elsewhere, and the increasing proportion of farm operators who do nonfarm work. These bits of evidence may be consistent with the proposition that farm and nonfarm labor markets have become more integrated. But had the wage differentials between farm and nonfarm work, say, between farm and factory work, been examined, the evidence supporting integration would not have been so convincing.

Several conflicting trends may be operative at the same time. The wage rate differential between farm and factory seems to have remained relatively constant over the past two decades, in California and in the nation as a whole. Yet here in California the main exodus of human resources from agriculture has been in the farm operator and family labor category. Average annual employment of hired workers has remained relatively stable.

With regard to the increased number of individuals who do both farm and nonfarm work, it may be that the hired farm labor market and the nonorganized nonfarm labor market are becoming more closely linked. Fuller and Van Vuuren suggest that the linkage is not symmetrical. A relatively larger proportion of those individuals who do both farm and nonfarm work are nonfarm workers who enter the farm labor market as a salvage operation, seeking to obtain such income as they can during those periods when they cannot find nonfarm work. The proportion of farm workers who move into nonfarm work when farm work is not available to them is on a much smaller scale. Fuller and Van Vuuren conclude "the dominant characteristic of the

John W. Mamer is with the Cooperative Extension Service, University of California, Berkeley.

hired farm labor market is clear. It is an open, ready-access market for salvage of zero and low opportunity cost time, and its earnings record reflects this dominant characteristic" (p. 154).

If the farm labor market is a salvage labor market in which farm workers face increased competition from nonfarm workers when nonfarm employment is cyclically or seasonally low, the farm worker may be absorbing a disproportionate share of the burden of economic adjustment. No doubt farm labor unions will want to regulate this inflow into agriculture of nonfarm workers.

Martin suggests that unions will also be interested in the flow of new technology into agriculture. He suggests that, unless unions are able to negotiate contracts that provide directly for labor a share of the benefits of new labor-saving technology, labor relations in agriculture will face another element of uncertainty.

This is a very difficult problem area. What is an optimum means of distributing the benefits of technological advance? United Farm Workers lobbyists operating in the California State Legislature have taken an antagonistic stand toward publicly supported mechanization research, focusing their attention on the fact that jobs are destroyed. Little or no attention is paid to the possibility of lower food costs, more stable annual employment, or the possibility of higher wages.

We have moved some distance from the President's Commission on Migratory Labor of the early 1950s. In its report, *Migratory Labor in American Agriculture*, the Commission suggested that the "mechanization of hand tasks may restore greater balance to the seasonal distribution of farm employment" (p. 16). In those days nearly everyone was confident that those workers displaced by machines would be quickly shifted to new and better jobs.

It is quite easy for academic economists to note that the fruits of technological advance in agriculture are passed along to the consumers (including farm workers) and that in the long run few or none of the benefits are retained by the farm employer operating under something approaching atomistic competition. But the reality faced by the farm worker is that the economy has not been expanding fast enough to enable the displaced farm worker to find a new and better job in anything like a reasonable amount of time, if at all, given his experience and skills.

The farm worker sees that as the mechanical tomato harvester came into use, the acreage and production of tomatoes increased so much that possibly total employment associated with tomato production, processing, transporting, and marketing may be higher now than it was before the tomato harvester came into use. But the farm worker does not perceive that he shared equitably in the benefits of the progress called the mechanization of tomato harvest. His perception of his welfare would no doubt be different if he had been facing a situation of expanding employment opportunities.

In drawing attention to these problems and issues, I do not want to imply that the farm and nonfarm labor markets are not becoming integrated. I would argue that here in California the laws and regulations pertaining to the employment of hired labor as well as the nature of farm jobs themselves have tended to, if not integrate farm and nonfarm labor markets, cause them to develop along parallel lines. The optimism that characterized these papers may be appropriate if we recognize that thorny issues and difficult problems remain to be resolved.

Agriculture and Energy Use in the Year 2000

Otto C. Doering III

As an exercise in crystal ball gazing, I can do little to improve upon the unenviable record of agricultural economists over the last few years. In fact, I am thoroughly convinced that I cannot predict the character of agriculture or the food system in the year 2000. However, some of the relationships that will determine the character of the system can be identified, and some important questions can be asked about the forces that will shape the system.

The sprint to the year 2000 is a relatively short time span, already shorter than the post-World War II era. My assumptions about this era are as follows. First, I do not see any more technological change taking place between 1977 and 2000 than occurred from 1945 to 1977. This assumption purposely negates any notions that technology will solve our problems. Futurists would claim that this does not allow for enough new technology, but remember that immense changes did occur in the agricultural sector in the 1950s and 1960s. In addition, new technology that substituted other resources for energy would be reversing a long trend.

In terms of energy resources, I assume that the economy will still be dependent upon the same fossil fuels in use today. Based on the projections of the Workshop on Alternative Energy Strategies (Wilson), oil production will peak around 1990, while natural gas production has already done so. The consumption of oil may be as high or higher than it is today, but the consumption of natural gas is projected to be 15% lower in the year 2000. Fuel prices will increase but not by as much as many imagine. The price of oil is projected at over $17 a barrel in 1977 dollars. The price of other fuels will be equivalent to this on a heat-unit basis, which is critical for the natural gas projections.

Most basic energy applications on the farm and in the food system will be much the same in the year 2000 as they are today. This stems from the particular nature of energy applications in the food system and from the fact that there are often good reasons why resources are being combined and utilized as they are today. In 1974, roughly 22% of the energy used in the United States was for the food, fiber, and forest product sector. Of this, some 16.5% was for the production, processing, marketing, and consumption of food and kindred products (table 1).

It is more helpful to look at the energy use by fuel type in the different sectors and then consider the purpose of use in each case. Utilization by fuel type is given in table 2. Most of the gasoline and diesel fuel used in production is for motive power. Fuel oil is used in processing and marketing largely for heat, while transportation requires gasoline and diesel fuel.

Most gas fuels are used on an indirect basis in production for petrochemicals, primarily nitrogen fertilizer. The direct use given here is for grain drying, flue-curing tobacco, and space heating. The gas used in processing is for heat applications, while most used in marketing is for space heating or cooling. In home preparation it is used for cooking and away from home for cooking, space heating, and cooling.

Most of the electricity used in agricultural production is for motor power and the remainder is for heating and cooling applications. That used in processing is for both heating and

cooling applications. Large amounts are used in marketing to keep foods refrigerated or frozen. The electricity used in the preparation and consumption of food is for cooking, refrigeration, and space heating or cooling. Finally, the coal is used for heat in food processing.

While this gives an indication of the specific uses by fuel type within segments of the food sector today, there are reasons for the application of energy to the food system in each case that provide us with a better basis for judging future use in conjunction with the specific knowledge about current use. Energy has been applied to agriculture in increasing amounts for the following general reasons: to replace human and animal labor, to increase production, to lessen risk, and to enhance or change product form or quality.

Given a specific reason for the application of energy in a segment of the food system, what would cause substantial change in this use between now and the year 2000? One such cause would be a change in the relative price of energy, energy-substituting inputs, and final products. Strangely enough, the new cadre of energy economists has tended to ignore the relative price issue, yet it is relative prices that drive or negate resource substitution. We hear that doubled gasoline prices have not reduced consumption, without being told that the price of gasoline, relative to other goods, has increased much less. In a number of cases, relative energy prices in the food system have remained much the same as in the 1960s. The operative question is: how much different will things be in 2000, in the aggregate and by regions?

Another cause of substantial change in energy use in the food system would be shortages of energy in the form, time, and place it is needed. The threat of a fuel shortage, given the attendant risk of spoilage that pervades the food system, might well induce fuel switching, conservation, storage, or changes in technology when relative prices would not.

How do these two factors relate to the basic reasons for applying energy to the food system as we do today? Energy has been substituted for human and animal labor throughout the food system not only because of the direct comparative costs but also because of the increased scale of operation possible for a given management input. Current midwestern crop budgets allow $7 to $10 for all fuels and oils, including drying fuel, per acre of corn. At the same time land charges are $70 to $100 an acre. Given the sunk cost in machinery, the

Source: Doering et al.

variable energy cost for motive power has been relatively minor in comparison to the cost of land and other inputs, especially with the advantages in systems, materials handling, and management scale that have been gained.

Fuel scarcities are more likely to be the major motivating force for moving away from the direct use of fossil fuels for motive power. However, in the short- and intermediate-term this might well lead to investment in storage facilities rather than to the substitution of human or draft labor for fossil fuels. While the use of fossil fuels for motive power should continue to the year 2000, systems and equipment will be modified to improve energy efficiency in response to relative price increases or availability problems for fossil fuels.

Fossil fuels will likely continue to be used to lessen risk in production, processing, marketing, and home preservation. In each segment of the food system, decision makers consider only their own energy cost against the total value of the product. Within each segment the value of the total energy input is a relatively small proportion of the value of the product, as is illustrated in table 3.

New systems that use less energy or renewable energy but result in increased risk have a severe hurdle to overcome for adoption. We may see intermediate-term changes in the type of energy that is used for this purpose. Natural gas is widely used in food preservation and processing. The equalization of the price of natural gas with that of other fuels as well as problems of availability will encourage a shift to other fuels. For example, crop drying should remain economic as a practice in comparison with field dry down and/or shorter season varieties (Peart and Doering). However, the gasification of corn cobs at the farm to provide a low Btu (British thermal unit) gas for drying can be economically feasible with a doubling of liquefied petroleum gas prices (O'Hare). The basic preservation and risk-averting systems will stay much the same while switching between fossil fuels and the introduction of some renewable fuels occurs to allow tested practices to continue.

More change should occur in the energy used to increase production, but this would depend on changes in the relative price of production enhancing energy inputs as compared with substitute resources and final product prices. Thirty-one percent of the energy used in agricultural production is in the form of nitrogen fertilizer and 13% is for irrigation fuel. Changes in production energy use are likely to be greatest in these two areas of indirect and direct use.

The price and availability of natural gas will be the critical factor. A current average crude oil price of $1.50 per million Btu's would more than double to $3.13 per million Btu's for oil at $17.50 a barrel in the year 2000. An equalized wellhead price for natural gas would be slightly over $3.00 per 1,000 cubic feet. This should not shock those intrastate markets that are currently at $2.00 or more per 1,000 cubic feet. However, half the intrastate market in Louisiana is contracted at 25¢ or lower. Assuming natural gas at 50¢ per 1,000 cubic feet, only $19.00 would be spent directly on gas in the manufacture of a ton of anhydrous ammonia. This would increase to $114.00 with gas at $3.00. Given anhydrous at $180.00 a ton in the Corn Belt, there is a potential cost increase of $95.00 to a price of $275.00 if this cost were passed through directly. However, the price of fertilizer has tended to be market determined rather than cost determined. Farmers paid over $400.00 a ton for marginal increments of anhydrous a few years ago for use on $3.00 corn. While there are conflicting views (Klepper et al.), large amounts of chemical nitrogen should continue to be used unless the relative price of commodities and land declined substantially between now and the year 2000 (Doering).

Pump irrigation fueled by natural gas faces a proportionally more severe increase in costs.

Table 3. Value of the Direct Energy Input Compared with the Value of Product

Stage of Use	Value of Product	Value of Energy Input	Energy Input as Percentage of Product
	----- Billion Dollars -----		
Production	90.8	4.5	5
Processing	151.7	1.4	1
Marketing	144	4.7	3
Home preparation	145.3	10.3	7
Away from home	67	8.1	12

Where current gas costs might be 50¢ or less per 1,000 cubic feet, the six-fold increase to $3.00 appears unsustainable in the light of current crop values and declining water tables (Skold). We can certainly expect to see a change in the amount of water used and in the extent and location of irrigated agriculture.

The greatest prospect for change exists for the energy used to enhance or change product form or quality. In the past, much of the energy that has been used for this purpose has been based on consumer preference. Given the wide range of energy requirements for different foods or different versions of the same food (Whittlesey and Lee), there is potential for great flexibility in energy use while still maintaining basic nutritional requirements. As an example, beef production can vary in the intensity of its fossil fuel energy requirement from 1.9 Btu's of energy input per Btu of food value of retail beef to 13.4 Btu's of input per Btu of food output (Ward). The change in product form takes place at various points in the food system, and sometimes extra energy expended at one locale may be saved at another. Thus, any analysis must be on a total food system basis.

So far, this view of the food system in the year 2000 may not have been sufficiently alarmist to be the product of a true believer in the energy dilemma. However, changes in the food system over the next two decades can still be modest even in the face of important changes in resource availability. It is worth reviewing some of the forces that will have impact on the whole economic system as well as the food system.

First, the physical geology of the energy dilemma is real. There is only a fixed amount of fossil fuel resources in the earth's crust. The fact that we may be able to keep going for another twenty-five years at current consumption level, with a mere doubling of real oil prices and a tripling or more of real gas prices, only indicates that more severe adjustments will be necessary after the year 2000.

Second, the United States is becoming increasingly vulnerable to the interruption of its petroleum supplies. During the Arab oil embargo we were importing a bit more than a third of our oil; we are now importing more than half.

Third, we are in a world of growing populations. The energy projections utilized here have the United States consuming about the same amount of oil and less natural gas in the year 2000. This implies that per capita consumption will decline.

Finally, given the very real equity and windfall profit issues, the urge to bypass the price mechanism will make government allocation and price regulation the crucial factor in the adjustments to scarce fossil fuel resources that will take place over the next twenty-five years. The potential for contradictory and counterproductive activities is tremendous. Using agricultural production as an example, Secretary of Agriculture Bergland has urged the agricultural research and extension establishment to devote its efforts towards perfecting and disseminating more energy efficient agricultural systems. At the same time, many officials appear to want to exempt agriculture from the energy price increases that could be expected under the president's energy plan in order to hold down food prices. This is completely contradictory! If agriculture is guaranteed the energy it needs at current prices, there is little incentive for technological development or adoption. In addition, if the agricultural sector is effectively shielded from energy price increases and shortages, it will be a technological dinosaur by the time the rest of the economy finally insists that it rejoins the real world.

Agriculture and Energy Use in the Year 2000: Discussion of Technological Changes

R. Thomas VanArsdall

Energy-saving technologies that currently are undergoing adoption normally are successful for nonenergy reasons. New technologies still are using energy to increase production, replace labor and other inputs, and reduce risk. Similar motivational forces likely will continue to underlie technological and structural changes for some time.

Over the next two decades, the food system will continue to rely almost entirely upon the U.S. and world community for energy, with very little evidence of decentralized energy production. Relative energy price increases will impact more adversely upon the small farmer. Regional specialization in commodity production is likely to continue. Diesel tractors will not be replaced by human and animal power. Natural gas price increases translated into increased fertilizer costs would result in more efficient fertilizer products and wider use of soil testing. Adjustments will mean more efficient use of both direct and indirect energy inputs to farm production.

Water problems for western irrigators should lead to increased use of moisture-sensing blocks and scheduling, with significant energy savings a byproduct. A sleeper could be intermittent irrigation in the humid East, as experiment station tests in Missouri and Georgia have shown that water applied during periods of plant stress could double yields. Shifts by food processors from oil and gas to coal may be accompanied by more off-peak electrical power use and cogeneration by large users. Improved efficiencies in commercial and home refrigeration will be realized as worn equipment is replaced. Consumer food choices will be similar to those of the present, with more extensive processing and packaging and with more meals eaten away from home.

Given the time, the "hard" sciences will develop the hardware necessary to cope with more serious energy problems. Our mission includes assessing the economic viability of options and dealing with catalysts and inhibitors to desirable change. Major catalysts include government actions such as selective penalties, regulations, and subsidies of both risk and cost; amount and emphasis of funding of research, development, and demonstration (RD&D) programs; sharply changing relative prices with the potential for stimulating substantial fuel shifts and economies; farmers' desire to reduce risks and costs; a competitive drive in other agribusiness to maintain or increase market shares; and real or artificial shortages.

Most inhibitors to change may be categorized in one of the following: unfavorable economics; risk and uncertainty associated with new and unproven practices; inertia, particularly in the form of sunk investment; capital availability and outlay; institutional restrictions in both the public (Environmental Protection Agency, Federal Energy Administration) and private sectors (labor unions); perception—energy users will not act to solve an energy problem unless they believe it exists; and resistance to structural change wrought by technological development, often a more serious obstacle than economics.

A true "worst case" energy scenario, involving severe chronic shortages of oil and gas and high energy prices, appears to be inevitable some time beyond 2000. If an energy shortage is induced artificially through embargo in the near term, the only alternative is government policy ensuring agriculture the energy needed in an allocation framework. The market mechanism alone as an allocator of resources is not enough to cope with the long-run energy problem.

Time is the overriding factor. On the average it takes fifteen years' incubation for a technology to move from the drawing board to widespread adoption, and for energy-related technologies it can be much longer. With

R. Thomas VanArsdall is with the National Economic Analysis Division, Economic Research Service, U.S. Department of Agriculture.

major breakthroughs rare, do not hope for "instant" solutions. Most new developments occur in small increments, requiring large investments in RD&D, often with no returns realized for several years. The economics of alternative energy technologies, many as primitive as the first computer, remain unfavorable, expanding the time elapsed before adoption if no subsidy occurs.

Energy prices do not reflect the true present value of energy, impending energy shortages, and a heavy dependence on uncertain foreign supplies. Given that energy is woven deeply within our socioeconomic fiber, the complexity of energy technologies, the overwhelming capital outlay involved, and the tremendous lead times, energy price changes likely will not signal impending problems early enough to permit solutions before the crisis is upon us. RD&D and incentive programs are vital now so that by the time economics justifies change we will be far enough along to avoid disastrous upheavals and dislocations.

Let me leave you with one thought. Development of biomass energy plantations to supply the general economy with energy is a "doomsday" alternative at present. However, one may reflect on the implications of a breakthrough in improved photosynthetic efficiencies upon today's agricultural system.

Agriculture and Energy Use in the Year 2000: Discussion from a Natural Resource Perspective

Joseph R. Barse

Doering is probably right that even major energy changes will not restructure the food system by 2000. Yet sudden energy shocks would be disruptive. Some kinds of new energy development might insure against economic disruption, but at what cost to our land, water, air, and climate?

The Doering et al. data show that our food sector, from farm to city kitchen, depends more heavily upon electricity than the economy as a whole. Electricity accounts for one-third of total energy used in the food sector, whereas it constitutes only 12% of all energy used in the economy. Moreover, electricity used in the food sector is about one-third of the nation's entire electricity consumption. Therefore, I concentrate on the natural resource impacts of electricity development.

There are numerous projections of electricity supply and demand to the year 2000. Teknekron postulates various growth rates in electricity demand and various mixtures of coal-fired and nuclear power. Electricity demand in 2000 ranges from almost quadruple to a bit more than double the demand of 1975. Associated coal output ranges from more than triple to almost double the 600 million tons of 1975.

To achieve such levels of coal production, I estimate that between 1.8 and 2.5 million acres would be disturbed (cumulative) by surface mining by 2000, with an additional 1.5 to 2 million acres taken permanently by the more than 800 new coal and nuclear power plants and facilities. Thus, from 3 to 5 million acres would be directly affected, although much of the mined land would ultimately be reclaimed for productive use. Undoubtedly, some land could not be reclaimed at all, but some would certainly become more productive than before. This assumes enforcement of reclamation laws. However, the distribution of land disturbance could differ greatly under various scenarios, with more disturbance in the West the faster coal output expands and the higher it goes. Given energy policy and development scenarios, geographic impact patterns of land disturbance within our 1.7 billion acres of crop, forest, pasture, and range lands can be estimated by locational impact modeling such as that now underway in the Natural Resource Economics Division, Economic Research Service (Barse, Bender, and Schaub). Then alternative effects in specific areas on land, other resources, or employment can be analyzed.

Degradation of water quality and the disturbance of underground hydrology from both surface and deep mining seem to be especially intractable problems. Some aquifers may be destroyed by mining, others polluted by acid mine drainage, usually beginning through the groundwater. About 6,000 tons of sulfuric acid from mine drainage are produced daily, eventually affecting 13,000 miles of streams. Wells in strip-mined areas are frequently impaired, even after surface reclamation. The area of disturbed hydrology and degraded water quality tends to be much larger than the area disturbed by surface mining. No effective methods have yet been developed to abate these problems on a large scale.

In the West, there is probably enough water in total to accommodate both energy and agriculture. However, in some river basins additional mining and electricity production could compete seriously for surface water with both aquatic needs and irrigated farming. Again, locational impact modeling under alternative scenarios will help to analyze competition for water.

By contrast, air quality impacts may be thought of in the aggregate, since air circulates

Joseph R. Barse is with the Natural Resource Economics Division, Economic Research Service, U.S. Department of Agriculture.

widely. Long-range atmospheric transport and deposition of pollutants from coal-fired electric plants are now well-established phenomena. Also well documented is the transformation of sulfur dioxide emissions into sulfate aerosols, which can then make rainfall acidic. Stack gas emissions from the Midwest today may join with other emissions as the air moves eastward, becoming concentrated, and may fall to earth in rains anywhere in the East after a few days, depending on weather patterns. There is serious scientific concern about the cumulative effects of frequent acidic precipitation on crop yields, woodlands, and inland lakes throughout the entire Northeast. The Southeast could feel this problem as well, as the Gulf Coast converts to coal-fired electric plants.

Emissions controls and new ways of burning coal could mitigate coal-caused degradation of air quality. In essence, effective mitigation is a three-way race among growth rates for total coal burned, number of emission sources controlled, and control effectiveness. As a society, we still have major choices to make about coal combustion.

According to one Teknekron scenario, annual emissions of sulfur dioxide could be lowered from the current 30 billion pounds to about 15 or 20 billion pounds even with heavy electrification based on coal and stay at about that level to 2000 provided that emissions controls far more strict than we now have can be made to work and are fully deployed. Yet, under a contrasting scenario (same electricity output, but current controls, progressively deployed), roughly 40 billion pounds of sulfur dioxide would be emitted by 2000, well below a level without controls but still a major increase in pollution. Thus, the struggle ahead for better air quality is likely to be extremely difficult, the more difficult the larger the role that coal plays.

Consider also the warnings of some scientists that the accumulation in the atmosphere of carbon dioxide from combustion of coal and other fossil fuels could raise the earth's average temperature and affect the climate. Should coal, then, be deemphasized and nuclear power stressed? Are there other scenarios that more sharply restrain growth in electricity supply and demand? By the year 2000, to what extent could "soft technologies" produce electricity and other energy from renewable sources?

Agricultural Energy Modeling for Policy Purposes

Earl O. Heady and Dan D. Dvoskin

Major economic problems of rural areas over the last three decades stemmed importantly from the large supply and low real price for energy and energy-related inputs. These problems were not analyzed and modeled as specific energy problems because the energy component was a small part of a broader economic and social system. It was impossible to isolate and quantitatively identify the impact of energy supplies and prices per se. It also is likely that high energy prices in the future will have economic impacts that are so broad that quantification of energy effects will be difficult.

There are, however, energy problems that can be modeled to supply important policy information. Those of the individual farm are rather obvious. The level of energy prices to cause pump irrigation to be unprofitable or grain drying from crop residues to be profitable can be analyzed readily with programming, simulation, or budgeting models. Hence, we turn to broader problem sets. Major future problems will relate especially to energy prices. Prices will be high because supply is short relative to demand or because institutional measures are used to encourage energy conservation, production, or substitution.

Price-Related Problems

Energy price uncertainty is a problem encountered by all types of modeling approaches. Between 1965 and 1972, the farm index of energy and fuel prices rose at the average rate of 1.5% per year (USDA). Over the period 1972–76, it rose at an annual average rate of 15%. Conventionally, we expect econometric models to be built to predict the structure of supply and demand for a resource and thus to forecast prices. But we doubt that data exist for doing so in face of changes in the energy market, which has broken from its past structure. While econometric models may not provide price forecasts, potentials for analysis under uncertain prices exist. Price uncertainty itself presents interesting modeling opportunities. For farms, various decision models under uncertainty might apply. Programming models with parameterized energy prices might be used to evaluate prospects in pump irrigation, substitute energy sources, etc. For more macro aspects of agriculture, different pricing environments provide alternative scenarios in evaluating impacts of varied prices for energy. Contrasting results from these scenarios can be communicated to administrators faced with decisions on energy price, conservation, production, and distribution policies. Alternative price scenarios seem particularly relevant for simulation and programming models developed to trace the impacts of changing energy prices through the agricultural systems.

With major impacts through energy prices, the supply prices of agricultural commodities might be expected to increase and bring forth a second problem set. With the supply function shifting to the left, gross revenue of agriculture should increase under inelastic food demands. If revenue effects override cost effects, net income of agriculture also would increase at sufficiently high energy prices. While these results of new energy price structures theoretically would prevail, we know nothing of the price levels needed to bring them about. Neither do we know the time lag that might cause output to decline under sustained high energy prices. Higher food prices augment problems of inflation, low income families, and export earnings. Tracing quantitatively the impact of high energy prices on food supplies and prices would have considerable potential utility for policy makers. Because

Earl O. Heady is distinguished professor and director of the Center for Agricultural and Rural Development, and Dan Dvoskin is staff economist, Center for Agricultural and Rural Development, Iowa State University.

Journal Paper No. J-8903 of the Iowa Agriculture and Home Economics Experiment Station, Ames, Iowa. Project 2106.

few time-series observations under the new energy environment exist, econometrically based models probably cannot predict the effect of higher energy prices on food supplies and prices. Alternatively, simulation and programming models might serve as imperfect substitutes in evaluating certain price impacts. For example, the commodity shadow prices generated under various energy price levels in a national programming model could suggest how supply prices of commodities may be affected. The normative nature of the estimates would, of course, need to be recognized. No model can answer policy questions of whether energy in agriculture should be subsidized to prevent negative impacts on inflation and low income consumers, but results of the model could suggest indirectly how serious these impacts might be.

As a third major problem set, higher energy prices will spawn inequitable income redistributions. While restrained commodity supply functions for agriculture could increase the sector's aggregate revenue, producers of some commodities and locations will gain at the expense of others. Shifts in income generally will parallel interregional redistributions in crop production and land and water use. Regions with chemicals or groundwater irrigation as dominant inputs can suffer large declines in net income. The decline in resource values can be drastic in areas where irrigation ceases. Linear programming models provide a capability for identifying these interregional shifts. Through shadow price analysis, they also may suggest magnitudes of compensation relevant for sacrificing farm groups. However, income equity problems extend beyond agriculture. Rural communities with an economic base linked to irrigation also may have a sharp decline in income and employment. Input-output models might capture some of the resulting impacts on other rural community sectors as the structure of agriculture shifts due to high energy prices.

The fourth major problem set relating to higher petroleum prices is that of substitution. With price increases for one energy form, other forms will be substituted for it under favorable substitution rates and relative prices. Policy increasingly will be directed at substitution of other energy sources for petroleum. Attention already is being directed to solar grain drying, solar-powered irrigation, anaerobic digestion of manure, harvesting agriculture's biomass for conversion to electricity, and production of energy crops. The feasibility of some of these conversions can best be tested by farm-level models. Harvesting and transporting biomass to a generating plant implies a model with spatial and allocative features such as linear programming. On a larger scale where biomass harvesting and energy plant production compete with food production in a national context, both simulation and programming could be model candidates. A nod seems to go to programming in its ability to incorporate more detail by location and to allocate resources and regions to energy or food crops relative to energy processing centers. Such models can provide information, although not on a predictive basis as in a statistical model, on levels of petroleum and coal prices necessary to cause either source of substitution to be economic, the number and location of generating plants needed, the land and crops best allocated to energy production, and similar items. Coupled with an input-output component, they could indicate requirements and impacts on other sectors of agricultural communities.

Opportunities and Limitations in Modeling

We designated four broad problem areas related to higher energy prices, namely, price uncertainty, higher supply prices for agricultural commodities and food, changes in income and its distribution, and the substitution of energy forms. Most specific energy problems fall in these categories. These problem sets vary so much in nature that a single overall model cannot be specified to provide a quantitative base for policy decisions in all of them. Aside from firm models, some of them will need to be on the scale of a small region, e.g., the supply area of a generating plant. In other cases, they will need to be on the scale of a large region, e.g., an entire region of groundwater irrigation. Some problems require a national model with interregional linkages to indicate pricing and income distribution effects.

Four categories of models are candidates for evaluating impacts under rising energy prices or energy shortages and include econometric models for estimating behavioral responses with respect to changing energy prices, simulation models to trace impacts through a system with synthesized or statistical estimates of parameters, input-output models to describe

interrelationships between energy and other subsectors under specified changes in demands, and mathematical programming that provides a normative approach in describing potential response, alternative allocations, resource values, and related quantities. Each approach has advantages and disadvantages relative to different problems to be analyzed.

Potentials for statistical models are limited because of restricted time-series observations in an economic environment where energy prices are high. They are even more limited for analysis of problems such as biomass utilization or energy crop production in agriculture. Similarly, input-output models can describe interrelationships in use of energy and other inputs or outputs but are restricted importantly by the amount of data available or a complete lack of historic data relating to nonconventional energy forms or utilization methods. Simulation models are more flexible in the sense that parameter estimates can be synthesized for new alternatives. Yet building up data sets can be burdensome for this method and for programming models. Programming has the potential of providing great detail of energy pricing or supply impacts on land and water use or the environment, resource values, interregional redistributions in production, farm income, and related quantities. Yet the results are generated in a normative framework and thus are somewhat qualitative characterizations of behavior expected under future "real world" conditions.

Data for programming and simulation models also are scarce. However, opportunity to generate coefficients for them does exist in engineering approaches. The estimates can be improved over time through engaging physical scientists in the process and in more detailed specifications of the models and their parameters. Initiation of federal projects for specific purposes of estimating basic quantities can help. An example is the project to provide county estimates of biomass availability from crop residues (Alich, Inman, and Ernest). Data will be improved as more people work on the problem set for a longer time period. Cooperation among different groups working on energy models can be helpful.

Validation problems exist both for estimates of parameters to be used in models and for the models themselves. Difficulty in validation of parameter estimates prevail especially where the coefficients must be generated by engineering processes. Perhaps validation is best approximated in breaking a process into its components and estimating the energy quantities separately. Checking parameter estimates with scientists experienced in particular fields could be useful. After an initial set of coefficients has been estimated, a Delphi survey could be conducted among scientists experienced in the area. Problems of model validation prevail especially for simulations or analyses of situations that have not previously prevailed. As a substitute, validation is best accomplished through use of careful logic in specifying the model, a detailed a priori representation of the system being modeled, and careful gauging of empirical results against general knowledge of the real world.

Modeling efforts will be improved as we have more experience. One seldom develops the all-time model on first effort. Instead, several generations of models must be built. While early generation models may be incomplete, they can provide information that allows more efficient policies than if decisions were made "in the dark." They improve as subsequent generations are more completely specified, include greater detail, and use improved data and as more persons work on energy problems.

A National Programming Model

Our research has been by means of a national programming model (Dvoskin and Heady; Dvoskin, Heady and English). It is specified for the analysis of the relationships of energy prices and supplies with land use, water use and supply sources, fertilizer use, tillage practices, commodity supply prices, and interregional shifts in resource use, production, resource values, and farm income. This model allows analysis of problems of importance to the whole of agriculture and its regions.

The current model has land restraints for 105 producing regions, 938 restraints overall, and 12,000 real activities. It provides regional detail on land and water use, crops grown, tillage practices, energy and fertilizer use, and shadow prices for resources and commodities. Activities in the model simulate crop rotations, water transfer and distribution, commodity transportation, chemical nitrogen supplies, manure nitrogen supplies, and energy supplies. Point commodity demands and a transportation submodel are defined for the model's 28 market regions. The model allows

replacement of nitrogen fertilizers by animal wastes and nitrogen fixation. It allows interregional shifts in crop mixes, substitution among minimum and conventional tillage practices, and different levels of nitrogen and water use on crops as energy prices vary.

Major scenarios analyzed include higher prices and reduced supplies of energy. One modification minimized national energy use in crop production (Dvoskin and Heady). Another examined policies of natural gas deregulation and curtailment for irrigation (Dvoskin, Heady, and English). A new version of the model evaluates potentials in harvesting crop residues and producing energy crops. Model solutions suggest important adjustments and regional redistributions under various energy situations. High energy prices cause important interregional shifts in resource use, crop production, and income. Impacts are greatest in the energy-intensive irrigated regions. The model identifies the regions shifting to dryland agriculture. It also shows dryland regions that would gain in producing crops formerly grown in irrigated areas. It indicates the extent by which land might be substituted for energy through interregional land use shifts. Future solutions may show whether this type of adjustment is more efficient than harvesting biomass, producing energy crops, or other energy adjustments. Since it generates shadow prices for land, water, and commodities in each region, the model provides normative indication within agriculture of the distribution of income sacrifices and benefits as energy prices and supplies are varied.

Agricultural Energy Modeling: Discussion of Input-Output Analysis

Hal W. Everett II

Heady and Dvoskin have done well in defining the quantitative problems related to higher energy prices. In addition, their discussion of the modeling approaches that can be taken towards analyzing these problems was quite comprehensive. Since little fault can be found with their paper, I turn to the primary task assigned to me: to elaborate on the merits and demerits of using the input-output approach in agricultural energy modeling.

Energy price changes affect the economy directly through substitution and income effects occurring in individual sectors and indirectly through the intersectoral effects that result from the changed input requirements, production levels, and prices of each of these sectors. The importance and primary advantage of input-output modeling is that it captures the interrelationships between the sectors of an economy, enabling one to determine the extent of these direct and indirect effects.

The information obtained from this modeling approach depends on the form of the input-output (I-O) model itself. The I-O model may be solved in its traditional framework of matrix inversion, or it can be solved in a linear programming (LP) or quadratic programming (QP) framework. In its traditional framework, the I-O model can be used to demonstrate the interdependence of an economy and to determine a set of multipliers that reflect the indirect impact on individual sectors of exogenous changes in the final demand of another sector. Both the technical coefficient and the multiplier can be used to examine the potential for income redistribution changes due to energy market changes, as suggested by Heady and Dvoskin.

When placed in a linear programming framework, the I-O model is given several additional positive characteristics. First, such a formulation enables the user to place constraints on the physical availability of a product in the model economy. With this constraint placed on the availability of petroleum, for example, one could determine the degree to which each sector's output may be affected by such a restriction. The LP formation also enables the user to model several sectors with alternative production processes, resulting in the potential to examine the use of substitute energy sources. Finally, the shadow prices that are determined in this formulation represent not only the multipliers of the traditional I-O model but also the added output that could be produced by obtaining an additional unit of a constrained input.

Still other benefits can be gained from an I-O model by placing it in a quadratic programming framework. In this formulation, linear supply and demand functions of factors and outputs are placed in the objective function of the model such that the result represents a price-quantity equilibrium in the economy. Thus, the demand for an input and production in this model responds to price elasticities corresponding to the demand and supply functions of each commodity. Substitution due to price changes may also be examined if cross-elasticity data are available. Yet another benefit of this formulation is the ability to determine real and inflationary impacts, making the problem set of price inflation approachable by input-output models.

Though input-output models appear to be applicable to several of the problem sets suggested by Heady and Dvoskin, they are not without their limitations. In the traditional and LP input-output models, there are the usual restrictive assumptions of horizontal supply and vertical demand functions, the absence of economies of scale, and relative prices being held constant. The I-O models are also quite macro in scale, with only the LP formulation affording disaggregation below the individual sector level. The major limitation of using I-O models, which overshadows those mentioned above, is the data. The Department of Com-

Hal W. Everett II is an agricultural economist with Data Resources, Lexington, Massachusetts.

merce data that form the national I-O tables are five to seven years old when released. One should be greatly concerned about the possibility of some structural change occurring in the economy between the data collection and release dates. This is especially true of the most recent I-O data, which were collected in 1967 and updated in 1970. In the years between now and then, the possibility of significant structural change occurring has greatly increased as a result of the ongoing changes in the domestic and world energy markets. Additional data problems occur in the LP and QP formulations. The LP formulation requires data that represent the physical distribution of energy to each sector by source. The QP formulation requires estimates of the price elasticities of supply and demand for each individual factor and product sector included in the model. While much of this information may be available through secondary sources, it is subject to an age limitation as well as other problems of estimation.

In summary, input-output models are applicable on a very macro level to the problems of determining inflationary, income redistribution, and substitution effects that result from energy market changes. They are recommended, however, only when intersectoral relationships need to be considered and when the limitations of the data are acceptable.

Agricultural Energy Modeling: Discussion of Linear Programming Models

Vernon R. Eidman

Many economic impacts are of interest in analyzing an energy scenario. It would be useful to have a set of models to estimate the effect of an energy scenario on the prices farmers pay for purchased inputs; the impact at the farm firm level on the product mix, systems of production, and income level by size of firm; the regional distribution of production; regional employment and income levels; the supply-demand balance for agricultural products and the resulting food prices; the major environmental effects; the impact on the structure of the agricultural industry; the quantities of alternative types of energy used on farms and in other parts of the food and fiber system; and the effect on other sectors of the economy. Furthermore, the model(s) should trace these effects through time rather than comparing the current situation with the static equilibrium at some future time.

Interregional programming models can provide several types of the information listed above. By considering regional availabilities of land and water resources, regional demands for agricultural products, and transportation from producing to consuming regions, the model estimates the regional distribution of production, the equilibrium food prices, environmental effects, and the quantity of alternative types of energy used in farm production and transportation. However, they provide little information on the impact at the farm level, regional employment, regional nonfarm income, and the impact on other sectors of the economy.

Simulation models can be developed to estimate the impact on other sectors of the economy. However, the difficulty of specifying the appropriate relationships and estimating the parameters will limit such development. As a result, both interregional programming and simulation models will be used. Two types of work should be carried out to complement these analyses.

One of the major problems with aggregate models that simultaneously select production systems for alternative regions is including enough detail on the relevant alternatives and constraints. Omitting the detail leads to broad shifts in the products and production methods, when resource constraints and production conditions on individual farms would lead to a very different adjustment.

Currently available models do not incorporate an adequate range of available technologies and possibilities of substituting one source of energy for another. Two types of tillage, the possibility of residue removal, and two levels of fertilizer do not adequately describe the production alternatives for a crop in many (perhaps any) areas. For example, changing from conventional to reduced tillage in the northern part of the Corn Belt affects not only the seasonal workload but also spring soil temperatures that affect the planting date, rate of plant development, and energy requirements for drying. Thus, the relevant system of production to include in an aggregate model must be selected considering the appropriate interactions.

The possibility of substituting one source of energy for another can be illustrated with estimates of energy requirements to dry 20,000 bushels of shelled corn from 26% to 16% moisture with currently available technologies. A Minnesota study indicates that high temperature drying requires 4,020 gallons of propane and 2,000 kilowatt hours of electricity, while a combination of high temperature drying from 26% to 20% and low temperature drying from 20% to 16% requires 1,860 gallons of propane and 10,400 kilowatt hours of electricity (Cloud and Walter).

These examples illustrate the need for detailed analyses of crop enterprise production

Vernon R. Eidman is a professor of agricultural and applied economics, University of Minnesota.

University of Minnesota Agricultural Experiment Station, Scientific Journal Series Paper No. 9982. The author acknowledges the helpful comments of Harald Jensen on an earlier draft of this paper.

systems at the firm level. Livestock systems should also be analyzed so that whole farm programming and/or simulation models could be used to select the product and technology mix for alternative price ratios both in the short run and after firms have had an opportunity to adjust their capital inputs. Representative farm models could provide input on the relevant production systems and constraints for aggregate models. The equilibrium prices determined with aggregate models could be used to evaluate the firm level impacts, including income level by size of firm.

My second concern is that the models consider embodied energy when evaluating alternative technologies. Estimates of embodied energy have been developed for many agricultural inputs, including selected categories of farm machinery (Federal Energy Administration; Doering, Considine, and Harling). However, estimates are needed for other categories of capital inputs, including other types of machinery, buildings, and livestock equipment. More detailed estimates of the embodied energy in these inputs are needed to properly evaluate the total energy requirements for alternative systems of production.

While Heady and Dvoskin have listed many areas for additional research, three seem to be particularly important. The combination of firm level and aggregate models is well suited to the analysis of each. The evaluation of alternative energy price scenarios with currently known technology is an obvious area of application. Using aggregate and firm level models in combination will provide information on regional production adjustments, product price impacts, energy demand, and firm level impacts.

Estimating the energy price levels and other conditions under which new technology will be adopted is a second area. In many cases firm level analyses will be sufficient. In some cases the impact may be great enough to justify an evaluation at the aggregate level.

The third area is the evaluation of changes in institutional arrangements to encourage energy efficiency. Are current investment credit and additional first-year depreciation provisions consistent with increasing energy efficiency? What additional incentives can be developed to encourage the agricultural sector to shift to more energy efficient processes? Much of the work in this area could be done using firm level models, although the aggregate implications should also be traced where significant changes seem likely. Analyses of such changes may suggest a reduction in the producer's ability to respond to uncertain production conditions, necessitating a careful examination of the uncertainties involved and the response of farmers to them.

Energy Policy and Research in Agriculture

Earle E. Gavett

The United States faces an energy problem arising from increasing demand for energy and a dwindling domestic supply. The nation has become increasingly dependent upon the world oil market. At the time of the 1973 embargo, we were importing about one-third of our oil. Now oil imports total over one-half. Concern is mounting over the increasing dependence on the world oil market and our growing vulnerability to supply interruptions.

For these reasons the president presented to Congress a comprehensive National Energy Plan (NEP) (U.S. Congress). This plan was designed to reduce domestic demand for oil and for natural gas for nonessential uses through an effective conservation and fuel efficiency program in all sectors of energy use, through restructuring of utility rates and conversion by industrial firms and utilities from oil and natural gas to coal and other fuels. It stressed the need to develop renewable and essentially inexhaustible energy sources to insure sustained long-term economic growth. This plan contained six national energy goals for 1985: (*a*) reduction of annual growth of U.S. energy demand to less than 2% from the current 5.1% (Federal Energy Administration 1977b); (*b*) reduction of the level of imports to less than 6 million barrels per day —for the first half of 1977, total petroleum imports averaged 8.9 million barrels per day (Federal Energy Administration 1977a); (*c*) achievement of a 10% reduction in gasoline consumption from the 1977 level, which was 6.9 million barrels per day based on first half year data; a 10% reduction to 6.2 million barrels per day would be lower than the 1973 preembargo level of 6.7 million barrels per day; (*d*) insulation of 90% of all American homes and all new buildings (46% are uninsulated; we do not know the proportion that is adequately insulated); (*e*) an increase in annual coal production to at least 400 million tons over the 1976 production of 671 million tons of coal; and (*f*) use of solar energy in more than two and a half million homes, the equivalent of all U.S. farmhouses.

Agriculture's mission is to develop policies to assure a continuous and adequate supply of food, fiber, and forest products at reasonable prices for American consumers and for export. With U.S. and world population increasing at 0.6% and 1.8% per year, respectively, (Population Reference Bureau), agricultural energy needs are likely to increase. We must consider the impacts of agricultural policies on resource needs and how they conflict with NEP goals. For example, a strong agricultural export policy will increase the impact on land, water, and energy resources. Likewise, we must examine the implication to agriculture of achieving NEP goals.

Achieving NEP goals implies substantial modification of long-established trends in resource use by agriculture and rural residents. These shifts must be considered in formulation of agricultural and rural development policies and in the administration of public programs. Examination of some of the trade-offs between energy policy objectives and food policy objectives may lead to reconsideration of both sets of objectives. I look at some of the major issues concerning energy development and conservation and interfuel substitution.

Energy Development

A major aspect of the NEP is to develop energy from plentiful supplies like coal or from renewable resources like solar and agricultural products. This may lead to land, water, labor, and community problems. Developing western coal resources has direct local impact on strip-mined land but little total impact. As we develop southern Corn Belt coal, impacts on farm land and production will be substantially greater. How coal is utilized also affects land. If hauled by rail to eastern markets, the land impact is slight. If slurry pipelines are used, the impact is also slight. If mine-mouth generating plants are established, high voltage transmission lines will cross many acres of

Earle E. Gavett is with the National Economic Analysis Division, Economic Research Service, U.S. Department of Agriculture.

farmland, taking permanently out of production a fifth of an acre per mile.

Of greater importance is the impact on water use to agriculture. Irrigation is needed to revegetate mined land. Transporting coal east by slurry pipeline will consume a ton of western water per ton of coal moved. Moving 400 million more tons of coal a year by 1985 will require 400 million tons of water annually (AAAS). This is the equivalent of 295,000 acre-feet of water, sufficient water for 16% of Colorado's irrigated cropland. Mine-mouth generation of electricity takes even more water. One estimate is 4 tons of water per ton of western coal used per efficient 1,000 megawatt steam generation plant (AAAS).

Western coal development can raise havoc with the rural labor market. Heavy equipment machinery operators require similar skills to farm equipment operators. Energy developers can pay sharply higher wage rates. How will farmers obtain needed labor?

The sudden influx of energy developers places a great burden on rural communities to provide housing, schools, hospitals, roads, and other facilities. These services are required prior to obtaining revenue from any coal sales. Local and state budgets will be severely impacted unless front end financing is provided. Also, the structure of local governments may be inadequate to deal with complex issues involving powerful energy companies.

Agricultural use of a low-grade, nonconcentrated, interruptable heat source like solar has many attendant problems. Large collectors are needed; storage is vital for nights and bad weather; and conventional back-up systems may be required. The technology is in its infancy and is expensive. The high initial cost is the main cost. There are many agricultural opportunities for solar power—water pumping, crop drying, livestock brooding, rural home heating, etc. Can it be afforded?

Plantations of field or forest crops for energy to replace fossil fuels are proposed. These will require vast acreages of land as well as fertilizer, pesticides, labor, machinery, and water inputs. Crop and livestock residues used for energy generation may affect soil fertility, structure, and tilth and speed up wind and water erosion.

Conservation and Interfuel Substitution

The NEP places a major emphasis on conservation of energy, efficient use of fuel, and conversion to fuel sources that are renewable or plentiful. The strategy is to increase fuel prices through taxes and offer rebates for conversion to desired fuels. To conserve electric power and reduce need for new facilities, a complete restructuring of utility rates is proposed. To adopt conservation technologies that may not yet be economic, a system of rebates and tax credits is proposed.

Impacts of this segment of NEP upon agriculture and rural America are many and diverse. What are the possibilities for interfuel substitution by agricultural firms? What are the consequences? Impacts often are energy source specific, so this paper addresses the issues by energy type.

Natural Gas

The food and fiber system uses natural gas for about one-third of its energy needs. In the processing industry it is over half. Fertilizer manufacturing used natural gas for over 90% of its energy. The NEP exempts agricultural uses, including irrigation pumping and feedstock for making anhydrous ammonia, from the oil and gas consumption tax but not for process heat use in fertilizer plants, food processing, and marketing.

Southwestern farmers have been shifting away from using natural gas to electricity for pumping irrigation water as gas increased in price and delivery was not assured. By 1985 Sloggett visualizes natural gas being denied for irrigation pumping requiring conversion of some 100,000 pumps. Southwest Electric Power Pool reserve generating capacity is expected to be only 13% by 1985 (Energy Resources Council). This is inadequate for accepting many large agricultural users having peak seasonal needs coincident with household and nonfarm business peaks. Further compounding the problem are interfuel conversion requirements for these generating plants.

Nonfarm agricultural industry must also convert to coal, electricity, or other sources. The financial impacts on highly seasonal operations such as fruit and vegetable processing plants may be so severe as to force termination of operations. Some may pay the taxes rather than incur the conversion cost.

Cost increases to fertilizer, chemical, and farm machinery manufacturers will likely be passed on in product costs to farmers. In shortage situations, such as the 1976–77 winter, vital food industries will also have gas

curtailed. Alternative fuels such as liquefied petroleum gas will be needed to prevent impacts from farmer to consumer.

Gasoline and Diesel Fuel

Gasoline and diesel fuel prices will be 10% to 20% higher as a result of the crude oil equalization tax and adversely affect rural residents who are personal vehicle dependent. Rural development may also be affected as rural areas are heavily reliant upon the trucking industry. Diesel price increases will be translated into higher costs for goods delivered to and from rural areas. This may disadvantage distant production areas.

Energy needs of farm producers and processors are unpredictable, being heavily affected by climatic conditions. This compounds fuel distribution problems. During the embargo, fuel distributors abandoned service to farmers and residents in remote areas. As fuel costs increase, the remoteness, unpredictability, and small capacity of rural accounts makes fuel delivery service more costly, and we may see increased abandonment.

Electricity and Coal

Conversion from oil and natural gas use to electricity will require land for transmission lines, water for steam generation, capital to convert equipment from oil and gas, and development of a reliable electric power grid distribution system. Higher rural electric rates are likely. Restructuring rates to eliminate promotional and block rates and introducing time-of-day metering, seasonal, and interruptable rates present many and varied impacts to agriculture. Must farmers irrigate only at night? Have they sufficient pump capacity? What is economical?

Conversion of agricultural processing and manufacturing plants to coal is capital intensive. New boiler costs including environmental protection equipment have been rising in excess of 8% per year. Many processing plants are located in production centers distant from coal supplies, requiring new fuel distribution systems.

Research Needed to Meet Both Energy and Agricultural Goals

Policy makers are interested in maximizing positive and minimizing negative impacts of alternative policy actions. One can not assess the impacts of a complex energy program on agriculture and rural America unless one understands the current patterns of energy use and the socioeconomic and environmental conditions that govern citizen response. It is vital to have a detailed, accurate data base on energy use in the food and fiber system and for rural living and rural development. Data must be valid at the state level. State conservation plans are currently being developed based on grossly inadequate energy use data.

Resource needs for energy development must be assessed against rural community and agricultural needs. Many of the energy problems transcend state lines, and policies developed will have local, state, regional, and national implications. They must be addressed by researchers at these levels. Let me be specific on a number of items.

Irrigation uses one-eighth of farm production energy. Economic assessment of water use is vital to agriculture. How much water is needed? At what price? How can it be applied more efficiently? Can we afford solar pumps? Can irrigated agriculture and energy development both survive in the West? Or should more food production occur in the East under supplemental irrigation?

Food processing takes twice the energy of production. How can we reduce energy costs and dependence on scarce fuels and satisfy consumer wants? Can the refrigeration and packaging demands be reduced? At what level of energy costs will new technologies be attractive, restructuring of product mix occur? Which producer group will be most affected?

Will increased energy costs force relocation of production and processing closer to consumers? What would be the impacts of such shifts? Can farmers market products direct to consumers? How can rural areas develop as energy costs increase? Can people afford to live there, work there?

Should agriculture, or just food production, receive top fuel priority? Should it get subsidies to reduce impacts of higher prices? How does this affect conservation and conversion to other fuels?

What are the prospects for energy production from agricultural materials? Can segments of agriculture be made energy self-sufficient? Would they be economically viable? Can we find the necessary large blocks of land?

How can the livestock industry be made more energy efficient? What are the economics of reducing high energy inputs to cattle and hogs?

If electricity is the energy source of the future, how can agriculture and rural America best use electricity? In striving for NEP goals of energy development, how can the adverse impacts on land, water, and transportation systems be minimized? Should there be national water and transportation policies?

A strong balanced research effort must be mounted now to address important agricultural and rural energy issues if we are to have any input in shaping the future for agriculture and rural America. Many of the issues are complex and require a multidisciplinary approach for solution. The following is one approach. The U.S. Department of Agriculture and the Energy Research and Development Administration (ERDA), recognizing the complexity of the issues, their varied responsibilities, and the research talents needed, developed a USDA/ERDA Memorandum of Understanding for the development and implementation of a National Program of Agricultural Energy Research, Development, and Demonstration (National Planning Committee). The Memorandum of Understanding calls for this jointly funded national program to be conducted in large part by the publicly supported agricultural research and technology transfer system—the land-grant institutions and the USDA.

How these agencies, having overlapping responsibilities but different goals, actually meld complex research, development, and demonstration issues into a comprehensive national program is of concern. They have different perspectives that I perceive as follows. ERDA's approach has been one of developing high technology in large scale operations with a limited number of adopters. It works closely with industry. Once a working model is developed, it relies upon industry to disseminate. Timing is more important than cost in its research program. The USDA's approach has been to strive for economic and technical efficiency and yet maintain small family farms. It serves a wide range and size of firms. It works closely with state agricultural experiment stations with little industry involvement. Technology transfer is mainly by extension service staff. Research activities tend to be modest with cost a paramount factor.

I challenge agricultural economists to participate as fully as possible in the development of this national program. You, in turn, should challenge these agencies when you perceive that they are taking the wrong approach. By such interaction we will likely develop a better program to aid policy makers and improve the future for agriculture and rural America.

Energy Policy and Research: Discussion from the USDA Perspective

Ralph J. McCracken

Gavett presented well the differences perceived between the Energy Research and Development Administration (ERDA) and the U.S. Department of Agriculture (USDA) approaches to energy research. As he indicated, ERDA concentrates on rapid development and early commercial adoption of research-derived technology. The USDA and its state agricultural experiment station (SAES) cooperators spend more time researching a topic and solving most technical problems; only then is a project released for information, technology transfer, and commercial adoption.

This difference in approach and the designation of ERDA as the federal lead agency for energy research has resulted in funding problems for the USDA. Specifically, the USDA does not receive enough funding from ERDA "pass-through" energy research funds to do its traditional thorough kind of research. Under the ERDA "rapid-development" approach funding is limited, is necessarily short term, and lacks continuity. This implies no criticism of ERDA. At the same time, however, the USDA has not been able to fund an energy research project from its own research budget because, under the ground rules set by the Office of Management and Budget, most funding for energy research must pass through the lead agency. General USDA research funds are heavily committed to other high priority research needs (level funding). In fiscal year (FY) 1977, $2.7 million in ERDA energy research funds will pass through ERDA to the USDA and cooperative SAES's under the lead agency concept, but these will be the only "new" funds the USDA will receive in FY 1977 for energy research projects. The USDA has special difficulty in funding those projects that are partially energy related. So, it has ended up with a relatively small amount of "continuity" funding for energy-related projects, all acquired by redirection of funds from other priority research areas in a period of level research funding—constant dollar basis.

Why do the USDA and SAES's specifically need continuing base funding for energy research? The answer is that they must have resources in place to respond to new research needs and to be able to apply incremental funds to their followup, that they must be able to plan and conduct research more effectively, and that they must carry on associated and related research leading to the development of new or modified food production or processing systems that are built around the new energy sources.

But this funding problem is on its way to resolution. I am confident that the ERDA-USDA Memorandum of Understanding, which Gavett discussed, will do much to solve this. Secretary of Agriculture Bergland has a strong interest in energy research. There have been recent positive discussions with ERDA officials about the need and responsibility of the USDA (and its cooperators) to research the systems adjustments needed to use solar technology in agricultural production and processing.

Meanwhile, there are lessons to be learned. We in the agricultural research community need to seek ways to become more rapidly responsive to high priority national research needs that are partly outside the agricultural sector. Especially, we must learn how to move new technology, as components of systems, into actual application more rapidly. Becoming more rapidly responsive to priority needs for new technology suggests certain policy changes: applying new techniques in project (matrix) management; improving interagency, federal-state coordination mechanisms; and finding new and more effective ways of redirecting existing programs and absorbing incremental funding like that received from ERDA. It means accepting and working with

Ralph J. McCracken is the associate administrator with the Agricultural Research Service, U.S. Department of Agriculture.

other agencies and organizations (including working with the lead agency mode), in other words, avoiding a "closed community" attitude in agricultural research.

I agree with Gavett's statements on energy research needs. I would add (*a*) greater emphasis on irrigation conservation practices, including efficient irrigation scheduling, use of less energy-intensive methods and economic analysis of center pivot versus other systems; (*b*) greater emphasis on tillage conservation and other energy-conserving crop management practices, especially extension of minimum tillage to the northern Corn Belt; (*c*) more efficient use of energy-intensive nitrogen fertilizer and use of less energy-intensive fertilizer and pest control practices; (*d*) reexamination of previous work and new research on organic matter and residues; (*e*) continued work in bioconversion on more precise predictions of role of crop residues in different soil and environmental situations (energy, erosion control, fertilization); (*f*) development (including economic analysis) and modification of production and processing systems for insertion of new energy sources; (*g*) analysis of the "biological imperatives" in economic and policy analysis, e.g., the importance of timely planting and harvesting and the associated high demand for and value of energy at these times, and (*h*) more emphasis and research on energy conservation and interfuel substitution on the postharvest side of the food system.

Looking ahead, reclamation research will loom large in the pass-through funding arrangement with the Environmental Protection Agency and ERDA and in in-house support with the recent strip-mining reclamation legislation.

In closing, I join in Gavett's challenge to agricultural economists to participate more fully in agricultural energy research. We in the physical and biological science sectors of agricultural research have not solicited your involvement and cooperation as aggressively as we should. There are many interesting research possibilities for you. Your help is badly needed in finding solutions to one of the nation's highest priority problems.

Energy Policy and Research: Discussion from the ERDA Perspective

Stanley J. Clark

To achieve the objectives of the president's National Energy Plan, all segments of the economy must do their part, and agriculture is no exception. The National Energy Plan must serve as the framework for establishing agricultural energy policy and research goals.

I agree with Gavett that reducing the annual energy demand growth rate of the agricultural industry will be difficult. However, analyses by the Energy Research and Development Administration (ERDA) show that increasing the efficiency of energy use can have the greatest immediate impact until about the year 2000. Improved energy use efficiency in animal and crop production; feed and grain handling and transportation; food processing; food packaging, handling, and transportation; and food preparation should therefore be the number one priority. This certainly does not mean forgetting about alternate energy sources. Due to the long development times for difficult new technologies, their major energy contributions will occur after the turn of the century. Research and development effort must therefore be pursued vigorously today.

The overall efficiency of energy use in the agricultural industries depends on how well systems analysis techniques are applied to each energy-intensive enterprise in the agricultural industry. Such an analysis does the following: defines the total system bounds; analyzes material and energy flows across the system boundaries and across each process within the system; determines energy use efficiency across each process or unit operation within the system; performs environmental, reliability, and safety analysis for proposed system changes; and performs economic analyses for proposed system changes.

If a systems analysis approach is not used, we will get at best piecemeal solutions and many reoccurring problems. Examples of problems are: a gain in energy use efficiency across one process in the system may result in a decrease in energy use efficiency for the total system; environmental, reliability, and safety considerations will not be properly addressed; and system changes suggested for saving energy or substituting alternate energy sources may not be economically viable.

In my opinion, water use should also be a part of the systems analysis. In many cases it is already included in such studies. Decreased energy use in irrigation systems can be most easily attained by pumping less water on the crop or decreasing the crop consumptive use.

The U.S. Department of Agriculture's (USDA) food and fiber production responsibilities have been outlined by Gavett. ERDA has indeed recognized the need for specific research, development, and demonstration (RD&D) programs that relate to the production of food and fiber. ERDA has specific programs dealing with the application of energy conservation technology to agricultural production and food processing. It also has specific programs dealing with biomass energy production and the use of solar energy, wind, and waste heat in agricultural production and food processing. Program needs are reviewed each year within each ERDA division. The major portion of most RD&D programs is performed by contractors. The contracts result from unsolicited proposals, program opportunity notices, program research and development announcements, and requests for proposals.

The Agricultural Production and Food Processing Branch of the Industrial Energy Conservation Division is attempting to establish RD&D programs for the most energy-intensive activities (irrigation, crop drying, fertilizer production, processing and packing, etc.). Emphasis is also placed on establishing RD&D programs for enterprises in agricultural production where energy costs are a significant percentage of total production costs.

Stanley J. Clark is the program manager with the Industrial Energy Conservation Division, Energy Research and Development Administration, Washington, D.C.

The Industrial Energy Conservation Division has conducted workshops in production agriculture, food processing, and waste heat utilization to assist in determining research needs and corresponding priorities. The Division has published reports from these workshops, which are available from the Technical Information Center, Oak Ridge, Tennessee, and is currently reviewing the workshop proceedings thoroughly and preparing publications that will indicate how ERDA has responded to the workshop suggestions. The Division firmly believes that feedback such as this is invaluable to ERDA's program.

In 1910 2 calories of cultural energy were used to put 1 calorie of food on the plate. In 1970 9 calories of cultural energy were used to place 1 calorie of energy on the plate. This trend must be reversed if the challenge of a decreasing energy supply and an increasing demand for food is to be met. Governmental agencies and private industry are going to have to cooperate much closer than they have in the past to meet this challenge. Duplication of effort must be minimized, current technology must be fully utilized, development of new technology must be accelerated, and technology transfer time lag must be minimized.

The forthcoming Department of Energy and the USDA are the two most important governmental agencies involved in the food-energy problem. Gavett referred to an ERDA-USDA Memorandum of Understanding that has been enacted to promote full cooperation between the agencies. Hopefully, the Memorandum will assist in determining program priorities, prevent duplication of effort, make possible full utilization of the strengths of both agencies, and provide the mechanism for cooperative research coordination and planning.

In conclusion I reiterate what Gavett has said: get involved in energy-related projects. We need the expertise of agricultural economists in trying to meet the challenge of the energy-food problems facing us in the near future.

Energy Policy and Research: Discussion from a Land Grant Institution Perspective

Henry R. Fortmann

Members of the agricultural research community of land grant institutions have deep concerns about agricultural energy. It is both logical and appropriate that they are concerned about energy policy and research as they affect agriculture. They do not make policy, but they do have both the capacity and the mandate to conduct research. My comments center on four points.

First, there is no energy need, local or national, more important than maintaining an adequate, reliable supply of energy for agriculture. This does not deny that certain other energy uses are also important. We can improve efficiency and shift to other forms. But unless we adequately produce, process, and distribute food and fiber, all our other goals, aspirations, and dreams are without point; in short, we will all "have had the course." I dismiss the suggestions that we revert to a labor-intensive agriculture.

Second, the research and development to eventually make this nation appropriately self-sufficient in agricultural energy will be done by a combination of performers: (*a*) the existing publicly supported research system, (*b*) other public and private research institutions, agencies, etc., (*c*) foundations, (*d*) industry, and (*e*) individual entrepreneurs. Data on research capacity are available only for the existing publicly supported agricultural research system (*a*). It is the only system that can tell you "who is doing what, where, how, and why?" Not only can it tell you but it regularly does in useful, logical, and systematic ways. It is organized to plan, cooperate, and coordinate research and to identify priorities and future needs.

Third, research is done by individual scientists. The superstructure of administrators, the bureaucratic hierarchy, the gaggle of "project-proposal writers," peer reviewers, and Office of General Council and Office of Management and Budget officials can contribute. They can expedite obtaining the resources necessary to carry on research. On the other hand, they, along with Congress, the Occupational Safety and Health Act, Environmental Protection Agency, Office of Civil Rights, and others, can aid and abet the proliferation of rules and regulations that can impede the conduct of research.

I concur with a concept expressed by Schultz, "But in fact a large organization that is tightly controlled is the death of creative research, regardless of whether it be the National Science Foundation, the U.S.D.A. [U.S. Department of Agriculture], or any other federal agency, a large private foundation, or a research oriented university. No research director in Washington can know the array of research options the state of scientific knowledge and its frontier can afford" (pp. 7–8). However, I am totally supportive of avowed intentions to reason together, plan together, and coordinate efforts so as to optimize use of available resources.

I also want to underscore a portion of the Memorandum of Understanding between the USDA and the Energy Research and Development Administration (ERDA) concerning agricultural energy research, development, and demonstration: "Section IV. Implementation. D. Insofar as possible, agricultural inputs into National Program development, implementation and review will reflect, but not be restricted to, the total system of publicly-supported agricultural research, development and technology transfer. . . . Further, the Steering Committee will encourage Land Grant university representation on the Steering Committee, the Working Committee and the Subject Matter Groups" (p. 3).

R. Dennis Rouse, chairman of the Experiment Station Committee on Organization and Policy (ESCOP), has named such a representative. This is the unequivocal signal by ESCOP, that the fifty-six state agricultural exper-

---

Henry R. Fortmann is the regional coordinator with the Northeast Association of State Agricultural Experiment Stations, Pennsylvania State University.

iment stations are ready to serve and expect to participate in the process of directing our destiny through helping formulate and implement a course of agricultural energy research and development.

Fourth, the report to the National Planning Committee of the Agricultural Research Policy Advisory Committee, "A National Program of Agricultural Energy Research and Development," contains three parts: the current situation, the plan, and recommendations for the future. The plan and the recommendations for the future are but a framework for moving ahead. They contain no cure-all solutions for the agricultural energy needs. They do delineate examples of problems and constitute the first iteration of a workable system to classifying agricultural energy research and development. Land grant scientists must devise the vehicles to solve the problems. The administrative structure and the Congress must provide the resources. The state agricultural experiment stations can do no less than commit themselves to full participation in the process. The future of this country, and indeed of mankind, demands that they be enabled to do so and that they do.

Symposia

Forecasting Methodology Update. Bruce Scherr, chairman (Data Resources, Inc., Mass.), William E. Kibler (SRS, USDA), Robert MacDonald (National Aeronautics and Space Administration, Houston), J. B. Penn (Council of Economic Advisers, Washington), James Liebfried (Canadian Wheat Board, Winnipeg), Dale B. Berkheimer (Sperry New Holland, Penn.), and Donald Schwartz (Cargill Investor Services, Chicago)

The volatility of worldwide agricultural commodity markets over the last five years has catalyzed a strong interest in forecasting agricultural supplies, demands, and prices. There has been a great deal of work by public and private organizations in refining and better communicating production, demand, and price forecasts. New technological developments, such as satellite tracking of crop progress, have been underway that should serve to supplement existing Statistical Reporting Service's production estimates. Furthermore, the requirements imposed by the new federal budget process in evaluating farm legislation costs and impacts have broadened the use of agricultural commodity forecasting activities across many agencies outside the U.S. Department of Agriculture. The use of baseline forecasts with alternative scenarios that define a series of risks around the base forecast have provided policy makers with a very detailed information set concerning the extent of government involvement in farm programs. Agribusiness forecasting work has also progressed dramatically in recent years by utilizing forecasting tools for planning purposes that cover a broad range of corporate needs, in particular, forecasting agricultural activity as it influences product-line sales, market share, purchasing plans, and other detailed firm informational needs.

Alternatives to the Debt-Free, Owner-Operated, Family-Sized Farm. Don Paarlberg, chairman (Purdue University), Edward W. Sparling (Colorado State University), Harold F. Breimyer (University of Missouri), and Kenneth E. Frick (Bakersfield, Calif.)

The debt-free, owner-operated, full-time, family-sized farm has been an ideal in much of America since earliest times. Increased size of farm, larger capital requirements, and changing structural concepts have made it increasingly difficult to hold to this old ideal. New structural forms are developing: leasing, perpetual debt, part-time farms, incorporation, vertically integrated farms, very large "family" farms, and farming enterprises of nonfarm corporations. Each of these organizational forms was discussed in this symposium.

Generally, this was the prevailing concept of the family farm: a farm with entrepreneurship in the hands of the operator, hiring not more than two man-equivalents. Pertinent issues raised were: What are the respective efficiencies of the various institutional forms? (The "family farm" came off rather well in this discussion.) Is land simply an input item, a means of earning income, like other production goods? Frick thought yes. Breimyer and Paarlberg thought no. Disputed issues were: Should large farms be passed intact from one generation to another? Do we want a hereditary land-owning class? Should the owner receive the unearned increment in land values resulting from inflation and from the scarcity factor associated with population growth? There was agreement on one point: if the body politic could decide what kind of farm structure was desired, it would be possible, through public policy, to tilt toward that type.

Impact on Rural America of the Federal Water Pollution Control Act Amendments, PL 92-500. Lee A. Christensen, chairman (ERS, USDA), C. Edwin Young (ERS, USDA), G. A. Carlson and James A. Seagraves (North Carolina State University), Wesley D. Seitz (University of Illinois), Clyde F. Kiker (University of Florida), Lawrence W. Libby (Michigan State University), and Thomas Waddell (Environmental Protection Agency)

PL 92-500, particularly the water quality requirements, has major implications for U.S. agriculture. It impacts rural communities, land use, the agricultural processing sector, and crops and livestock production. The high costs of upgrading the level of wastewater treatment in rural communities is influenced by significant economies of size in wastewater treatment. The increased emphasis given land application of wastewater provides rural communities an economical method for advanced wastewater treatment but also raises competitive land use issues.

The location and operation of agricultural processing plants is influenced by the cost-sharing provisions of the law. The present subsidy system provides a strong incentive to buy capital-intensive systems and expensive designs, often leading to suboptimal decisions. Industries often treat their own wastes rather than hook on to municipal systems due to high costs and cost recovery programs. Investment in waste treatment systems in arid states, which previously had little need for expensive waste treatment plants, has increased substantially.

A third set of impacts relates to the control of erosion and sedimentation required (section 208). An analysis found that reasonable soil loss restrictions do not have adverse economic impacts but stringent soil or nitrogen restrictions do. Farm income generally increases at consumer expense. A watershed model of the long-run impacts of soil erosion indicated a complete loss of topsoil in the

Corn Belt within 100 years if present practices are continued. Farmers cannot be expected to implement soil loss controls without subsidies.

A spirit of "ethically inspired voluntarism" would help economists have more impact on environmental policy formulation. Legislation comes out of a technological and legal mind set. The Environmental Protection Agency often goes to technical solutions because of the transactions and implementation costs of nontechnological solutions. Economists typically take a broader view of problems and sometimes appear to be uncompromising but can make real contributions in developing economic compromises.

Private versus Public Organization of U.S. Grain Exports, Paul L. Farris, chairman (Purdue University), Clarence Palmby (Continental Grain Co., N.Y.), Alex F. McCalla (University of California, Davis), Andrew Schmitz (University of California, Berkeley), Lauren K. Soth (Des Moines Register and Tribune, Iowa), Robert Handschin (Farmers Union Grain Terminal Association), Lowell D. Hill (University of Illinois), and Gary G. Storey (University of Saskatchewan)

The policy issue addressed is the institutional organization of the U.S. grain export system. The primary advantage of the prevailing U.S. system, in which large private grain exporting companies play a central role, appears to be the unique ability of private companies to match grain supplies and demands effectively and efficiently in accordance with market conditions. Nevertheless, the world market for grain is not a classical free market. Large grain traders may be in positions to influence grain trading and government export policies in such ways as to favor themselves relative to U.S. farmers and consumers. U.S. bargaining ability might also be disadvantaged by the centralized control exercised by most foreign governments over their own grain buying and selling in international markets, while no centralized agency handles grain marketing in the United States.

Comparisons between the Canadian and U.S. grain marketing systems showed U.S. production to be ten times larger than Canadian and more diversified in terms of crops grown and the dispersion of production areas and markets. Grain production and exports have grown absolutely in both countries, but the relative rate of growth has been higher in the United States. The lead in developing grain handling technology has come from the United States. The Canadian system emphasizes equity considerations of pooled prices, equal market access, and known marketing margins and places less emphasis on the role of the individual and firm than does the U.S. system, which is premised on free market efficiency goals.

The marketing systems are unique functions of the socioeconomic history of each country, with cooperatives and the Canadian Wheat Board (which has a monopoly on export sales) playing major roles in Canada, while private firms are more important in the United States. Grain marketing systems are not necessarily transferable among countries. Policies for improving the U.S. system will likely be most successful if they recognize and build upon basic characteristics of the U.S. economy and socioeconomic values of U.S. citizens.

Small Farm Oriented Agricultural Policy. W. Arden Colette, chairman (University of Florida), Chris O. Andrew (University of Florida), Eldon D. Smith (University of Kentucky), and Charles D. Whyte (Virginia State College)

A broad definition of the small farm based on annual gross sales may be useful for policy direction, but a more specific delineation of audience characteristics is necessary to identify audiences and develop specific programs. Societal and individual goals must be considered. Profit maximization and economic efficiency may not be the principal criteria for developing and evaluating program success. Stability, security, and family well-being rank very high in the small farmer's goal structure. We must determine not only the values, beliefs, goals, and aspirations of individuals in the target audience but also production and marketing behavior and must design programs to encourage the greatest possible change within the small farmer's environment.

Even if self-sufficiency is not attained, both the individuals and society benefit from programs for small farmers. Increases in farm income result in increased tax revenues, offsetting program costs. Government expenditures incurred as welfare payments would not have similar effects. Raising the education and training level increases the alternatives for off-farm employment. Since the majority of black farmers operate small units, the impact of declining economic position of the small farm is more evident in the black population. Special programs may be necessary to address problems of the black small farmer.

Changing either the economic conditions or the characteristics of the small farm audience requires considerable time, effort, and financial assistance. It is important that Congress and state legislatures not be misled into thinking that increased funding over a short time period will solve the problems. Such high expectations could result in disappointment and failure of the overall program.

Economics of Integrated Pest Management. Arnold L. Aspelin, chairman (Environmental Protection Agency), K. L. Reichelderfer (University of Maryland), Darwin C. Hall and Andrew P. Gutierrez (University of California, Berkeley), James E. Casey (Oklahoma State University), Joseph C. Headley (University of Missouri, Columbia), Hovav Talpaz (Texas A&M University), David W. Parvin, Jr. (Mississippi State University), James Stewart (Pest Management Associates, Calif.), and Jake MacKenzie (Environmental Protection Agency)

An economic evaluation of alternative pest man-

agement strategies utilizing simulation modeling that focused on the Mexican bean beetle and simulated an intraseasonal dynamic system was presented by Reichelderfer. The profitability of integrated pest management was examined by Hall using case studies for cotton and citrus in the San Joaquin Valley. Conventional pest management strategies were compared for profitability, pesticide use, crop yields, total expenditure, and risk. Casey presented a paper evaluating selected pest management strategies in Texas cotton production. Opportunities for integrated pest management exist for developing production management strategies to deal with cotton pest problems. Headley presented an evaluation of alternative pest control technologies for grain crops and soybeans. The relative importance of chemical pesticides, mechanical methods, biological methods, and cultural methods throughout 1978–92 in these U.S. crops were discussed. Talpaz presented a composite model of the boll weevil-cotton crop system, incorporating three independent developmental time scales: weevil development, fruit drying, and cotton plant development. Sensitivity analysis showed that timing of pesticide applications is moderately sensitive to a change in pesticide price and highly sensitive to a change in the price of cotton.

A discussion lead by Aspelin as moderator, including Parvin, Gutierrez, Stewart, and MacKenzie drew the following conclusions. Risk under integrated pest management is quite variable, while pesticide usage averages out this risk. Variability of yield as well as long-term average yield needs consideration. Institutional support is required in research and training; a multidisciplinary thrust is needed (economic biological analysis must be incorporated early in the planning and implementation stages as well as after the program has been implemented). Council on Environmental Quality recommendations are in line with President Carter's message on environmental quality, which recommended that the federal government encourage the development of pest management techniques that emphasize use of biological controls, relying on chemical uses only as needed.

USDA Crop Reports: How? How Good? William E. Kibler, chairman, Charles E. Caudill, Robert A. McGregor, and Bruce M. Graham (SRS, USDA)

The technology used in producing crop reports has advanced dramatically during the last two decades. The Statistical Reporting Service (SRS) uses both area frames and list frames in selecting samples for agricultural surveys. The area frames have been improved in a series of steps from the master sample of the 1940s to the 1977 model, which is stratified by land use and updated to incorporate changes revealed by remote sensing. A list frame of all farm operators is now being developed with the aid of sophisticated computer software. Illustrations were given of the dramatic gains in efficiency resulting from the use of the superior but costly new area and list sampling frames.

The step-by-step data collection procedures used in SRS surveys were illustrated by a series of slides related to the corn production reports. Comparative advantages of both traditional nonprobability mail survey and modern probability survey techniques were noted. The flow of data was traced from the farmer or field observer to review by Crop Reporting Board and assembly into a national crop report. Review techniques for both speculative and nonspeculative data were illustrated by examples of actual summarized data and Board action. The power of aggregated regional data to improve upon the simple summarization of data from individual states was demonstrated.

Several measures of the quality of U.S. Department of Agriculture crop estimates were discussed. Handouts were used in making comparisons of early season forecasts with final estimates over an extended period of years. The number of monthly forecasts higher than the final estimate is about the same as the number lower than the final estimate. The deviations of the monthly forecasts tend to diminish as the crops move toward maturity.

Agricultural Business Curricula and Industry Needs. William Herr (Southern Illinois University), Carl W. O'Conner (Oregon State University), and Walter M. Meyers (ContiCommodities Services, Chicago), chairpersons, R. Stuckey (Santa Clara University), Leroy Davis (Southern University), W. David Downey and E. C. Oesterle (Purdue University), Phillip Sisson (Quaker Oats, Chicago), Carl R. Saathoff (Kroger Co., Cincinnati), and T. M. Hammonds (Food Retailing Institute, Washington)

Agricultural business programs for undergraduate and graduate majors (including the M.B.A.) were discussed. Emphasis focused upon courses and material that would prepare the student for solving problems and making decisions. Among courses meeting this objective were economic theory, statistics, business and government policy, law, finance, and marketing. The importance of entry level skills such as sales, accounting, or personnel supervision was discussed. Establishing rapport and involving the business community in the agribusiness program through internships, exchanges, field trips, presentations, and advisory councils were suggested as requirements for developing a strong program. Coping with a changing environment resulted in suggestions for greater emphasis on foreign trade, monetary policy, regulatory laws, and meteorology. Agricultural business curricula should help the student develop thinking patterns and attitudes about management and decision making. Flexibility is needed along with more information so that the system for educating and employing students in agribusiness can function more effectively.

Distribution Effects of Natural Resource Policy. Harry W. Ayer, chairman (ERS, USDA), Robert B. McKusick, Gerald Horner, and Daniel Dudek (ERS, USDA), Don Reading (Idaho State University), John E. Keith (Utah State University), Craig Infanger (University of Kentucky), Kenneth Scott (California Polytechnic University), Marilyn Altobello (University of Arizona), and Richard Adams (University of Wyoming)

Natural resource agencies of the federal government currently spend $17 billion annually—5% of the entire federal budget. The programs and policies of these agencies almost certainly affect the distribution of real income among income classes of people. In the papers, current and future natural resource policies likely to affect income distribution are discussed, and old and new empirical methodologies for distribution research are evaluated. Five papers then report on recent empirical studies of the distribution effects of particular natural resource policies. Forest and range policies in an area of Arizona are evaluated by input-output methods to estimate their impact on employment of different income groups. The impact of a reservoir project in Washington on income distribution of both farmers and recreationists is estimated. Another study utilizes linear programming to investigate the impact of water quality regulations, both management and pricing policies, on the distribution of income among income classes of irrigation farmers in California. An econometric model of the New England sea scallop fishery is used to estimate distribution impacts of the Fishery Conservation and Management Act of 1976. A final paper estimates the distribution impacts of alternative energy policy, both price increases and quantity restrictions, which may affect California agriculture. Quadratic programming, a method accounting for both changing energy and product prices, is employed. The papers demonstrate the importance of the distribution problem, research methodologies, how particular policies affect distribution, and policy conclusions and suggest pressing research needs. Also, all papers give key references.

Management of Nonmetropolitan Governments. Fred J. Hitzhusen, chairman (Ohio State University), Alvin D. Sokolow (University of California, Davis), John W. Malone (Pennsylvania State University), Paul H. Gessaman (University of Nebraska), and Gerald Doeksen (ERS, USDA)

There are over 50,000 nonmetropolitan county, township, and special district governments in the United States serving a growing population. Policy making in these governments is mainly a function of elected governing boards characterized by a commitment to unanimity at virtually any cost, adherence to the status quo, emphasis on personal and informal government, and limited policy specialization. The behavior of administrators and other employees of these nonmetropolitan governments is generally very informal.

Citizen-consumers have expressed varying degrees of satisfaction with the services provided by nonmetropolitan governments. A recently completed survey in four Great Plains states found the level of discontent over existing services not generally high, rural households supplying privately many services that are publicly provided in an urban setting, and, with the exception of health care, services delivered through interactions between individuals most subject to criticism.

Pennsylvania State University has a long-standing local government extension program including correspondence courses, special circulars, and handbooks. The program emphasis is on the legislative problem-solving process, the interrelations of public agencies and private institutions, the roles of the democratic process and dispersion of political control, and the significance of size and density of population in the financing and control of public services. Since late 1974, the Economic Research Service has been involved in a project to provide economic analysis for nonmetropolitan government decision making in the Great Plains. Research has included budget studies of alternative delivery systems for specific services, optimum location of certain services, and impact studies and projections. Considerable need exists for additional research and extension activity in the management of nonmetropolitan governments.

Returns to Land in the Corn Belt, Government Crop Price Guarantees Based on Cost of Production, and Land Values. John T. Scott, Jr., chairman (University of Illinois, Champaign-Urbana), Franklin J. Reiss and Steven T. Sonka (University of Illinois, Champaign-Urbana), Michael O. Boehlje (Iowa State University), and Marshall Martin and Bob F. Jones (Purdue University)

Costs of production on different sized grain farms for 1976, including both fixed and variable nonland costs, were presented in relation to the price of corn and target prices. The residual between costs of production and target was analyzed to estimate the price of land the residual would support. Lease arrangements were discussed, indicating the variation in returns that would be available as payment to land on different qualities of land and when land is on crop share or cash lease. An important policy question is whether and to what extent a return to land should be included in the costs of production used for calculating target prices. A simulation model shows that, if a return for land is included in the cost of production, spiraling land prices will occur. In fact, from the first to tenth year, land prices would approximately double, due mainly to the inclusion of a 3.5% return to land in the target price that causes a ratchet effect. The advantage for large farms would be greater than for small farms, resulting in increased financial ability of large farms to bid higher for additional land than small farms could. This would likely increase the concentration of land ownership and economic power in agricul-

ture into fewer hands. This would be in contrast to past policies in this country of attempting to stimulate a wide distribution of land ownership. It may become necessary in the future to make a greater distinction between land ownership, the various benefits of owning land, and the distribution of land ownership versus the rights to operate farm land and distribute the production from that land.

New Arrangements for Involving the Profession in International Agricultural Development. Charles E. Hanrahan, chairman (ERS, USDA), D. Woods Thomas and John W. Mellor (Agency for International Development), and A. T. Birowo (Agricultural Economic Survey, Indonesia). Abstract prepared by Thomas H. Lederer (ERS, USDA)

New arrangements for professional involvement center on opportunities in Title XII legislation and in policies evolving at the Agency for International Development (AID). These conclusions emerged: a need for human capital development in the less developed countries (LDC's) and the United States, a need for institution building in the LDC's, a recognition of the long-termness of development and the related need for long-range efforts, a recognition of mutuality of interests between LDC's and the United States, and a need to improve country-specific technical expertise within U.S. and LDC organizations. Thomas spoke optimistically about Title XII, indicating that it reflected present thinking about and future needs for long-term professional and university involvement in the development process. Mellor addressed the need for institutional capacities in the LDC's and the United States as a basis for desired technological change. He traced the evolution of AID policies from the emphasis on growth to present concerns for equity. Recognizing that helping the "poorest of the poor" appears to conflict with such investments as agricultural research, he stated the need for a synthesis of growth and equity policies. Birowo provided an LDC perspective stressing the relevance of development in the research and publications of the profession. He pointed out the deficit of experts trained in country-specific development issues and suggested a quantum increase in training of development-oriented professionals in the United States and the developing countries.

Economic Regulation in the Milk Industry: Estimated Impacts and Future Policy Prospects. Robert E. Jacobson, chairman (Ohio State University), William D. Dobson (University of Wisconsin), Emerson M. Babb (Purdue University), Paul Christ (Land-O-Lakes, Inc.), and James W. Gruebele (University of Illinois)

The federal milk marketing order program has become subject to considerable public criticism in recent years. The criticism largely has been directed at the classified pricing plan and the height of class I differentials in order regulations. An evaluation of federal order performance by Dobson indicates that price enhancement was not reflected in class I pricing during 1965–75, that class I differentials may have been higher than necessary to provide adequate supplies of Grade A milk, that federal orders have reduced market instability, and that a substantial reduction in class I differentials would generate a limited net gain to society.

A basis for evaluating proposed policy changes in the federal order program by utilizing a highly specified simulation model was presented by Babb. The simulator projects the effects of changes in pricing and pooling provisions for up to twenty quarters relative to several response variables including blend prices, milk production, returns over direct milk production costs, retail milk prices, class I sales, and milk movements. One significant feature observed from the projection of several alternative pricing-pooling arrangements was the high degree of stability in all response variables for the aggregate of federal orders, given a level of class prices, when radical changes in class and blend price structures were imposed.

Extensive discussion was directed to two areas. The assumed rate of Grade B conversion was debated in terms of its impact on the order program and the impact of order provisions on conversion. The consequences of class I price obligations for reconstituted milk on milk markets were also considered.

The Evaluation of Nonmarket Goods and Services. Reuben N. Weisz, chairman (ERS, USDA), Alan J. Randall (University of Kentucky), Shaul Ben-David (University of New Mexico), and Louise Arthur (ERS, USDA)

Just as economists are beginning to perfect an ability to conduct traditional types of benefit-cost analyses, they are being required to be equally competent in the evaluation of nonmarketable goods and services. This symposium provided an intellectual marketplace for the exchange of ideas on this issue. The following four papers were used as a point of departure.

"Evaluating Nonmarket Goods and Services: Some Conceptual Issues" answered the following questions: What can the various measurement instruments measure? How can one infer from this the value of nonmarket goods? How does this relate to the concept of consumer's surplus? "A Model of Voting Behavior for Revealing Public Sector Demands" illustrated how location theory can illuminate public preferences when the political process is used in lieu of the market place. "Epidemiology and Microeconomics" indicated that the etiology of environmental impacts on human health depends on economic as well as biological factors because the exposures and life styles of individuals are frequently matters of choice. "Development of Environmental Quality Indices: A Utility Approach" illustrated how preference values can be used to weight social indicators describing the physical impacts of a policy. A survey of public attitudes on the

coyote-predator control problem indicates that, while the individual utility functions differ greatly, differences in relative utilities of various control policies are surprisingly constant across individuals.

The New Agricultural Policy Process. Don F. Hadwiger, chairman (Iowa State University), Charles Wiggins and William P. Browne (Central Michigan University), James Guth (Furman University), and Alan S. Walter (ERS, USDA)

Three papers presented at this panel were from the Agricultural Policy Symposium, held in Washington, D.C., on 25 and 26 July 1977. Guth described the evolution of classic "subgovernment," which set federal dairy policy since the 1930s, consisting largely of the National Milk Producers Federation, the House and Senate Dairy Subcommittees, and the U.S. Department of Agriculture marketing authorities, and its fragmentation during 1950–70 with consequent greater involvement of the secretary of agriculture. He then describes the development of consumer group involvement in the 1930s and again during the past five years, focusing on the interaction of groups selective to the 1973 and 1975 farm bills and in the administrative process. He concludes that the role of consumer groups has been episodic, and they do not currently speak with one voice.

Browne and Wiggins (both political scientists) examine the current internal and external constraints upon general farm organizations and specify several conditions under which they are likely to have some political impact: when policy is handled in the traditional centers, when economic considerations predominate, when members are strongly committed to ruling objectives, and when only a few agricultural issues are salient. Walter provides an introduction to the new congressional budget process and assesses its effect upon commodity policy. It is difficult to budget because costs are often delayed for several years, and budget decisions are also greatly affected by administrative decisions, weather, and other variables. Although the direct impact of the budget process is small, Walter finds that the cost estimates provided by that process and its intended legislative constraints serve as important guidelines for congressional voting on agricultural policy.

Evaluation of Programs under Title V of the Rural Development Act of 1972. Lee M. Day, chairman (Cornell University), J. Patrick Madden (Pennsylvania State University), David L. Chewning (National Rural Center, Washington), Delworth B. Gardner (University of California, Davis), Edward O. Moe (Cooperative State Research Service, USDA), and Raymond D. Vlasin (Michigan State University)

The Rural Development Act of 1972 authorized the land grant universities of all 50 states and Puerto Rico to embark upon an experiment in rural development research and extension. The program was to receive $45 million during the first three years. The pilot program was started in fiscal year 1974. Three years later the program had received only 20% of the funds authorized. At the end of the pilot stage, the U.S. Department of Agriculture entered into a cooperative agreement with the National Rural Center (NRC), a private nonprofit organization in Washington, D.C., to conduct an external evaluation of the program. NRC contracted with Pennsylvania State University to provide the services of a principal investigator (Madden) to design and conduct the evaluation.

The Act provided only very general guidelines regarding the kinds of activities the land grant universities should perform, but it was very explicit as to several of the procedures and processes to be followed. Nonland grant institutions of higher education were also to be included; over 100 were involved, including 13 of the 16 1890 land grant colleges. Title V efforts were to be coordinated with those of various federal, state, and local agencies; widespread cooperation with agencies at all levels was reported by the states. A state rural development advisory council was to be appointed, including members from several specific kinds of agencies and institutions; all states had such a council, and a few states found it to be useful in designing their programs. The states reported a vast array of projects and outcomes. While this evaluation has not validated the impact of the state projects, enough information is presented by the states to indicate that the program has been generally successful in meeting the expectations of Congress, both in terms of the process used and the end products of rural development.

Consumer Economic Issues: Impact of Legislation and Policy. Sylvia Lane, chairperson (University of California, Davis), E. Scott Maynes, W. Keith Bryant, and Jennifer Gerner (Cornell University), Loren Geistfeld (Purdue University), Barbara S. Zoloth and Lawrence Shepard (University of California, Davis), Jean F. Bowers (Ohio State University), William C. Dunkleberg (Purdue University), and Jean Kinsey (University of Minnesota)

Two sample products, term life insurance and pocket cameras, were used in a demonstration of an economic approach to the documentation of the degree of informational imperfection of local consumer markets. The suggested corrective policy for markets found to be informationally imperfect is a sales tax supported local pro-consumer information system that would provide consumers information on price, quality and availability of products, and ratings of retailers.

Product warranties serve as market signals providing consumer information. Those parts of appliance warranties about which consumers are well informed exhibit considerable uniformity. Therefore, requiring manufacturers to provide more warranty information tends to reduce the var-

iety of warranty terms available. Consumers' ranges of choices are reduced.

Abolishing fair trade appears to have led to limited price cutting by retailers, in particular, "discount" outlets, a reduction in nonprice competition, and an increase in the frequency of business failures in fair trade states during 1976. Pricing policies of chain stores and department stores have not become more aggressive on fair trade items since repeal.

State-imposed rate ceilings on consumer credit, lessening creditor remedies, and truth in lending legislation have caused credit rationing to higher risk low-income consumers. Existing policies with respect to consumer credit imply decision makers believe there is a difference between preferences and welfare, classing consumer credit with other "sumptuary" goods.

Risk and Uncertainty for Small Farmers in the Developing Countries. Marcelino Avila, chairman (University of Missouri, Columbia), James Roumasset (East-West Center, Hawaii), Richard K. Perrin (North Carolina State University), Christina H. Gladwin (International Fertilizer Development Center, Alabama), Colin Gellatly (North Carolina State University), Luis Navarro (Tropical Agricultural Research and Training Center), and Jean-Paul Chavas and Gustavo Arcia (University of Missouri, Columbia)

In recent years, much emphasis has been given to agricultural development programs that encourage the adoption of new technologies by the small farmer. One of the most important aspects of the adoption of new agricultural methods is the risk that they represent from the view of the peasant farmers. Therefore, one of the main objectives of development plans is to seek technologies that offer a minimum risk so that acceptance can be higher. This seminar focuses on the different methodologies that are being used to measure risk and uncertainty and the difficulties that arise in the adoption of new techniques by small farmers.

Roumasset's paper deals with the identification of risk and uncertainty measurement methodologies. Perrin's presentation considers the policy implications of small farm risks in developing economies. Gladwin presents a limited model of risk taking that is hierarchical in form. Gellatly's paper concentrates on the technology adoption questions with a few comments on supply response. Navarro describes some preliminary observations concerning the manner in which small farmers have dealt with situations of risk and uncertainty. Finally, the paper prepared by Chavas and Arcia, based on the expected utility theorem, derives the optimal operating conditions for a multiproduct firm where output and output prices are uncertain and correlated. The participants are in agreement that there is great need for continued efforts in this field, particularly in reference to empirical investigation.

Structure and Performance of U.S. Food Manufacturing Industries. Bruce W. Marion, chairman (Ohio State University/University of Wisconsin), John M. Connor (ERS, USDA), Loys L. Mather (University of Kentucky/University of Wisconsin), Brian W. Peckham and John D. Culbertson (University of Wisconsin), Leon Garoyan (University of California, Davis), Marvin L. Hayenga (General Foods), and A. C. Hoffman (retired)

Connor found that asset concentration among the 100 largest food manufacturers was about the same in 1950 and 1975. "Stability coefficients" indicate the relative position of largest firms has remained very stable with no apparent trend from 1950 to 1975. Mather found the concentration of advertising among large firms in food manufacturing is high and increasing. Advertising as a percentage of sales is particularly high in industries producing highly processed foods. Preliminary results suggest that large firms cross-subsidize the advertising of brands acquired through product extension mergers.

Contrasting analyses of technological changes were reviewed by Peckham and Culbertson. Peckham conducted an innovative and detailed analysis of significant inventions in the U.S. corn-refining industry. The markets for invention were distinguished and related to product markets, the size of firms, and industry structure. In contrast, Culbertson conducted an econometric analysis of patents and research and development employment in ninety large food manufacturing companies during 1950–56. Market concentration had a consistent positive relationship to innovative activity. Relative market share and firm size were generally positively related but nonproportional in some models. Technological opportunity dummy variables were highly significant in most models.

Public Regulation of Economic Activity: Its Institutions and Impacts on the Agricultural Sector. Conrad F. Fritsch, chairman (ERS, USDA), Stan G. Daberkow and Edward V. Jesse (ERS, USDA), James D. Shaffer (Michigan State University), and Richard G. Walsh and Forrest E. Walters (Colorado State University)

Research measuring the impact and effectiveness of public regulation of economic activity does not lend itself easily to traditional economic inquiry. While costs may be measured, given a set of normative assumptions, benefits received are often diffused and poorly identified. Costs associated with regulation of given products have been computed. For example, direct and indirect costs of about 8¢ are incurred per pound of ground beef. Yet cost measurement does not necessarily identify the significant changes in choices available to different economic actors. Regulations restrict the choices of some persons, but they expand those of others. In the same way market processes also expand choices for some persons while restricting them for others.

A loss of faith in the ability of the market system to provide acceptable degree of product quality and safety is seen by some as the reason for an increase in the activity of regulatory agencies since 1970. Regulation of economic activity, however, is not the only means of attaining socially desirable outcomes. A desired goal of reduced workplace accidents in the agricultural sector, for example, is currently being pursued through market incentives via variable rate insurance schemes, direct regulations, resort to judicial processes, and voluntary action programs. To adequately deal with the economics of influence, information, and bureaucracy associated with the regulatory process, economists need to do considerable conceptual and empirical work and the scope of the discipline will need to be expanded.

Applications of Stochastic Control to Agricultural Policy and Decision Making. Richard E. Howitt, chairman (University of California, Davis), Gordon C. Rausser (Harvard University), and Karl A. Fox (Iowa State University)

An agricultural policy analyst is faced with problems such as structural change, parameter variation, and the formation of expectations that complicate the assessment of alternative policies. Policy analysis is thus an ongoing process utilizing econometrics, optimization systems, simulation, and data base improvement. One framework that consistently integrates the foregoing is stochastic control theory.

A classification of stochastic control approaches based on the information structure used was advanced. The simplest structure is the certainty-equivalent, open loop specification initially proposed by Theil and Simon, while the most complex structure is specified in the adaptive closed loop solution of Tse, Bar-Shalom, and others using active learning. A simple analytical example illustrates the value of active learning, and approximate solution techniques for the adaptive stochastic control problem are compared for solution complexity and policy decision advantage.

The operational advantages of the simpler open loop feedback control specification are considered for the linear-quadratic-Gaussian and nonlinear gradient solution procedures. The practicality of these methods is shown with a nine-state simultaneous equation model, and some caveats concerning objective function specification and inequality constraints are offered. The consistency of optimal policies derived by stochastic control with the theory of economic policy based on Tinbergen's seminal work is shown. An inconclusive verdict was offered on the current policy advantages of the more complex adaptive stochastic specification, while the practical utility of the open loop feedback solutions under the more restrictive information structure was affirmed.

Report of Workshop on Agr Data: Improvement of Conc Gaylord Worden, chairman (O and Budget), James P. Houck nesota), and Clark Edwards (I

A workshop was held in May 1 cepts and operation of severa tems. The workshop consisted data suppliers and data users and recommendations made each topic. Study teams then ports by including changes rec shop participants.

The purpose of reporting on annual meeting of AAEA was audience to the topics studied sions and recommendations of topics on which reports were p teams were a history of agricu agricultural prices and price r the capacity of the agricultural data for indicators of well-bein in farming, definition and meas ployment, and employment da ment research and policy.

Emerging Issues of Minorities Labor Markets. Harland I. Pad gon State University), Emiel W. Houston), Christine R. Heator and Rufugio I. Rochin (Univ Davis)

Rural labor markets are histor presence of migrant field w Mexico, and, more recently, force participation rate of fe Heaton and Martin indicates th to predict labor force participa ban, single females do not exp pation rates of rural women an cal models are necessary to ass behavior, especially the differe and single women. Migrant w by Owens to determine the ext workers experience pesticide-r chemical analysis of cholineste exposure to pesticides indicate East Coast migrant stream are variety and high dosage of p which are lethal. A study by Ro can workers in agriculture iden plain the process of illegal imm nomic factors manifested in the sis are important for explainin Mexico, immigration laws hav and changed to control the inflo ers in tune to the domestic req labor. Another explanation g influx from Mexico is that larg workers willing to work in a exhausted because of a combin

as the war on poverty and the liberalization of welfare and food stamp programs, giving rise to a situation in which employers rely on the seasonal workers from Mexico to fill a domestic "labor vacuum." A common theme noted by Padfield is the extent to which women and minorities have been subjected to adverse conditions in rural labor markets without the full benefits of research and public policy interventions.

Relationship of Extension Economists to the AAEA. Charles Rust, chairman (Montana State University), Robert L. Christensen (University of Massachusetts), Norbert A. Dorow (North Dakota State University), William W. Wood (University of California, Riverside), A. Gene Nelson (Oregon State University), Sharon Q. Hoobler (Extension Service, Washington, D.C.), Richard W. Schermerhorn (University of Idaho), and Fred A. Mangum, Jr. (North Carolina State University)

A survey of extension economists sought suggestions and criticisms. Those surveyed felt that annual meetings offer little to extension economists. They repeatedly suggested that there should be more orientation toward applied work and micro level analyses. A need for sessions at the annual meeting for extension economists was also a popular request. A large majority felt that the *Journal* has limited value to them; a small minority indicated that the *Journal* publishes a mix of articles that is acceptable. Opinion was divided on the performance of the AAEA in promotion of professional development and excellence. However, 80% felt the level of services to extension professionals was less than that offered to research and teaching.

Not only do extension economists need the AAEA but the AAEA, representing the profession in general, needs extension economists. The responsibility for drawing extension economists into a closer working relationship with the AAEA needs to be shared jointly. Extension economists need the AAEA for professional enhancement, influence on research directions, and efficiency. One area of continuing need is a forum for informed discussion and debate on broad and current issues related to agriculture. In general, the AAEA does not meet the most commonly expressed needs of the extension economists.

The AAEA is a professional association of agricultural economists. Its members are engaged in 27 work activity areas including extension. There are 15 fields of specialization divided into 102 subject matter areas. The Board's position is that it should provide a form for all elements of the Association to do whatever a group of members feels is important. There are two constraints: funds to conduct programs and some assurance that the activity proposed will reflect favorably on the total Association. The records show that where extension economists have taken the initiative we have achieved our objectives. The degree of participation by extension economists will largely determine what share of the support it obtains from the AAEA.

Contributed Papers

Food and Agricultural Policy (Martin K. Christiansen, University of Minnesota, Chairman)

"Participation in the Food Stamp Program and Implications Concerning the Need for Outreach Programs." W. Keith Scearce and Robert B. Jensen (Virginia Polytechnic Institute and State University)
This paper focuses on the likely effectiveness of outreach efforts for the USDA Food Stamp Program. A discriminant function is developed that ranks characteristics affecting participation or nonparticipation by eligible families. These results raise questions as to whether any outreach effort will improve the participation rates among eligible families.

"Comparison of Federal Subsidies to Cotton Producers." George A. Shumaker and Ronald M. North (University of Georgia)
Some American cotton producers realize two forms of federal subsidies: the USDA Cotton Program payments and subsidies brought about by the methods utilized for the repayment to the Bureau of Reclamation for irrigation water resource projects. The two subsidy forms were analyzed and compared with respect to inter- and intraregional incidence. Crop years 1971 and 1974 were selected for intensive investigation.

"Peanut Market Structure: Analysis of Its Influence upon Peanut Policy Trade-Offs." James N. Trapp (Oklahoma State University)
Analysis of the potential to discriminate between the edible and nonedible peanut markets indicates that opportunities to reduce treasury costs exist through peanut programs that conduct market discrimination. Consideration of market discrimination capabilities in administration of the current peanut program could reduce treasury costs while raising farm income.

"An Analysis of the Effects of Government Policies on the United States Oilseeds, Oils, and Oil Products Industry Using a Monthly Econometric Model." R. McFall Lamm, Jr. (ERS, USDA, Virginia Polytechnic Institute and State University)
The effects of government policies on the domestic vegetable oilseeds, oils, and oil products industry are evaluated in this paper by analytically deriving impact multipliers and by performing deterministic simulation experiments. Significant decreases in some industry prices are indicated if government controls are removed from the industry.

"Adjusting Price Supports: Comparison of Alternative Methods." Jerry A. Sharples (ERS, USDA, Purdue University)
Five price support adjustment methods are discussed: parity, prices paid index modified by yield changes, cost of production, historical price trends, and discretionary authority. After a brief description, they are compared relative to a theoretical ideal, on an objectivity scale, on ease of measurement, and over a historical period.

"Implications of Uncertainty in Yields and Exports." Theodore F. Moriak (Office of Management and Finance, USDA)
A prototype procedure is presented for developing subjective, probabilistic evaluations for future uncertainties about commodity yield and export expectations. The subjective uncertainty information is incorporated into a large multicommodity systems model in order to estimate future commodity price uncertainties that are useful for public policy and program decisions in agriculture.

Transportation (C. Phillip Baumel, Iowa State University, Chairman)

"Modeling the Economics of Rail Terminal Operations in Grain Transportation: A Brazilian Case Study." Charles L. Wright, Richard L. Meyer, and Francis E. Walker (Ohio State University)
Transportation costs are decomposed into line-haul costs and terminal costs. Physical handling efficiency at terminals decreases overall transportation costs and augments service capacity. A capacitated network model is used to apply this general concept to rail transportation bottlenecks on a Brazilian export corridor.

"The Economic Impact of Alternative Policies on the Illinois Grain Marketing System." James M. Harris (University of Illinois), E. Dean Baldwin (Ohio State University), Lowell D. Hill (University of Illinois), and C. Thomas Worley (Ohio State University)
Policy makers confront a complex world and have many alternatives. An economic and analytical framework was employed to evaluate the effects of alternative policy options on the Illinois grain marketing structure and flow patterns. Firms, transport modes, firm services, and flows among intrastate regions and firms are endogenously determined.

"A Regional Perspective of Agriculturally Exempt Motor Carriers in the United States: Problems and Characteristics." Robert K. Stump (Cominco American, Inc.) and Kenneth L. Casavant (Washington State University)
This paper analyzes the problems facing truckers as well as their operating characteristics in relation to regional location. Regionality has a strong impact

on trucker problems and operating characteristics. Commodity specialization, which is closely associated to region, might be a determinant of many problems and operating characteristics experienced by these truckers. Results indicated that policies based on aggregation of the national trucking industry should be instituted with some reservations.

"Research and Data Needed to Improve Transportation Mobility of Rural People in the West." Jerome J. Hammond (FDD, ERS, USDA) and Erhardt O. Rupprecht (NEAD, ERS, USDA)
Western rural residents depend upon the automobile for their transportation needs. Coupled with the lack of transportation alternatives, this can have serious consequences for the transportation disadvantaged. Research and data are needed to determine demand, cost, and feasibility of alternate means of providing mobility to rural people.

"A Modified Lockset Approach to Routing for Backhaul Effectiveness." Lynn W. Robbins (University of Kentucky)
Transportation micromodels' inadequate adaptability to specific routing problems—backhaul effectiveness, irregular dealer demand, and partial loads—are evaluated. A specific lockset modification is presented with examples from its application. The related discovery of a potential theoretical breakthrough in transportation research is outlined along with suggestions for capturing that potential.

"Alternatives to Railroad Line Abandonment." Marc A. Johnson (Oklahoma State University)
Railroad preservation projects are composed of four functional parts: ownership, right-of-way rehabilitation, right-of-way maintenance, and rail service operation. These functions may be performed by one agency or distributed among agencies in a variety of ways. Rail preservation alternatives are of three types: short-line railroading, rehabilitation assistance, and subsidization. Each is feasible under different traffic conditions.

Economic Issues in Developing Countries (J. C. Andersen, Utah State University, Chairman)

"Packages of Practices: A Step at a Time with Cluster?" Charles K. Mann (Middle East Technical University, Turkey)
Despite increased use of modern technology, few Turkish wheat farmers have adopted the complete recommended package of practices. Reconsidering the package as clusters of practices adopted in an agronomically and economically logical sequence provides a better explanation of farmer behavior and a guide for useful agronomic experimentation and economic analysis.

"A Socio-Economic Analysis of Technology Adoption in an African Livestock Industry." Gregory M. Sullivan, Donald E. Farris, M. J. Yetley, and W. J. Njukia (Texas A&M University)
The study examines the Tanzanian livestock industry to explain low levels of improved management and commercial sales. Level of technology adoption and two perceived economic values by producers are estimated in 792 herds. Communal grazing and depressed government regulated prices of cattle are determined as factors causing low levels of technology adoption.

"Coca Substitution in Bolivian Agriculture: Political Economy or Expediency?" Morris D. Whitaker (Utah State University) and Clovis Villegas (Bolivian Ministry of Rural Affairs and Agriculture)
Bolivia, with concessional U.S. aid, is implementing programs for substituting other crops for E. coca, from which cocaine is derived. Survey data are analyzed to determine the profitability of alternative crops. Results indicate coca is the most profitable and imply low returns to public investment in crop substitution programs.

"Rational and Beneficial Use: Chile's Criterion for Irrigation Water Reallocation." Loren L. Parks (Oklahoma State University) and David E. Hansen (University of California, Davis)
The 1967 Water Code requires equalization of water rights per hectare in a "homogeneous farming area." Analysis of a typical region using representative farm linear programming models indicates that equalization would result in regressive income redistribution, whereas the optimum economic reallocation would result in progressive income redistribution. Aggregate income gains in either case would not exceed 5%.

"An Analysis of Capital Requirements of the UNCTAD Integrated Program for Commodities." John W. Murray (NEAD, ERS, USDA) and L. Jay Atkinson (FDD, ERS, USDA)
Developing countries have proposed a common fund for an "Integrated Programme for Commodities" to finance several international agreements. Ordinary least squares is used to establish unit value and export earnings trends. Estimates of capital requirements are calculated for compensatory financing and export earnings and unit value stabilization using buffer stocks.

"The Economics of Sharecropping in Northeast Brazil." Lee W. Bettis, Richard L. Meyer, and Francis E. Walker (Ohio State University)
Incentives exist for landowners to employ sharecroppers in Northeast Brazil. Four components of a sharecropping contract were parameterized for measuring the sensitivity of landowner income, number of sharecroppers employed, and enterprise mixes, revealing unexpected relationships. These results are important to policy makers interested in regulating sharecropper contracts.

Energy (F. Larry Leistritz, North Dakota State University, Chairman)

"Energy Price Changes: The Impact upon Farm Production Methods and Energy Consumption." Michael Hammig, David Holland, and William Pietsch (Washington State University)
This inquiry examines the sensitivity of agricultural production techniques to increases in selected input prices. A linear programming model was developed incorporating production practices under a wide range of capital, labor, and energy intensities. Findings indicated relatively inelastic input demand functions and not much potential for energy saving in response to energy price increases.

"Waste Heat Utilization in Agriculture: Economic Feasibility and Institutional Alternatives." Ronald L. Meekhof (CED, ERS, USDA)
Recycling of energy resources is an issue of national concern. The economic feasibility of utilizing thermal effluent from power plants in a system of agricultural and aquacultural use is evaluated. Such a system is an economically feasible alternative to conventional methods of dissipating waste heat under selected management and acquisition options.

"Adjustments in a Farm Business in Response to an Energy Crisis." Robert O. Burton (Purdue University) and Ralph G. Kline (Virginia Polytechnic Institute and State University)
Adjustments to an energy crisis are investigated from a farm manager's point of view. Using linear programming models, the effects on returns, cropping systems, and energy use for Grade A dairy farms with till and no-till corn systems and solid and liquid manure systems are determined.

"Breakeven Natural Gas Prices for Irrigation: Texas High Plains." Daniel C. Hardin (Texas Water Resources Institute) and Ronald D. Lacewell (Texas A&M University)
The effect of natural gas price on irrigated agriculture is of major concern in many regions. This study estimates for the High Plains of Texas producers' ability to pay for natural gas by land tenure arrangements and irrigation well characteristics and discusses the implications for crop adjustments and land values.

"Impact of Energy Cost of Irrigated Production, High Plains of Texas." John L. Shipley (Texas A&M University) and D. W. Goss (ARS, USDA, Texas A&M University)
Irrigation well cost data and value of water in crop production were used to estimate price of electricity to equate net returns from irrigated and dryland production. Rising energy prices without corresponding rises in product prices could result in energy, rather than water, being the limiting factor in High Plains irrigation.

Water and Marine Economics (Melvin D. Skold, ERS, USDA, Colorado State University, Chairman)

"A Method for Estimating Benefits to Fishermen of a Channel Dredging Project." W. Davis Folsom (Clemson University)
The benefits to fishermen of a channel dredging project are in the form of increased fishing time and decreased hull damage. A more reliable estimate of the benefits can be derived when allowances are made for the boat draft and number of days per fishing trip.

"A Model for Determining Optimal Multi-National Exploitation of a Marine Fishery." Marilyn A. Altobello (University of Arizona) and Jon M. Conrad (University of Massachusetts)
The Fishery Conservation and Management Act of 1976 provides the institutional framework needed for managing fishery resources in U.S. coastal waters. This paper outlines a discrete-time bioeconomic model that may be employed by a central decision maker in managing a single-species fishery characterized by multinational exploitation.

"Projected Impact of Lower Granite Dam and Suggested Waterway User Fees on Pacific Northwest Wheat Movement." Robert Thayer and Kenneth Casavant (Washington State University)
This paper reports on a regional study of the impact of improvements in water navigation and waterway user charges on wheat movements. A transportation model minimizing transportation costs served as the analytical model. As expected, shippers and geographical areas in close proximity to the river gained from improved navigation. Not so expected, the strong competitive reaction of the railroads allowed distant areas and producers to gain from improved waterways. User fee charges had impacts similar to the lower water-induced rail rates.

"Economic Interdependencies in Fisheries: Empirical Evidence and Management Implication." Ivar Strand and Aldo Matteucci (University of Maryland)
The federal government is charged with determining a "socially optimal" flow of fisheries resources. Economic interdependencies between fisheries are empirically examined for crabs and oysters to substantiate the argument that joint management plans are necessary to assure "socially optimal" flow.

"Impact of the Elimination of Water Rights on Land Rent and the Distribution of U.S. Agricultural Production in 2000." W. Arden Colette (University of Florida) and Earl O. Heady (Iowa State University)
Alternative solutions of a national linear programming model indicate that *(a)* at normal demand levels total returns decrease but at high levels of export total land rent increases, *(b)* more dryland is used and returns per acre are higher, *(c)* returns per irrigated acre decrease, and *(d)* the North Central region becomes more dominant both in proportion of cropland and total returns.

Human Resource Development (A. Frank Bordeaux, Jr., University of Kentucky, Chairman)

"Human Capital and Labor Turnover in Manufacturing Industries: The Case of an Economically Depressed Region in Southeast Ohio." Emmanuel T. Acquah (Virginia State College) and Leroy J. Hushak (Ohio State University)
The study examines labor productivity and quit and layoff behavior of manufacturing production workers. Manufacturing firms employ relatively unskilled workers and make relatively small investments in specific human capital. To generate increasing income levels over time, industrial development efforts need to focus more on employment opportunities that require increasing skills.

"Factors Influencing Physician Location Decisions in Oklahoma." Marcia Huddleston Salkin and Michael S. Salkin (Oklahoma State University)
Many rural communities in Oklahoma are without adequate physician service because doctors locate in more urban communities. Here, we attempt to explain the physician location decision process by testing several hypotheses. The role of personal characteristics of physicians and community characteristics are examined. Conclusions include ways in which rural communities can attract doctors.

"An Income Determination Model with Implications for Occupational Mobility in a Rural Labor Force." Joe B. Stevens (Oregon State University) and David E. Ervin (University of Missouri)
"Excessive" job changing by workers is perceived as irrational behavior by employers in Oregon's wood products industry. A hypothesis of equimarginal returns to firm-specific and general work experience is tested with a partitioned income determination model. The revealed incentive structure encourages frequent job changing.

"The Influence of Psychic Costs on Human Resource Allocation." Brady J. Deaton (University of Tennessee), Larry C. Morgan (Texas A&M University), and Kurt R. Anschel (University of Kentucky)
Eastern Kentucky migrants in two urban centers were studied to determine the income levels required to induce a return to their home region. The average income specified was $1,777 below 1971 earned family income and close to the actual 1971 average earnings in eastern Kentucky. Roughly 50% of the variation in the income differential was explained by regression analysis.

"Household Migration into a Small Rural Southern Area." Leon B. Perkinson (ERS, USDA, North Carolina State University)
Households migrating into a small rural area had higher average incomes than native households but had heads that were younger and more educated. Multiple regression results indicated migrant households had over 15% less income in 1974 than native households with similar characteristics.

Environmental Quality (Richard W. Schermerhorn, University of Idaho, Chairman)

"Benefits and Costs of Surface Mine Reclamation in Central Appalachia: A Case Study." Alan Randall, Angelos Pagoulatos, Orlen Grunewald, and Sue Johnson (University of Kentucky)
The benefits of reclamation under current Kentucky regulations exceed reclamation; the incremental benefits of reclamation, under the currently introduced federal bill, are positive and under certain assumptions exceed costs. Even assuming application of best available reclamation technologies in the study region, surface coal mining generates residual social costs.

"Impact of Construction Subsidies on Optimal Crop Mix for Land Treatment of Municipal Wastewater." C. Edwin Young (NRED, ERS, USDA), Edward B. Bradley (University of Wyoming), and Donald J. Epp (Pennsylvania State University)
Least-cost solutions for land treatment of municipal wastewater are estimated for three levels of capital cost subsidy: no subsidy, 75%, and 85%. Irrigation of reed canary grass is superior to alfalfa, corn, forests, and natural vegetation (weeds). If the local municipality minimizes its costs while receiving subsidies, inefficiencies result.

"Application of a Multi-Goal Linear Programming Model to Measure Trade-Offs Between Cost and Environmental Variables in Agriculture." Gary Vocke, Earl O. Heady, and Orhan Saygideger (Iowa State University)
This study uses a large-scale multigoal interregional linear programming model to derive trade-off information between the goals of economic efficiency and soil conservation for U.S. agriculture. This information concerning resource use and implied income distribution effects can be used in formulating national land use policies for agriculture.

"Internalizing Externalities of Phosphorus Discharges from Crop Production to Surface Water: Effluent Taxes versus Uniform Reductions." George L. Casler (Cornell University) and James J. Jacobs (University of Wyoming)
An empirical test confirms the hypothesis that effluent taxes are economically more efficient than uniform reduction or uniform treatment. In this situation, costs to dischargers (farmers) are greater for the tax policy than for the uniform reduction policy, a point overlooked by many advocates of effluent taxes.

"Optimal Extraction with Stochastic Externalities: The Case of Offshore Petroleum." Jon M. Conrad (University of Massachusetts)

A model of offshore petroleum production is constructed where the rate of extraction positively affects the distribution of spills. An optimal rate of extraction is derived that takes into account the conditional distribution on spill damages, and an optimal liability rule is identified. An adaptive control formulation is outlined.

Management of Productive Inputs (T. Kelley White, Jr., Purdue University, Chairman)

"Break-Even Land Prices: A Normative Analysis of Their Determinants." Robert P. Zentner and Kurt K. Klein (Agriculture Canada)
Break-even land prices are derived for various factors affecting disposable net income per acre. The analysis includes a frequently overlooked consideration—the repayment capacity of the existing stock of assets. In addition, the effects of alternative cropping patterns with varying degrees of riskiness in net income are determined.

"An Economic Theory of Production, Investment, and Disinvestment." Alan E. Baquet (Michigan State University)
Durable inputs in production have long been an imbroglio. A theoretical model linking production, investment, and disinvestment is presented. Both the optimal flow of services and the economic life of the durable are determined internally. This formulation allows for consideration of both stock and flow quantities in the production process.

"Impact of Wage Rates on Optimal Machinery Complements." Darrel D. Kletke (Oklahoma State University) and Steven C. Griffin (Iowa State University)
The complex problem of choosing optimum machinery complements is approached using mixed integer linear programming. Wage rates and farm size are varied with the resulting optimal complements compared. Higher wage rates cause capital to be substituted for labor, and machinery costs per acre decrease as farm size is increased.

"Labor Management Time Allocations in Economies of Farm Size Studies." Roger G. Johnson and Steven Hvinden (North Dakota State University)
Data from North Dakota farmers were used to develop regression equations estimating seasonal farm operator labor and management time use by farm size. Management time had a large fixed component and increased linearly with farm size. Labor supervision time increased at an increasing rate with amount of labor supervised.

"Farm Real Estate Disinvestment Strategies." D. Lynn Forster and Richard D. Duvick (Ohio State University)
Seller financing of real estate sales is a predominant source of farm real estate credit. Annual consumption and savings of sellers are modeled over time under alternative selling strategies. Rules of thumb are developed for optimum lengths of sales under alternative seller financial characteristics.

"The Use of Shadow Prices in Determining Marginal Values." Fred J. Stewart and Richard A. Greenhalgh (ERS, USDA, University of Florida)
The problem of evaluating the need for land development projects for agricultural uses is addressed in a marginal analysis utilizing shadow prices. A linear programming framework was used with physical and historical characteristics of the land resource being defined and constrained. A procedure for assigning marginal values to an entire package of land resource characteristics is presented.

Demand and Supply Analysis (Richard Green, University of California, Davis, Chairman)

"Price Stability and Carry-Over Levels of Tart Cherries." Stanley R. Thompson and Leslie J. Butler (Michigan State University)
An econometric model is developed that is used in conjunction with a dynamic programming model to examine the unstable nature of prices in the cherry industry. The model delineates some areas of marketing strategy that may enable the cherry industry to deal more effectively with uncertain market conditions.

"An Econometric Analysis of the Supply Response for North Carolina Field Crops." Stanley M. Fletcher and Colin Gellatly (North Carolina State University)
This paper empirically evaluates the importance of risk in decision making. The Just model is applied in the analysis of North Carolina field crop supply response. Results indicate that effects of stabilization, possibly through government programs, might have partially offset the acreage-reducing effects of voluntary acreage restriction.

"Risk in Supply: The Case of U.S. Pinto Beans." Timothy J. Ryan (University of Minnesota)
Some simple risk specifications were estimated for pinto beans during 1953–75. The two preferred equations, one containing a weighted standard deviation of prices, the other a weighted coefficient of variation of prices, were superior to the no-risk variable specification. Policy initiatives to reduce price fluctuations need to incorporate the effects of supply.

"U.S. Demand for Fish Meal." Joseph Havlicek, Jr. (Virginia Polytechnic Institute and State University) and Faustino Ccama (La Universidad Nacional Technica del Altiplano, Peru)
Fish meal quantity demanded is inelastic with respect to its own price and that of soybean meal but elastic with respect to chick and lagged broiler

prices. Quantity demanded adjusted fairly rapidly to economic stimuli and in the long run is elastic except with respect to the price of corn.

"The Economics of Coupons." Ronald W. Ward (University of Florida) and James E. Davis (Bullock County Bank of Georgia)
Coupons are widely used in the promotion of food products. Theoretically, they should stimulate consumer responses through the informational effect as well as with the direct price discount effect associated with redemption. A pooled cross-section time-series model is developed to show both effects of coupons on the consumption of frozen orange juice.

Marketing (James A. Niles, University of Florida, Chairman)

"Impact of Alternative Class I Pricing Systems on the Location and Structure of the U.S. Dairy Industry." Richard F. Fallert, Harold W. Lough, and David E. Cummins (CED, ERS, USDA)
The projected regional aggregate impacts on the dairy industry of continued classified pricing under the federal milk marketing order program and under elimination of federal milk orders are evaluated. The effects are measured on milk production, fluid consumption, and price, with special emphasis on industry location and structure.

"The Average-Marginal Conflict in Milk Pricing." Floyd A. Lasley (CED, ERS, USDA)
Pooling and pricing under federal milk marketing orders have helped create a more stable marketing situation by translating marginal incentives and risks into averages. However, this paper considers how current instabilities stem from lack of satisfactory retranslation of average needs, costs, and incentives back into marginal response.

"A Review of the Experimental Effects of Increased Price Information on the Performance of Canadian Retail Food Stores in the 1970s." D. G. Devine (University of Saskatchewan)
Recent Canadian studies on measuring the impact of improving retail food price information reveal that information is a valuable economic resource that may be used as a tool in modifying retail conduct and performance. The publication of comparative retail food prices resulted in lower price spreads between stores, lower average city prices, and increased consumer satisfaction with the market. Retail price information seems to have many of the characteristics of a public good.

"Advanced Estimates as Predictors of Receipts at Six Markets." John R. Franzmann (Oklahoma State University)
The advanced estimates of livestock receipts is of potential value to those who market and/or hedge livestock. Usefulness is dependent on the accuracy of the estimates. This paper examines the accuracy of the six market advanced estimates and their usefulness in making marketing or hedging decisions.

"Rational Price Formation in the Fed Cattle Futures Market." Stephen E. Miller and David E. Kenyon (Virginia Polytechnic Institute and State University)
The failure of fed cattle futures prices to forecast fed cattle cash prices is traced to the presence of rational price formation in that futures market. Implications for cyclic fed cattle production and cash price variability are drawn from the presence of rational price formation in that futures market.

"A Framework for Evaluating the Economic Impact of Classified Pricing of Milk." Boyd M. Buxton (ERS, USDA, University of Minnesota)
Alternative classified pricing policies for milk are evaluated using a nine-region model of the U.S. dairy industry. Higher (lower) class I differentials generally are of advantage (disadvantage) to producers in the Northeast, South, and West regions and of disadvantage (advantage) to producers in the Upper Midwest, especially Minnesota and Wisconsin.

International Trade (Thomas S. Clevenger, New Mexico State University, Chairman)

"Effects of Currency Adjustments Given Free Trade and Trade Restrictions." Maury E. Bredahl (ERS, USDA, University of Minnesota) and Abner W. Womack (CED, ERS, USDA)
Comparative static models are developed that measure changes in equilibrium prices and quantities traded due to an exchange rate change. Effects are determined for a free trade model and compared with that incorporating trade restrictions similar to those employed by the European Community. Quantity changes exceed price changes. Exchange rate effects are greater if trade is restricted.

"Factor Intensity of U.S. Agricultural Trade." Gerald Schluter and Gene K. Lee (NEAD, ERS, USDA)
The labor and capital intensities of U.S. agricultural trade during 1974 are examined through an input-output model. The empirical results indicate U.S. agricultural exports tend to be more capital intensive, while agricultural imports are more labor intensive, a result counter to Leontief's Paradox.

"The Distributional Impact of Trade Liberalization in the U.S. Grain/Livestock Sector." David Blandford (Cornell University)
Regional estimates of gains and losses by economic class of farm are derived for the base year 1970. Theil's inequality index is used to assess distributional impact. Although free trade leads to greater interregional inequality, intraregional inequality declines. The effect is a decline in total inequality.

"The Impact of Imports of Manufactured Milk Products on the U.S. Dairy Industry." Andrew M. Novakovic and Robert L. Thompson (Purdue University)
The time paths of adjustment of consumption, production, and price of specific dairy products and raw milk are estimated under three alternative levels of manufactured product imports. Much larger than historically "normal" import levels are required to bring about a substantial impact upon the dairy industry in the longer run.

"Exchange Rates in International Commodity Models: The Common Currency Question Revisited." William H. Meyers (University of Minnesota)
This paper clarifies the difference between estimating supply and demand equations for individual countries in national currencies or converting to common currency prior to estimation. The appropriate procedure for a pooled cross-country time-series estimation model depends upon the cross-sectional constraints and whether nominal or real values are used.

"An Econometric Model of World Wheat Trade with Emphasis on U.S. Exports." Donald O. Mitchell (Michigan State University)
An econometric model of the international wheat market is developed and evaluated. The model attempts to capture the essential elements of the demand for U.S. wheat exports by explaining the linkages between wheat importing and exporting regions. A market share approach is used to link the exports of wheat from the United States to the world market.

Production Analysis (Chauncey T. K. Ching, University of Nevada, Chairman)

"Technological Change and Labor's Relative Share: The Mechanization of U.S. Cotton Production." Marshall A. Martin (Purdue University) and Joseph Havlicek, Jr. (Virginia Polytechnic Institute and State University)
Labor's relative share is determined by the elasticity of factor substitution and the bias of technological change. U.S. cotton production was rapidly mechanized after World War II. The adoption of labor-saving technology, given an elasticity of factor substitution greater than one, resulted in a decline in cotton labor's relative share.

"Using Cobb-Douglas Functions in Nonlinear Programming: A Regional Sector Model." David L. Watt (NEAD, ERS, USDA)
Combining Cobb-Douglas production functions and a programming algorithm into a single framework provides an effective tool to determine optimal input levels and commodity production levels. A regional application of the model involving an eight-year tracking period is reviewed. Profit maximization is enforced by equating the marginal value products with input prices. Input and output prices are represented by continuous functions.

"The Demand for Farm Tractors in the United States." Dean W. Hughes and John B. Penson, Jr. (Texas A&M University)
Several shortcomings are noted in previous studies of the aggregate demand for farm tractors, including the measurement of the cost of capital and capacity depreciation. Empirical results presented in this study show that net investment regressions based upon the USDA's capital series are inferior to those based upon engineering data.

"Research Expenditures, Education, Weather Variables, and the Agricultural Production Function." Bernard J. Morzuch (University of Wisconsin–Madison) and Stanley R. Johnson (University of Missouri–Columbia)
Using the production function concept, Griliches attributed changes in U.S. agricultural output to time-related education and research quality indices. This procedure was duplicated using Missouri farm survey data, allowing for measured weather variables. Ordinary least squares with dummy variables and an error components model were the estimation procedures used.

"Development of an Innovation Possibility Frontier for Purposes of Research Planning and Evaluation." Kurt K. Klein (Agriculture Canada) and Earl W. Kehrberg (Purdue University)
Agricultural research activities can be planned and evaluated on the basis of an innovation possibility frontier. Procedures for estimating such a frontier (to be employed in a normative context) are developed. Its uses for screening projects and for sensitivity analyses are emphasized.

"A Study of the Interaction of Weather with Alternative Environmental Policies." Won W. Koo (Montana State University), William G. Boggess and Earl O. Heady (Iowa State University)
This study evaluates the relationship between various agricultural environmental policies and weather variations. The indices for relative weather variability in each state are estimated by grafted polynomials and are incorporated into the changes in production patterns under alternative environmental policies to evaluate the impacts of the policies on the variability in production due to weather.

Regional Analysis (Martin Redfern, University of Arkansas, Chairman)

"Construction of a Multiregional Input-Output Model for the Pacific Northwest from Secondary Data." John R. Wilkins (ERS, USDA, Oregon State University)
Existing state input-output models for Oregon,

Washington, and Idaho were updated to 1972 and aggregated to a common sector pattern. Import and export submatrices were developed using a national multiregional I-O model and a theoretical technique. The matrix was pieced together and balanced by adjusting individual matrix elements. Preliminary model application was on northwestern U.S. energy and irrigation alternatives.

"A Comparison of Agricultural Net Returns and Regional Household Receipts Under Alternative Strategies of Groundwater Depletion." James E. Casey (Oklahoma State University), Lonnie L. Jones and Ronald D. Lacewell (Texas A&M University)
Northern Texas and western Oklahoma agricultural producers face the prospect of inadequate groundwater supplies to sustain future agricultural production. Given decreasing water levels, the extraction costs or physical capacity of the wells will prohibit bringing additional acres under irrigation and force reductions in the number of irrigated acres. A regional model for evaluating alternative strategies of utilizing the existing groundwater supplies is presented.

"An Analysis of Income Distribution in the Northeast Using the Gamma Density." Richard N. Boisvert (Cornell University)
Family income distribution for 1970 in the Northeast is approximated by a gamma distribution. From regression results, increases in labor productivity and education were effective in raising average incomes. Reducing income inequality or the numbers of families with low incomes requires educational training and employment programs aimed directly at disadvantaged groups.

"Elasticities: Better Policy Statistics from Interindustry Studies." Harry W. Ayer (ERS, USDA, University of Arizona) and James Baskett (Loyola University)
It is argued that multipliers from interindustry studies are easily misinterpreted. Elasticities are developed and presented as a more relevant policy statistic. A current example of the relative advantage of elasticities is given. Elasticities better reflect the potential for needed sector growth and use more readily available and comprehended data.

"Modeling Local Fiscal Behavior: The Response of Oregon County Governments to Mental Health Grants." Bruce A. Weber and John F. Savage (Oregon State University)
Regression results from a theoretically based model of county spending suggest (*a*) mental health grants do stimulate new county mental health spending but not to the full extent implied by matching ratios and (*b*) under current conditions, marginal changes in matching ratios may not be an effective policy tool to stimulate county spending.

"The Economic Impact of Manufacturing Plants in a Five-County Region in Southwest Ohio." Leroy J. Hushak and Alan Osman (Ohio State University)
This study examines the net benefits generated by manufacturing plants on local, county, and regional communities. Use of incremental income instead of consumption to measure primary benefits results in a significant increase in net benefits. Significant increases of internalized benefits occur from local to county and county to regional levels.

Land Use Policy Analysis (Jack D. Edwards, Bureau of Land Management, U.S. Department of Interior, Chairman)

"The Model Land Development Code—Economic Impacts of Area of Critical State Concern Designation." Clyde Kiker and Gary D. Lynne (University of Florida)
A large area in Florida was designated an "Area of Critical State Concern" to protect water resources. Economic analysis of the region indicated water was not a scarce resource and the area could sustain large transfers of water to other areas and still support major increases in land use. The regulations, based on physical criteria, curb economic uses. The code, while having many desirable features, could lead to economic efficiency and distributive problems.

"Location of Agricultural Districts Relative to Urban Places in New York." Nelson L. Bills (ERS, USDA, Cornell University)
Forty-two states allow farmland to be assessed at use rather than market value. New York has combined preferential assessment with the concept of agricultural districts. Several districts are located within commuting zones around central cities, but few are adjacent to or within 10 miles of an urban place.

"Land Use Policy and Agricultural Land." Charles A. Sargent (Purdue University)
Current agricultural land use issues are analyzed in terms of urban development demands and agricultural needs. Loss of total farm land acreage, efficiency of land use, externalities, public and private costs, and urban development quality problems are examined. Four kinds of policy options for community growth management are evaluated.

"Land Use Change Detection from Satellite Imagery." John T. Cygul, James E. Hariston, Wesley N. Musser, and Fred C. White (University of Georgia)
This study focuses on the practical utility of using satellite imagery to determine agricultural land use changes in Georgia. Procedures used in analyzing LANDSAT data and associated cost effectiveness compared with traditional survey methods are discussed. Results indicate that using LANDSAT data is an economical and reliable method for monitoring natural resource use.

"Land Appreciation Rates and Economic Justification of Land Values." Glenn A. Helmers and Myles J. Watts (University of Nebraska)
A capital budgeting model is applied to land investments. Yearly net incomes from land are assumed to be less than opportunity costs yielding negative yearly net economic flows. Land appreciation rates necessary to economically justify the investment are determined on a before and after-tax basis.

Decision Making Under Risk (A. Gene Nelson, Oregon State University, Chairman)

"Teaching Decision Making Under Risk and Uncertainty to Farmers." John Holt (University of Florida) and Kim B. Anderson (Oklahoma State University)
A manager's central role is making choices among uncertain outcomes. A teaching approach is reported that can help managers analyze the component parts of a decision, clarify the risk involved in each action, and help to analyze that risk in a systematic manner. The analysis—whether or not to graze stocker cattle on wheat—embodies production and marketing risk for both cattle and wheat.

"A Direct Solution Alternative to E-V Analysis in Utility Maximization Models." Edward E. Ives (Governor's Energy Advisory Council, Texas)
Utility maximization models of farm cropping decisions typically use E-V analysis as a solution technique, requiring the solution to a number of quadratic programming problems. The problem can be solved using a single quadratic programming problem. The direct solutions advantages may sometimes be outweighed by other factors, however.

"Incorporating Multiple Sources of Risk into the Determination of Optimal Fertilization Rates." Hovav Talpaz and C. Robert Taylor (Texas A&M University)
A theoretical framework for incorporating three sources of risk—weather, price, and production response—is presented. The decision criteria considered are the maximization of profit subject to risk constraint, where risk is defined as the probability of not recovering cost of fertilization. A two-source risk numerical application is provided.

"A Bio-Economic Model of Beef, Forage, and Grain Production for Western Canada." Bernard H. Sonntag and Kurt K. Klein (Agriculture Canada)
Multidisciplinary research can provide a better understanding of agricultural production problems. A bioeconomic model of beef, forage, and grain production is described in terms of its biological and economic components. Special applicabilities for this type of model are noted.

"Expected Return and Risk—A Trade-Off in Farm Enterprise Choice." Bryan W. Schurle and Bernard L. Erven (Ohio State University)
A modified linear programming alternative, Hazell's MOTAD model, is used to address an enterprise choice problem in which the enterprise alternatives differ substantially in average net return and risk. Examination of several specific questions related to the trade-offs between return and risk demonstrate the model's usefulness.

"Procedures for Estimating Exponential Utility Functions." Steven T. Buccola (Virginia Polytechnic Institute and State University)
Exponential utility functions have the desirable feature of constant absolute risk aversion but present estimation problems. Logarithmic transformations of these functions do not conform to Von Neumann-Morgenstern axioms and hence cannot be used as bases for a best fit. A proper criterion for selecting such a fit is described.

Award-Winning Theses

Holliday, Douglas C. "An Analysis of Economic Relationships and Performance in the Canadian Broiler Industry." M.Sc. thesis, University of Guelph, Canada, 1976.

This study quantifies economic relationships in the North American broiler chicken industry for the purpose of investigating the performance of marketing institutions in this sector. The economic problem is set in the confines of marketing board policy in Canada. A recursive spatial equilibrium model of the Takayama and Judge type was constructed to provide the framework for the analysis.

This analysis of performance was questioned, however, because of the difficulty encountered in defining an overall measure from which to draw concrete conclusions. Potential impacts of selected modifications to the market structure were studied. Two types of modifications were studied. These included the removal of past or present structural characteristics that were built into the validation model and an analysis of several potential changes to the existing market structure. The latter considered the establishment and operation of a national marketing agency in Canada.

The removal of the artificial trade barrier between Canada and the United States suggested *(a)* that the methods of costing and pricing used by provincial boards tend to overinflate prices, *(b)* that past pricing practices have jeopardized the long-run import position of the Canadian industry, and *(c)* that past price levels in Canada could have been obtained only through the control of imports.

Several policies concerned with the formation of a national agency in Canada were simulated. One policy suggested that the quota control mechanism of the Ontario Board has been unduly restrictive relative to that of other provincial boards. The second policy showed a substantial increase in revenue to Canadian producers and a consequent reduction in consumer welfare if imports from the United States were controlled. The final policy showed an aggregate benefit to the Canadian industry through the reallocation of regional market shares on the basis of population growth.

Novakovic, Andrew M. "The Impact of Imports of Manufactured Milk Products on the United States Dairy Industry." M.S. thesis, Purdue University, 1976.

In 1973 and early 1974, the U.S. government relaxed traditionally tight import quotas for American cheese, butter, and nonfat dry milk in an effort to reduce higher than normal dairy prices. These actions sparked a debate over the effect of imports on the dairy industry. The principal objective of this thesis is to estimate the impact of changes in the level of dairy imports upon the production, consumption, and prices of major dairy products and raw milk.

To this end an econometric model of the U.S. dairy industry is developed. The model describes retail and wholesale level markets for fluid milk products, American cheese, butter, nonfat dry milk, and frozen desserts as well as the farm level supply of raw milk. The farm supply of raw milk includes a capital-theoretic herd adjustment component. The model is estimated using two-stage least squares. The Gauss-Seidel procedure is then recursively applied to trace out the time paths of adjustment of consumption, production, and price of dairy products and raw milk under three alternative levels of manufactured milk product imports.

Results of the analysis indicate that, as imports increase, prices and production decrease while consumption increases. More significantly, the analysis indicates that much larger than normal import levels are required to bring about a substantial impact upon the dairy industry.

Rosera, Eugene S. "The Economic Impacts of Industrialization on a Rural Louisiana Economy: LaSalle Parish." M.S. thesis, Louisiana State University, 1976.

The objective of this study was to identify, by selected economic and demographic measures, the impact of industrialization on a rural Louisiana economy. Economic impacts generated by industrial and other sector output increases were estimated through a modified input-output model. Sectors comprising the LaSalle parish economy were identified and sample data were collected from 65 households, 81 businesses, and government sources by personal interview. Intersectoral trade effects were described by output multipliers, income and employment effects and multipliers, and the components of those measures attributable to the industrial sector were identified. It was estimated that, per dollar output increase by any parish sector, the greatest output impacts generated by manufacturing occurred due to its household sector payments and resulting induced effects.

A sample of 321 new industrial sector employees was used to estimate selected demographic and economic changes not measured by the input-output model. A profile of employee demographic characteristics was developed. The previous employment status and changes in employment and salary levels of workers were estimated. A survey of 27 of 29 businesses that opened or expanded

during the period of manufacturing growth was used to estimate other parish employment increases. Additionally, the expenditure of resident manufacturing employee salaries to local businesses was estimated.

Direct public costs of attracting and installing industrial production facilities in the parish were determined through a survey of local governments.

Barros, Geraldo Sant'Ana de Camargo. "Asking Wages, Market Wages, and the Off-Farm Labor Supply by Farm Operators." Ph.D. thesis, North Carolina State University, 1976.

The objective of this study was to investigate the factors affecting the farmer's decision to participate in the off-farm labor market. The problem was analyzed with a theoretical model of multiple job holding in which household and farm activities determined the farmer's value of time. A logit analysis was applied to estimate the effect of several variables on the probability of working off farm. Weighted regressions were used to estimate the offered wage equation and the hours of work equation. The entire procedure led to consistent and asymptotically efficient estimation of a common set of parameters that underlie the function determining the probability that an operator works off the farm, his hours of work, his market wage, and his asking wage.

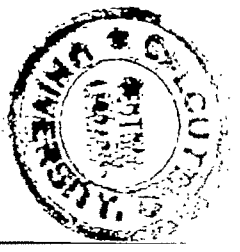
The model was tested by using data from a 1971 survey of farm operators in Illinois. The results indicated that the operator's schooling affected positively and with equal intensity both the asking wage and the offered wage. The effect of operator's schooling on the probability of working and the hours of work off farm was negligible. Farm operators tended to work longer until middle age and then reduce hours of work. Area operated, hours of family labor employed on the farm, the wife's schooling level, and farm experience were negatively related to the probability of working and to hours of work off farm. Operator's previous job experience and operator's health were positively related to the probability of working and to hours of work off farm.

Bockstael, Nancy Elaine. "Analysis of Investment Behavior and Price Determination: Analytical Input for the Formation of Policy in the Fisheries." Ph.D. thesis, University of Rhode Island, 1976.

The Fisheries Conservation and Management Act of 1976 defines the term "optimum" as that "which will provide the greatest overall benefit to the nation," implying that the objectives of the act extend beyond the welfare of the fishing industry. Policy decisions regarding allowable level of foreign fishing will affect the actual gains accruing from diminished foreign fishing and the distribution of those gains among U.S. interest groups. Rational decision making will require an understanding of consumer demand, retail and exvessel price determination, and U.S. fishermen's supply response, such that the impact on domestic producers and consumers can be predicted from initial exogenous changes.

This study's objective was to provide two segments of a comprehensive, dynamic model. The first segment of the study modeled disaggregated firm investment behavior in the U.S. groundfish industry using logit analysis. The feasibility and usefulness of logit analysis for handling the complications introduced by fishery investment behavior was demonstrated, and promising results were achieved for two partitions of the data set—those who changed capital stock and those who entered the fishery. Fishermen's decisions were explained in terms of differences in gross revenues and capital costs associated with different capital stock alternatives. A tendency towards inertia was identified.

The second segment, an econometric analysis of the behavior of economic agents in the groundfish market, was successful in explaining the interaction of consumer demand, imports, and domestic landings in determining exvessel groundfish prices to domestic fishermen and retail prices of various groundfish products. Results supported the hypothesis that foreign groundfish harvesting within the U.S. 200 mile zone affects U.S. import prices, and thus all U.S. groundfish prices, through the mechanism of the world market.



Dixon, Bruce Lawrence. "A Stochastic Control Approach to Harvest Scheduling in a National Forest." Ph.D. thesis, University of California, Davis, 1976.

A natural resource manager faces the empirical problem of intertemporally allocating product flows and resource stocks under conditions of uncertainty. The timber management problem of national forests is conceptualized in this study as a stochastic, optimal control problem. Theoretical procedures exist to obtain optimal solutions to stochastic control problems, but the computational requirements for even moderately sized problems are excessive. Hence, approximate solution techniques are employed.

The approximate solution technique used is the linear-quadratic-Gaussian (LQG) control method. The optimization philosophy of the LQG method is to keep the actual evolution of the resource system "close" to a set of predetermined stock and control levels. The method utilizes Taylor's theorem to construct a simplified model of the original problem. This model is characterized by quadratic preferences and linear growth dynamics. The solution to the problem given by the simplified model is quickly computed, allowing the policy maker to

determine the harvest flows under a wide spectrum of policies. The costs of various sources of uncertainty are also derived as part of the solution.

The LQG method is applied to timber management of mixed conifer stands of a California national forest. The experimental results show that timber flows change markedly when nonstumpage uses of timber are recognized explicitly in the objective function. This result underscores the need to be able to quantify and evaluate multiple-use values accurately. The recursive estimator used in the LQG model results in an estimate of timber stocks with a lower variance than conventional static estimators.

Committee Reports

Report of the President

I have enjoyed the opportunity to serve as president in 1976–77 and to contribute in some small way to the advancement of the Association and the profession. Although I had served on the Executive Board four consecutive years prior to becoming president, I had not fully appreciated the scope and complexity of AAEA activities until 1976–77. I look forward to relief from some burdens that accompany the office, but I nevertheless leave the office with feelings of optimism and excitement concerning opportunities for the Association to better serve the diverse interests of its members and society.

In my judgment the keys to development of the Association are to be found in continued support of high standards of scholarship, independence and objectivity of inquiry, tolerance and encouragement of differing professional viewpoints, and selective expansion of services to better serve the interests of groups of members—students, newly established professionals, and the several institutional, subdisciplinary groups—that comprise our membership.

The single greatest need and opportunity for the Association is that of better relating the profession to current and emerging socioeconomic issues of our times concerning food, agriculture, resources, people, and communities. I believe the Association can perform in that role to the long-run benefit of its members and society and at the same time continue to serve its prime purpose of advancing the scientific, scholarly content of the profession of agricultural economics. To do so, agricultural economists must find ways of relating more effectively to other disciplines with whom we must interact in resolution of complex socioeconomic issues, and the officers and members must develop a viewpoint that the Association has purposes both internal and external to the profession. There is, I believe, the interest, capacity, and leadership in the profession to achieve those goals.

The affairs of the Association are conducted in large part through its committee structure. Currently, there are fifteen standing committees, seventeen special committees, and three ad hoc committees. We have six liaison representatives to other organizations. In total nearly 260 members were involved in committee activities in 1976–77. The work of these committees is essential to the Association, and whatever the accomplishments of the president and the Board, they derive usually from the work of such committees. I appreciate the excellent assistance given by all committees to me and the Board during 1976–77.

One ad hoc committee and one major special committee were created during the year. The ad hoc committee was created to review policies and procedures concerning the *Journal* page charge. A special committee on business organization and management was charged with responsibilities of reviewing the management structure, methods, and procedures of the Association and recommending steps that might be taken to improve effectiveness of our operations and managerial processes.

Several conditions give rise to the need for this review. Foremost is the growing complexity of the Association as we strive to develop services to meet the diverse needs of the membership. The development and delivery of these services is dispersed among several institutions and locations and requires substantial managerial efforts by the president, secretary-treasurer, and committee chairmen. The annual turnover in members of the Executive Board and committees poses problems in maintaining continuity in management. The secretary-treasurer is called upon to perform a myriad of functions, some above and beyond those of a secretary or a treasurer. Routine management duties limit the ability of the president to concentrate on broad policy matters of the Association. A need exists to review possible application of modern data and information processing techniques in the executive affairs of the Association.

This committee, under chairmanship of Burt Sundquist, University of Minnesota, has been assigned a large, complex task. They have been asked to file a final report with the Board in the summer of 1978.

One of the most important decisions of the Board during the year was selection of new editor and associate editor of the *Journal*—V. J. Rhodes and S. R. Johnson, respectively, of the University of Missouri. The transition from Cornell University to the University of Missouri has been largely completed. The February 1978 issue will be the first official output of the new editors. We are indebted to W. G. Tomek and Cornell University for their support during the past three years and to the University of Missouri for the support they will be providing in the next three years.

Two of the most visible products of the year were the new *Handbook-Directory* and volume 1 of *A Survey of Agricultural Economics Literature*. As of 1 September 1977, sales of volume 1 totaled 480 copies. Volume II of the *Survey* will be published in late fall 1977. Work on volume III is nearing completion with projected publication in late 1978. The *Handbook-Directory*, totaling over 600 pages, represents an important personal contribution of John Redman and his staff. We are indebted to them for their diligence and persistence in compiling the publication. To economize on labor and other costs, the

Employment Services Committee has examined the feasibility of publishing the next edition of the *Handbook-Directory* from the computerized professional registry. With some modifications and expansion of inputs the registry would appear suitable for such purposes. We shall further explore those possibilities in the year ahead.

Another major decision of the Board relates to the professional (employment) registry service. Since its inception in 1974, the computerized employment registry has been financed solely by grants from the U.S. Department of Labor. A final funding grant was received during the year to extend operation of the registry to 15 February 1978. In anticipation of expiration of the grant, the Board asked the Professional Registries Committee, under chairmanship of Dave Boyne, Ohio State University, to examine alternative institutional arrangements for continuation of the registry on a permanent user-sustained basis. The committee also was asked to explore means of expanding the scope of the registry for the purpose of educational-manpower planning.

The Board has approved a plan whereby the registry will be housed in the U.S. Department of Agriculture (Economic Research Service) and financed by annual grants from institutions that might use the registry services. For U.S. and Canadian agricultural economics departments, annual grants of $50 to $300, depending upon the number of faculty, have been solicited. Grants of $100 are being solicited from agricultural business organizations. Solicitations have been sought from the Ford Foundation, U.S. Agency for International Development, and USDA agencies.

Based upon response to these solicitations it appears that grants might total $15,000 in 1978. With the placement officer to be provided by ERS, the Board concluded that these grants would be adequate to sustain operation of the registry in 1978 at near current levels of activity. Thus, the Board has authorized formal acceptance of grants and development of an agreement with the ERS. Similar financing arrangements will likely be extended to 1979 and 1980.

Although these arrangements meet our immediate financial needs and provide for continuation of the service at current levels, a concerted effort is needed to increase the number of registrants, maintain currency of information in the registry, and encourage use of the system by employers of agricultural economists.

In my presidential address, I recommended that the Association initiate activities to encourage expanded and more effective public policy research and education programs. I am pleased that the Board has seen fit to establish a new Distinguished Policy Contribution Award, which may be awarded annually beginning 1977–78. The Board also adopted a policy statement to encourage AAEA sponsorship of seminars, workshops, symposia, colloquia, and other professional activities in the interest of a significant proportion of the membership or a recognized subset of members. I hope that you will offer suggestions for such activities to the incoming president and the Professional Activities Committee.

A year ago the Board adopted policies to limit membership on AAEA committees and presentation of papers at annual meetings to AAEA members except as the condition is waived by the president. A differential member-nonmember fee structure at annual meetings was also authorized and has been implemented. I encountered no major difficulty in implementing these policies. I have judiciously utilized authority to waive the membership requirement particularly when I felt the requirement was not consistent with the need for participation in the annual meeting by persons from other disciplines or by persons who could not be expected normally to be AAEA members by virtue of their profession or position.

Including those who paid membership dues at the 1977 summer meeting, it appears that we have maintained individual membership and increased institutional membership in 1977 relative to 1976. Given higher dues and the one-time membership-increasing effect of the *Handbook-Directory* in 1976, this is a satisfactory achievement, attributable in no small part to the work of the Membership Committee under chairmanship of John Lee. The secretary-treasurer reports more fully on membership.

The Membership Committee initiated several activities during the year to systematize recruitment of members. These include automation of membership lists of AAEA, the regional associations, and the Canadian Agricultural Economics Society including lists of potential members and development and circulation of a membership information leaflet.

The Alternative Publications Committee, under chairmanship of Verner Hurt, is examining information services of the Association including the *Journal*. A report for action by the Board will be filed in late 1977.

Just a few comments on the summer 1977 meeting in San Diego. It was a unique occasion with respect to AAEA meetings—the first in more than 40 years held in commercial facilities. One of the major differences from meetings on university campuses is the fact that no local arrangements committee existed to which we could delegate the numerous decisions concerning lodging, room arrangements, equipment, travel, printing of program, etc. This meant that the burdens of those tasks have fallen upon relatively few individuals.

However, thanks to the hard work and support of those individuals it has been, on balance, a good experience. It has been a pleasure to share responsibilities with William E. Martin, president, Western Agricultural Economics Association. He has been imaginative, cooperative, and understanding

even at times when he must have questioned the jointness of planning and decision making.

I must acknowledge the steadfast support of my secretaries, Mildred Evano, Carol Kotch, Sharon Warwick, and Geneva Riddle, who have worked very hard in preparation of this meeting. Loyd Martin of the ERS has worked hard throughout the year in carrying out decisions with respect to program, travel, lodging, and committee functions.

The staff of the Town and Country Hotel have been efficient, professional, and responsive to our every need within constraints of the facility. Patt Potter, in particular, has been decisive, well organized, and helpful.

We are indebted to John Redman and his staff. In addition to regular duties that attend these meetings, John assumed major responsibilities for advance publicity of the meeting, printing of the program and other brochures, catering arrangements, registration procedures, and other duties too numerous to mention. He has served cheerfully and competently with, as usual, the best interests of the Association in mind.

I also wish to acknowledge the assistance of James Boles, University of California, Berkeley, B. C. French, University of California, Davis, and Jimmye Hillman, University of Arizona, and graduate students from each of those institutions for their assistance in operating employment services at the meeting. Finally, I appreciate the assistance being provided by the San Diego Convention Bureau at the registration desk and by Pacific Telephone at the message center.

I wish to thank retiring board members Fred Mangum and B. F. Stanton for their three years of thoughtful effort on behalf of members of the AAEA. Bud Stanton, of course, will be serving on the Executive Board for three more years in his presidential capacities.

It has been a pleasure for me to work with the current Executive Board. They have worked diligently and harmoniously with me even through grueling Board meetings. To Past-President James Bonnen, who set in motion many of the initiatives I have pursued this year, I am grateful for sage advice and insights even late at night!

I now turn the presidency over to R. James Hildreth. Jim, please accept my thanks for your assistance in the past year and my very best wishes for the coming year. I am sure I speak for the new Board and our members in saying that we stand ready to do everything possible to make your year as president a productive one. Congratulations and good luck.

Kenneth R. Farrell, President

Resolutions

Wishing to acknowledge the support given to the *American Journal of Agricultural Economics* during the past three years, be it resolved that the American Agricultural Economics Association expresses its appreciation to Cornell University and to the Department of Agricultural Economics of Cornell University for the support given the *American Journal of Agricultural Economics*. The special thanks of the Association are due the editor, William G. Tomek, the associate editors, Richard N. Boisvert and Donald K. Freebairn, and the assistant editor, Nancy M. Larrabee, as well as the Editorial Council for their outstanding services. In addition the Association wishes to express its deep appreciation to Francis E. Walker of Ohio State University for his services as book review editor.

Be it further resolved that a copy of this Resolution be sent to the appropriate administrative officials of Cornell University and Ohio State University.

Wishing to acknowledge the contributions made to production of the 1977 AAEA *Handbook-Directory*, be it resolved that the American Agricultural Economics Association expresses its appreciation to John C. Redman and Willetta Hager for the many long hours of hard, demanding work, without which the 1977 *Handbook-Directory* would not have been possible.

Be it further resolved that a copy of this resolution be sent to the appropriate administrative officials of the University of Kentucky.

Report of the Secretary-Treasurer

The AAEA membership for 1976 totaled 5,841 as compared with 5,966 for 1975, a decrease of 125 members (table 1). Two opposing forces affected membership—the publication of the *Handbook-Directory* and a dues increase. If history repeats, 1977 will be a critical year. A bylaws amendment authorized the corresponding membership category to be combined with the regular membership and the establishment of a senior membership category for those who have reached the age of 65 and retired from active professional work. The number of members who had paid on or before 1 April 1977, and therefore received a ballot to vote, remained close to the previous two years (table 2).

The operating statement for 1976 showed a surplus of $17,349.95, which is good news, particularly since a deficit was experienced for each of previous three years (table 3). Caution must be exercised in analyzing operating statements because extraordinary items often convey normal activity. The U.S. Department of Labor (USDL) grant to support the activities of the Employment Committee was separated this year into its own operating statement (table 4). Since we are the custodian of these funds, this separation gives a more accurate indication of our financial activity.

On the income side, two significant changes are to be noted. The large increase in income from dues and subscriptions resulted from the dues increase

[b] Category combined with regular members in 1976.

made effective 1 January 1976. Also, the page charge that was collected for the first full year produced a sizable increase. The miscellaneous income included $123 for postage collected for remailing the *Journal* and $100 return from the International Association of Agricultural Economics grant.

On the expense side, printing bills were paid for six issues of the *Journal* instead of five. Included in the $15,207.76 literature review expense was a grant in aid of $15,000 made to the University of Minnesota Press for publishing two volumes of reviews. The miscellaneous expense of $810.30 was comprised of $509.00 in refunds, $225.00 for dues to the Federal Statistics Users' Conference, $36.00 for copyright fees, $6.00 for Iowa registration fee, and $34.30 for IRS assessment.

As you are aware, the AAEA received a grant to develop a computerized national registry and employment service for agricultural economists. In previous reports, these funds were included in the operating statement and, with unexpended balances, misleading impressions of financial activity may have been conveyed. Thus, the USDL grant funds were separated (tables 4 and 6). The year ended with a deficit of $753.05, but it was known that the grant had been extended with additional funding.

In accordance with the policy established in 1973, the income-expense statement for editorial support as provided by the editor is incorporated as a part of this report (table 5).

The balance sheet for the AAEA (table 6), which had deteriorated rapidly over the past three years, improved considerably because of the positive balance of $17,349.95 (see table 3). Again, the unspent USDL funds were carried separately to give a better indication of our net worth. A second item of note is that the total assets are carried at cost. The approximate market value is for information only and is not included in the totals. A third item lies in the item of prepayment of dues. The 1975 figure was prepayment for 1976, the year of the *Handbook-Directory*. The year 1976 was for 1977 with no *Handbook-Directory*, and the amount paid with a dues increase was approximately the same as the previous years. As stated at the beginning of the report, 1977 may be a critical year.

The year 1976 was extremely busy for me with the preparation of the *Handbook-Directory* and the increased number of activities and requests, but I enjoyed every minute.

John C. Redman, secretary-treasurer

changes in financial position for the year then ended. Our examination was made in accordance with generally accepted auditing standards, and accordingly included such tests of the accounting records and such other auditing procedures as we considered necessary in the circumstances.

"In our opinion, the financial statements referred to above present fairly the financial position of the American Agricultural Economics Association as of December 31, 1976, and the results of its operations and the changes in its financial position for the year then ended in conformity with generally accepted accounting principles applied on a basis consistent with that of the preceding year."

Report of the Investment Committee

The portfolio of the AAEA, which did not change during 1976, produced an income of $9,535.75. The stocks carried on the books at cost of $102,551.99 had a market value of $202,490.50 on 31 December 1976, increasing by $43,180.375 from the previous year (table 1). Our investments in stocks yielded $9,527.32 in dividends (table 2).

All stocks were worth more at the end of 1976 than at the beginning. Five stocks—American Cyanamid, Commonwealth Edison, Goodyear, Jewell Tea, and Texaco—were worth less than their cost. However, the total value was about two times the cost. Based on cost, the stocks produced a 9.3% return, but when based on value at the beginning of the year the yield was 6.0%.

tions for the office of secretary-treasurer, and consider alternative methods of managing the investment portfolio and recommend a procedure for future management.

The committee is pleased to note that the AAEA's final operating statement for 1976 showed a positive balance after three successive years of deficits. Projections for 1977 also indicate a positive balance is likely. We commend the secretary-treasurer and all the operating groups for their efforts to work within budget guidelines.

Individual members of the finance committee have followed one or more of the Association's important enterprises and activities to monitor expenditures and assist in developing the budget. Assignments were Barr—*Journal*, Barry—literature retrieval, Boehlje—employment, and Stanton—office of secretary-treasurer.

During the year the committee met twice by use of conference call and once for an all day meeting in May in Washington, D.C., to develop initial budget estimates for 1978 and to prepare a recommendation for the Board on management of the investment portfolio.

With the assistance of the secretary-treasurer the committee developed the following set of general guidelines for cash flow and account transactions in that office:

(*a*) The Finance Committee is available to assist or advise the secretary-treasurer at any time if there are short-run decisions on transfers of funds or loans required.

(*b*) The secretary-treasurer has direct authority from the Board to borrow up to $25,000 for Association needs if required.

(*c*) Earnings from the investment portfolio will be forwarded automatically and deposited monthly into the checking account of the Association.

(*d*)) Cash and savings balances of the Association will be reviewed annually by the Finance Committee. Funds accumulated in savings, time deposits, or certificates of deposit will then be considered for appropriate investment in the AAEA portfolio.

(*e*) The following are suggested as guidelines with respect to maximum balances in individual accounts to hold at the commercial bank where AAEA accounts are located: checking account, $5,000; savings or time deposits, $20,000; and short-term certificates of deposit, multiples of $10,000.

The management of the investment portfolio has been under review for the past 18 months. Professional management has been investigated and discussed with the Board at two previous meetings. A report discussing external and internal management of the portfolio has been prepared (printed below) and a recommendation with procedures for internal management developed. We recommend that the Board take action on this proposal at the August 1977 meeting and that the procedures provided be

Table 3. Enterprise Budgets for Publication of the *Journal*

Description	Approved 1976 ($)	Approved 1977 ($)	Approved 1978 ($)
Expenses			
Printing 1,100 pages	77,500	80,000	76,000[a]
Postage	2,000	5,000	6,000
Storage, labor, other	0	0	1,500
Editorial support	20,000	20,000	22,500[b]

Advertising	1,000	1,000	1,500
Submission fees, other	0	0	0
Total	23,500	27,000	25,500
Net enterprise cost	78,500	91,000	83,200

Note: An important part of the expenses associated with the office of the secretary-treasurer is directed to support of *Journal* activities.

[a] New printing contract starting 1 January 1977 with Heffernan Press on an issue of 1,100 pages has costs of $69 per page. The contract calls for no increase in printing charges for the second year and a maximum of 6% in the third year (1979). Paper and mailing cost increases can be passed on.

[b] Editorial support may need to be increased to reflect secretarial-clerical costs.

[c] A new editor for the *Journal* was appointed for the 1978–80 issues. Funds to operate during the transfer of the editor position were budgeted for July 1977 through 30 December 1977.

[d] Page charges are assumed collected on 585 pages at $40 per page.

implemented before the January 1978 meeting of the Board.

B. F. Stanton, chairman

Report on Management of the AAEA Portfolio

The investment portfolio of the American Agricultural Economics Association provides valuable revenue for ongoing operations, serves as a source of reserves in periods of need, and provides a credit rating for the Association. Although changes in the portfolio have occurred in the past, such transactions appear to have occurred infrequently and without thorough review of the portfolio. To obtain maximum benefits from the portfolio, systematic, periodic management is proposed. The purpose of this report is to discuss briefly some of the issues involved in comparing professional and internal (an AAEA committee) management of the AAEA portfolio and to propose a procedure for managing the portfolio in the future.

General Considerations

At least six factors should be considered in evaluating the management of the portfolio.

Quality of management. It is difficult to assess the quality of management without reference to a particular management service. However, one might expect improved management from a professional service compared with a committee of AAEA members because of (*a*) specialization in investment analysis and portfolio management, (*b*) accountability for management decisions, (*c*) more frequent portfolio analysis, and (*d*) size economies in transactions costs and acquisition of information. An AAEA committee might have or acquire the same characteristics as a professional service, although the commitment of time and effort would be substantial.

Costs. Recent discussions with trust departments of some large commercial banks indicate that the annual management fee charged for a portfolio of the size held by the AAEA would likely range from $1,300 to $1,600. This fee would include all transactions and reporting costs as well as management charges. This annual cost is roughly equal to 0.75% of the portfolio's current market value.

Returns. Evidence on the performance of professional management services is somewhat mixed and worthy of brief review. On one hand, one might expect the quality-of-management features outlined above to enable a professional management service to consistently beat the market; that is, to earn returns over and above the payment they command for their own services. The record certainly shows that there are investment funds that have outperformed random portfolios with equivalent risk. However, such superior performance is generally either limited to relatively short periods of time or, where it persists long, to a small enough number of firms that it could have occurred by chance. Moreover, these results are based on past performance with no certainty about performance in the future.

An alternative view cites increasing evidence on the inability of professional firms, or anyone else for that matter, to consistently outperform the market. This view is premised on the belief that the markets for equities and debt are indeed highly efficient in the sense that prices at any time reflect market judgment obtained from all available information. Furthermore, as new information (on earnings, production, losses, sales, discoveries, etc.) becomes available, it is so quickly reflected in current prices that no market participant can take action to benefit from it. Finally, if the new information becomes available in a random, unpredicted fashion, it will generate price movements that essentially follow a random walk.

Those analysts ascribing to the "efficient market hypothesis" believe that a "buy and hold" strategy will yield rates of return that are at least comparable

with and perhaps superior to those arising from any other investment strategy. The only potential for increasing expected returns occurs because some investments fall into higher risk classes than others and yield a higher expected rate of return to account for the greater risk. Hence, only a willingness by the investor to bear greater risk will lead to higher expected returns. These conditions lead to the following general investment strategy. First, choose a risk class of securities that is commensurate with the investor's risk preferences. Then buy and hold a well-diversified portfolio of securities within that risk class. The result is an expected rate of return that is as good or better than any other investment strategy. Finally, periodically monitor the portfolio to check for changes among risk classes in individual securities. Only changes among risk classes warrant portfolio revision.

The "buy and hold" is not a totally naive strategy. It requires identification of risk classes, effective diversification within the risk class, and monitoring for changes in risk classes. Hence, management is needed. In the AAEA's consideration of returns arising from external versus internal portfolio management, the key questions appear to be whether the AAEA could perform the tasks needed to follow a "buy and hold" strategy and, if so, whether its results would be comparable with those of professional management.

Willingness to act. One of the major concerns with respect to portfolio management is the willingness to act based on available information. A committee of AAEA members may be hesitant to act because of potential criticism that they may receive from colleagues if performance is below expectations or because of lack of strong consensus on the appropriate action. This type of problem could be solved by delegating responsibility to a professional management service.

Accountability. The payment for services rendered may lead to a higher degree of accountability for professional management than with internal management. In addition, inadequate performance may be more easily corrected in a professional service. Potential problems in interpersonal relationships in internal management could be reduced with professional management where termination of services could occur without concerns about criticizing personal friends and colleagues. In like fashion, discussions of lack of performance could occur without concern for the "personalities" involved.

Time commitment and timeliness. Portfolio management requires a commitment of time and timely decisions in response to market changes that warrant portfolio adjustments. A professional management service whose primary functions were to manage such portfolios would be compensated for making such a time commitment. In addition, a professional service that monitors financial markets more closely than an informal investment committee should be more responsive to market changes that warrant portfolio adjustments. However, the timeliness criterion may not be as crucial for internal management following an investment strategy suggested by the efficient market hypothesis.

A Specific Proposal

A specific procedure is recommended by the Finance Committee to manage the AAEA portfolio. It is a combination of the "internal" and "external" management options. In general, the procedure would involve the specification of goals concerning the desired performance of the portfolio (current income, growth in dividends, risk), periodic reviews of the portfolio by a brokerage house or investment service holding the account, and implementation of any recommendations concerning changes in the portfolio by a committee of AAEA members. Such a procedure would provide flexibility in utilizing the services of several advisory services if conditions warrant, would offer lower cash costs than the professional service option, and would enable the Association to move from growth-oriented equity issues to income-oriented debt issues as market rates or needs of the Association change.

The steps to be followed in implementing this procedure follow. (*a*) Specify and periodically review the goals concerning portfolio performance. These goals will include the risk, current income, and growth dimensions of the portfolio. For 1977 conditions the following objectives on performance are recommended: choose a low risk portfolio of securities, achieve a 7.0% annual rate of return, and achieve a 5.0% rate of growth in dividend payout. Initially, the portfolio will be comprised approximately of 85% equity issues and 15% debt issues, although these proportions may change as national economic conditions change.

(b) The portfolio will be managed according to the "efficient market hypothesis" discussed earlier. The following procedures will be used. *(i)* A minimum of two reviews of the AAEA investment portfolio will be conducted each year as part of the responsibility of the Finance Committee. These reviews and resulting actions will be completed before each regular meeting of the AAEA Board of Directors.

(ii) A portfolio subcommittee of the Finance Committee, consisting of two members of that committee plus the secretary-treasurer, will undertake an initial review and analysis. As part of this process at least one other set of professional opinions concerning the portfolio will be obtained besides that of the brokerage firm currently holding the AAEA portfolio. The subcommittee will be encouraged to use the expertise of selected AAEA members and/or facilities of their employers as they deem necessary and appropriate.

(iii) The portfolio committee will present a sum-

mary of their analysis and recommendations to all members of the Finance Committee for review and discussion. The Finance Committee, as a whole, will recommend specific actions on portfolio changes including specific risk management procedures to all AAEA Board members. Both the recommendations and explanatory materials will be forwarded to all Board members.

(iv) Changes in the portfolio will be authorized with the agreement of two-thirds of AAEA Board members. If such approval is not received, no changes in the portfolio will occur. Board members wishing to indicate a negative response must notify the chairman of the Finance Committee within two weeks after receiving a recommendation; otherwise, a positive response to the recommendation will be assumed.

(v) Review of individual transactions made with respect to the investment portfolio will be an agenda item for AAEA Board meetings. Discussion of procedures followed by the Finance Committee, mechanisms used to review the portfolio, and specific target objectives for managing the portfolio will be appropriate items for discussion.

Prepared by the Finance Committee
B. F. Stanton, Chairman

Report of Tellers Committee

Ballots received from the secretary-treasurer of the AAEA were counted in accordance with the bylaws of the AAEA to preserve the secrecy of the ballots. Candidates receiving the largest number of votes were: Bernard F. Stanton for president-elect, and G. Edward Schuh and Joseph D. Coffey for directors.

Report of the Editor

When I became editor three years ago, a committee to evaluate the *Journal* had just completed its report. They made seven recommendations to the editor, and in the first part of my report I summarize the responses made to the recommendations. I also comment on certain premises (views about the *Journal*) that served as a basis for the recommendations. I conclude with a discussion of the current status of the *Journal*.

Three of the evaluation committee's recommendations related to the mechanics of journal operation such as making authors anonymous in the review process. These were helpful suggestions, and it was relatively easy to respond to them. Another recommendation suggested that review articles be commissioned. Since the AAEA is publishing a three-volume literature review, I commissioned only one such article. It appears in the August 1977 issue.

Three other recommendations followed from views that articles in the *Journal* are usually methodological in nature and that few policy-oriented papers are published. The committee suggested that articles include only "essential" mathematics and that the editors instruct authors to focus on the policy implications of their work. In addition, articles dealing with problems, ideas, and issues in a literary style should be given full consideration. Nonmathematical essays are, of course, welcomed by the editor, and we have worked to eliminate redundant and unnecessary mathematics. While it is difficult to force authors to highlight the policy implications of their analyses, the editorial staff has stressed this point on many occasions.

The implementation of these recommendations has probably been beneficial, though readers must judge whether observable changes have occurred. However, in my view, the general premises that served as a basis for the recommendations are misleading. Moreover, the recommendations involve cosmetic-type changes to submitted manuscripts. Thus, the potential benefits of implementing the recommendations could be exaggerated.

Perhaps the greatest myth perpetuated by the evaluation report is that the *Journal*'s contents are highly methodological. Related to this myth is the charge that current and past editors select only methodological papers for publication. Just the opposite is nearer the truth. Our profession is applications oriented; the majority of manuscripts received are empirical applications; and the material published is mainly of an applied character. Those who doubt this view should examine the entire contents of the *Journal* for the past several years. I also invite comparison with the *American Economic Review* or other leading economics journals. I believe that such examinations will show that the *Journal* is an applied journal both in a relative and in an absolute sense.

The editors—past and present—have been open to diversity in submissions. For example, in 1976–77, seven manuscripts directly related to teaching were submitted. Four were accepted for publication, an acceptance rate substantially above the average for all manuscripts. Varden Fuller in his 1971 report and Max Langham and Leo Polopolus in 1974 admitted to similar "biases" toward contributions in extension, teaching, and business. This long-time emphasis by editors on breadth in the *Journal*, however, does not stimulate much response in terms of submissions.

Another misleading premise of the evaluation report is that published articles do not address current

policy issues. Again, I invite review of the *Journal*'s contents. One will find papers on many current policy issues such as energy, land use, rural labor, price stabilization, and dairy imports. A more accurate criticism is that many published articles are not useful for public or private decision making nor do they always provide useful ideas or insights. The real challenge is how to stimulate more manuscripts that have direct decision-making applications. If received, editors would be delighted to publish them.

Still another misconception is that a large number of high quality papers are rejected. While editors sometimes make incorrect decisions, the material published is largely determined by what is submitted. Thus, the major determinant of the *Journal*'s quality is the quality of submissions. Put another way, the actions of the editor—in selecting manuscripts, in screening out redundant mathematics, in issuing invitations, in being open to essays, and so forth—are not the major determinants of the *Journal*'s quality. As a necessary condition, authors must contribute the thought, time, and effort to produce high quality manuscripts. This is a challenge to the entire profession, not just to the editor.

A policy implication of the foregoing is that the marginal returns in terms of quality to making further evaluations of the *Journal*, making changes in the *Journal*'s format, or in cosmetic editing of manuscripts are not large. Rather, a more interesting question is: can the AAEA do more to stimulate high quality research and writing on topics of special relevance to agricultural economists?

Turning to the routine duties of your editor for the past year, I continued to devote considerable time to the business management of the *Journal*. This included serving on an ad hoc page charge committee (reported elsewhere), granting numerous permissions to reprint material, as well as other correspondence. The editors-elect, V. James Rhodes and Stanley R. Johnson, visited Cornell in April to discuss the transfer of the editorship. The new printing contract is working reasonably well, and the *Journal* is living within the budget.

Table 1. New Submissions, Manuscripts Published, and Publication Rate, 1967/68–1976/77

Year	Number of New Submissions[a]	Number of Manuscripts Published	Publication Rate (%)
1967–68	212	100	47
1968–69	268	105	39
1969–70	249	95	38
1970–71	250	96	38
1971–72	264	96	36
1972–73	263	90	34
1973–74	285	98	34
1974–75	332	91	27
1975–76	263	92	35
1976–77	311	90	29

[a] Excludes proceedings papers and book reviews.

In 1976–77, 311 new submissions were received, and 90 refereed articles and notes were published in 1977 (table 1). In addition, five folders were forwarded to the new editor with a recommendation to publish in 1978. These were manuscripts that could have been published in 1977 except for a budget constraint. This is the first time in my editorship that the budget has been a constraint on publication, but it is too early to tell whether a backlog of manuscripts will build up. In my three-year editorship, 906 new manuscripts were received, and 273 (30%) were published. This does not mean that 70% of the submissions were rejected, but often the revisions required are so large that authors choose not to make them.

The number of manuscripts published per year has ranged from 90 to 105 over the past 10 years (table 1). Typically, 90 to 95 refereed pieces are published. However, the total number of pages per

Table 2. Allocation of Pages to Alternate Types of Material

Year	Refereed Papers: Articles	Refereed Papers: Notes[a]	Proceedings Papers	Misc.[b]	Proportion Pages Refereed	Total Pages (No.)

volume has increased about 10% from 1971 to 1976 (table 2). I doubt that this was a conscious decision, but I hope that the AAEA's budget is sufficiently flexible to absorb additional modest growth if acceptable papers become available.

Of the total pages published per year, about 55% are devoted to reviewed papers, 30% to proceedings papers, and 15% to miscellaneous material (table 2). In essence, the editor and the book review editor have direct control over about 60% to 65% of the material in the *Journal*. Invited proceedings papers, abstracts of contributed papers, committee reports, and other miscellaneous material constitute the remainder. Whether or not this balance is appropriate is a matter of judgment. I recommend that from time to time the AAEA Board undertake a conscious review of the trade-off between invited and reviewed papers. Obviously, this becomes more important if the budget should become a constraint to the prompt publication of high quality, refereed manuscripts.

Jim Rhodes and Stan Johnson have my best wishes as they assume the duties of the editorship. In parting, I wish to express appreciation to a number of persons for their cooperation and assistance: the 434 reviewers (table 3), the editorial council (Martin E. Abel, Garnett Bradford, Rachel Dardis, Gene Futrell, Ray A. Goldberg, Richard C. Haidacher, Dale M. Hoover, Timothy E. Josling, Gordon A. King, Donald W. Kloth, Ronald Lacewell, Wyn F. Owen, Darrell Plaunt, Robert Raunikar, Herbert H. Stoevener, and Finis Welch), the *Journal* secretary, Ruth Mezei, the assistant editor, Nancy Larrabee, the book review editor, Francis Walker, and my associates, Richard Boisvert and Donald Freebairn. I also want to acknowledge the cooperation of my Cornell colleagues as I borrowed their secretaries and asked for their assistance in identifying reviewers. Finally, I wish to express my gratitude to the members and to the Board of the AAEA for the opportunity to serve as editor.

William G. Tomek, editor

Report of the Awards Committee

The Awards Committee this year helped to develop a statement for a Distinguished Policy Contribution Award (published in the November 1977 issue), a recommendation on the question of restricting nominees for awards to AAEA members (appendix), and a nomination document for the Browning Award. As part of its regular duties, it conducted the various competitions and selected the winners.

The delays and frustrations associated with the weather and postal services were much greater than in previous years. In consequence, substantial extra costs were incurred by departments in duplicating lost or undelivered documents, and deadlines had to be extended. Problems arose with both the master's and doctoral awards because one or more members of the committee had served as major professor for a thesis in the competition. Such committee members abstained from voting on that entry, but this in turn distorted the outcome. Supplemental judges were used and rereading of the top six entries was required to resolve one such situation. However, no change is recommended since when members are appointed to a committee for a three-year term, there is no way of knowing what entries will be submitted.

Suggestions made by members for improvement can and will be incorporated into the operational framework for next year. The Awards Committee structure works smoothly and functions well. Cooperation from committee members is excellent. Their contribution to the AAEA and through it to those who are recognized is indeed great and is made without fanfare or public acclaim.

The AAEA award winners for 1977 appear below.

Distinguished Extension Program

Less than ten years. **Otto C. Doering III,** associate professor, Purdue University.
Ten or more years. **Phillip C. Baumel,** professor, Iowa State University.

Distinguished Undergraduate Teaching

Less than ten years. **David E. Hahn,** associate professor, Ohio State University.
Ten or more years. **Milton M. Snodgrass,** professor, New Mexico State University.

Outstanding Master's Degree Program

Douglas C. Holliday. "An Analysis of Economic Relationships and Performance in the Canadian Broiler Industry." University of Guelph (adviser: L. J. Martin).
Andrew M. Novakovic. "The Impact of Imports of Manufactured Milk Products on the United States Dairy Industry." Purdue University (adviser: Robert L. Thompson).
Eugene S. Rosera. "The Economic Impacts of Industrialization on a Rural Louisiana Economy: La Salle Parish." Louisiana State University (adviser: L. J. Guedry).

Outstanding Doctoral Degree Program

Nancy E. Bockstael. "Analysis of Investment Behavior and Price Determination: Analytical Input for the Formation of Policy in the Fisheries." University of Rhode Island (adviser: Darrell L. Hueth).
Geraldo S. De Camargo Barros. "Asking Wages, Market Wages, and the Off-Farm Supply by Farm Operators." North Carolina State University (coadvisers: Walter J. Wessels and Dale M. Hoover).
Bruce L. Dixon. "A Stochastic Control Approach to Harvest Scheduling in a National Forest." University of California, Davis (adviser: Richard E. Howitt).

Quality of Research Discovery

J. A. Edwards, K. C. Gibbs, L. J. Guedry, and H. H. Stoevener. *The Demand for Non-Unique Outdoor Recreational Services: Methodological Issues.* Oregon Agr. Exp. Sta. Techn. Bull. 133, May 1976.
Ronald W. Ward. *The Economics of Florida's FCOJ Imports and Exports: An Econometric Study.* Florida Department of Citrus, Econ. Res. Dep. Rep. 76-1, Aug. 1976.
Honorable mention: Oscar R. Burt. "Ground Water Management and Surface Water Development for Irrigation." *Economic Modeling for Water Policy Evaluation,* pp. 75–95. Amsterdam: North-Holland Publishing Co., 1976.
Honorable mention: S. R. Thompson, D. A. Eller, and O. D. Forker. "An Econometric Analysis of Sales Response to Generic Milk Advertising in New York State." *Search-Agriculture,* vol. 6, no. 3. Cornell University Agr. Exp. Sta., 1976.

Quality of Communication

W. W. Cochrane and Mary E. Ryan. *American Farm Policy 1948–1973.* Minneapolis: University of Minnesota Press, 1976.
Honorable mention: John G. McNeely and Ronald D. Lacewell. *Flood Plains Management.* Texas A&M University Agr. Exp. Sta. B-1166, Nov. 1976.
Honorable mention: George F. Smith and M. B. Badenhop. *An Economic Evaluation of Environmental Quality: Opportunity Costs of Channelization and Land Use Change in The Floodplain of the Obion-Forked Deer River Basin of West Tennessee.* University of Tennessee Agr. Exp. Sta. Bull. 522, Dec. 1975.

Publication of Enduring Quality

Karl A. Fox. *Econometric Analysis for Public Policy.* Ames: Iowa State University Press, 1958.

Outstanding Journal Article

Per Pinstrup-Andersen, Norha Ruiz de Londoño, and Edward Hoover. "The Impact of Increasing Food Supply on Human Nutrition: Implications for Commodity Priorities in Agricultural Research and Policy." *Amer. J. Agr. Econ.* 58 (1976):131–42.

Appendix

The Awards Committee was asked whether the AAEA's awards should be restricted to AAEA members. Only one member of the committee suggested without qualification that competitions be restricted to AAEA members. It is, therefore, the recommendation of the committee that the AAEA should not restrict its awards to members only.

The AAEA must first decide the basic issue of why it has an awards program—to encourage and recognize outstanding contributions by agricultural economists or by AAEA members. If it is the former, the question is answered, and contestants would not have to be AAEA members. If it is the latter, obviously those who are not current AAEA members would not qualify. This might cause difficulty where a person had his membership cancelled for nonpayment of dues by a specific date. Even then contestants for the Outstanding Master's Program and Outstanding Doctoral Program do not submit their own thesis in competition and do not even know that has happened and should not, therefore, be required to be AAEA members; otherwise, departments might be forced to submit their fourth or fifth best thesis.

While there is a valid argument that persons nominated for the other awards should be interested in and actively participating in the profession, it is more than counterbalanced by the realization that all agricultural economists as well as society at large benefit from these outstanding contributions and recognition of them.

The majority of the Awards Committee agree. Therefore, the recommendation of the committee is that the AAEA recognize outstanding contributions

within the profession rather than only within the AAEA.

A. Gordon Ball, chairman

Report of the Postwar Literature Review Committee

Volume I has been available for purchase by AAEA members from the AAEA and by others from the University of Minnesota Press since December 1976. All the material for volume II is in the hands of the Press, the copy editing is complete, and almost all the corrected galley proofs have been returned by the authors. The expected publication date is November 1977. Volume II is entitled *Quantitative Methods in Agricultural and Resource Economics, 1940s to 1970s*. It was edited by George Judge, Richard Day, S. R. Johnson, Gordon Rausser, and Lee Martin. The table of contents is reported in the December 1976 issue of the *Journal*.

When completed, volume III will be entitled *Economics of Welfare, Development and Natural Resources, 1940s to 1970s*, edited by Lee Martin. The table of contents will be approximately as follows.

I. "Economics of Rural Poverty" by Lee Bawden and Keith Bryant.
II. Rural People, Communities and Regions, George Tolley, coordinator
"Economic Bases for Growth" by Clark Edwards.
"Rural Development: Problems and Prospects" by Dean Jansma, Hays Gamble, Pat Madden, and Rex Warland.
"Population Distribution: Migration and Settlement Patterns" by Marian Clawson and P. Graves.
III. Agriculture in Economic Development
"Africa" by Carl Eicher.
"Asia" by John Mellor.
"Latin America" by Edward Schuh.
IV. "Natural Resource Economics, 1946–1975" by Emery Castle, Maurice Kelso, Joe Stevens, and H. H. Stoevener.
V. "Philosophic Foundations of Agricultural Economic Thought" by Glenn Johnson.
VI. "Organization and Performance of Agricultural Markets" by Peter Helmberger, Gerald Campbell, and William Dobson.

The surveys of "Natural Resource Economics" and "Rural Development" have reached us in final form. The Edwards survey is being prepared in final form at the present time. We expect first drafts from Glenn Johnson, Carl Eicher, and Edward Schuh in the next three or four weeks. We have been promised the other four first drafts within the next three months or earlier. We anticipate having all the material to the University of Minnesota Press by March 1978 or perhaps a little earlier. That would yield a publication date of September or October 1978.

Lee R. Martin, chairman

Report of Committee on Publication of Postwar Literature Review

An agreement dated July 1976 between the AAEA and the University of Minnesota Press for publication of volume II of the Review was signed. Terms of the agreement were essentially the same as for volume I. Volume II is scheduled for delivery in December 1977.

Sales of volume I as of 15 June 1976 amount to 433 copies, of which 201 went to AAEA members. An additional 50 copies were distributed for reviews. The Press has taken steps to expand sales outside the United States, and the AAEA has sent material to members informing them of the special purchase price. Royalty on the above nonmember sales amounts to $1,160 (232 copies × $5.00) and thus recovers part of the AAEA $7,500 grant in aid for publication.

The committee will negotiate terms of an agreement for volume III after its acceptance by the Press and will make recommendations to the Board.

Emerson M. Babb, chairman

Report of Literature Retrieval Committee

The Literature Retrieval Committee held a breakfast meeting in San Diego on 1 August 1977. Planning and other activities have been carried out through correspondence and telephone, while several committee members have talked with Mr. Ogden and Miss Kenyon at the demonstrations they have been giving at major meetings of agricultural economics organizations. We believe that the demonstrations have been helpful in encouraging agricultural economists to send their publications, with abstracts, to the American Agricultural Economics Documentation Center, although much remains to be done by members of the committee and the university cooperators.

Members of the committee have been active in securing interested cooperators at the land grant universities and other institutions. This is a task that requires continuing attention. Our greatest need is to make agricultural economists aware of the availability and usefulness of the literature retrieval system. Committee members and Documentation Center staff must give emphasis to this effort. We also urge members of the Executive Board to make the profession more aware of this resource.

The following points on the first nine months of the operation of the Documentation Center under

the new arrangement deserve special mention. (*a*) The Center is currently adding citations to the information base at the rate of 2,400 a year, compared with 800 a year in prior years. (*b*) The Center staff and the Literature Retrieval Committee are investigating the possibilities of closer cooperation with WAERSA (World Agricultural Economic and Rural Sociology Abstracts). (*c*) Cooperative arrangements with the National Agricultural Library have reduced duplication and made the Documentation Center responsible for accessioning articles in all U.S. and Canadian agricultural economics journals and all Economic Research Service publications. (*d*) Substantial economies have been made in the cost of each entry in the data base. The proposed AAEA budget for next year is basically the same as for this year. However, Director Kenyon urges that the Board consider adding $12,000 to this budget to hire an additional person to assist in indexing and terminal operation.

The committee recommends that the Literature Retrieval Committee be extended as presently constituted for another year, that the Executive Committee approve the budget as submitted and give serious consideration to an additional sum of $12,000 to hire an additional person, and that the Executive Board endorse further explorations with the Canadian groups and WAERSA to achieve further coordination of the information retrieval programs.

Wayne D. Rasmussen, chairman

Report of the Professional Activities Committee

This committee has held one lengthy meeting and used the mails to conduct two substantive pieces of business during 1976–77. In midwinter the committee prepared a policy statement regarding the AAEA's posture toward sponsoring and/or endorsing seminars, colloquia, and symposia. The statement was returned for amendment before being adopted by the Board. The committee also began inquiries into the possible use of the National Science Foundation's (NSF) "Science for Citizens" program, in which the NSF underwrites activities that provide opportunity to increase public awareness of the impact of scientific achievement on the welfare of U.S. society. These inquiries are continuing.

At a two-day meeting in April, the committee continued its deliberations on the selective and collective goods offered by the AAEA, the organization of the AAEA, and the future configuration of the AAEA. The committee also took leadership in preparing the "AAEA—Issues and Answers" session for the 1977 annual meeting.

The organization's future is intimately bound up in its capacity to deliver goods and services that are useful to the membership. An element of disquiet seems to pervade the AAEA, so it can be inferred that the AAEA is not acting to capacity. A strategy to cope with disquiet should be developed. This strategy should recognize the changing nature of the profession and of the individual professional. It should include elements of retraining, a new configuration for publications, and a new base for AAEA membership. Although these dates are subject to modification, this committee feels that by 1980 the AAEA should have an updated and responsive set of publications and a retraining program available to agricultural economists. By this date, the AAEA should also have a policy of broadening membership to include more undergraduate students and more professionals who currently work in occupations outside the federal government, the land grant system, and the major private firms.

The AAEA should work toward reorganization by 1985. The reorganization should make a specific place for the several subdisciplines now recognized within agricultural economics. It should also have a permanent secretariat and expanded involvement of the president-elect in program planning.

At the request of President Farrell and President-Elect Hildreth, the committee examined the role and interrelationships among several standing and ad hoc committees. We recommend that the visiting lecturer program and committee be discontinued unless a suitable source of funding can be found to sponsor its intended activities; that a program committee be established to assist in planning the content of the annual meeting; that the Professional Activities Committee have one of its members enjoy joint membership on the Alternative Publications Committee; and that the Professional Activities Committee have one of its members enjoy joint membership on the Industry Affairs Committee.

The committee feels that a number of significant issues need in-depth study by the AAEA and its membership. This is not easily accomplished. One method of attaining this goal is by publishing analyses of issues in the *Journal* or in some other AAEA publication. To that end, we recommend that the president and the editor collaborate in commissioning articles dealing with (*a*) accreditation and certification of agricultural economists; (*b*) the AAEA: a federation or a guild?; (*c*) keeping up with the expanding boundaries of economic knowledge; and (*d*) the complexity of present information systems.

The committee feels that many issues surrounding the quantity and quality of individuals in the profession could be solved in the teaching departments that now train the nation's agricultural economists. The AAEA should go on record as encouraging chairpersons and heads of these departments to become more insistent about updating the skills of their staff and integrating the packages of services they provide for both undergraduate and graduate students.

The next year will see intensive committee involvement in the Science for Citizens program, retraining and updating of agricultural economists, and alternative forms of organization for AAEA membership.

Paul W. Barkley, chairman

Report of the Economic Statistics Committee

The terms of Harry Trelogan, Quentin West, and James Hildreth expired, and they were replaced on the committee by Arlo Biere, Kansas State University, Howard Hjort, director of Agricultural Economics, USDA, and Norman Whittlesey, Washington State University.

The principal activity of the committee during the past year was the sponsorship of the Agricultural and Rural Data Workshop in conjunction with the Statistical Reporting Service, Economic Research Service, and Agricultural Marketing Service of the U.S. Department of Agriculture. Held 4–6 May 1977 in Washington, D.C., the workshop brought together data producers and users to develop suggestions and recommendations for use by agencies responsible for improving data and data series. The workshop was comprised of two series.

The topic for series A was price reporting and capacity of the food and fiber system (William Kibler, leader). Team leaders were James Bonnen, Michigan State University (price reporting), and Earl Swanson, University of Illinois (capacity of the food and fiber system).

The topics for series B were indicators of economic well-being of people engaged in farming and farm and rural employment data (Gaylord Worden, leader). Team leaders were Luther Tweeten, Oklahoma State University (data for indicators of well-being of people engaged in farming), James Holt, Pennsylvania State University (definition and measurement of farm employment), and Clark Edwards, Economic Research Service, USDA (employment data for rural development research and policy).

The workshop was well attended; the discussion was lively and constructive. Papers were revised after the workshop. Series A papers are being published by the Statistical Reporting Service (Bill Kibler, liaison) and the series B papers by the Economic Research Service (Ed Reinsel, liaison). In addition, a seminar is being held at the San Diego meeting to summarize the proceedings of the workshop. In addition to revising papers presented at the workshop, each team is preparing a plan of action (two to three pages in length) to use as a concise statement for administrators and policy makers in appraising action to implement operationally the recommendations from the papers.

The Economic Statistics Committee met after the workshop. In addition to laying the groundwork for publication of the workshop proceedings, the committee recommends several actions requiring approval of the Executive Board of the AAEA.

(*a*) The committee requests the Executive Board to approve the commissioning of two task forces to lay out the conceptual framework and operational guidelines for implementation on the following respective subjects: the economic value of statistical information (Bill Kibler will arrange for a task force to carry out the project based on suggestions from the Economic Statistics Committee) and measuring agricultural productivity (Luther Tweeten will arrange for a task force to carry out the project based on suggestions from the Economic Statistics Committee). Personnel from the USDA as well as "outsiders" will be included on these task forces.

(*b*) The Economic Statistics Committee requests that the Executive Board empower the committee to appoint an ad hoc task force on "Survey of Agricultural and Food Outlook." The purpose of the task force is to investigate the feasibility of a periodic survey of agricultural and food outlook specialists to obtain their forecasts for agricultural prices, production, etc., and to disseminate and evaluate the results in a suitable manner. The task force is to design a system to accomplish said tasks on a regular schedule. If the proposal of the task force appears workable and desirable in the judgment of the Economic Statistics Committee, the committee will present the proposal to the Executive Board for approval before implementation on a regular basis.

(*c*) The committee proposes the appointment of a statistics editor for the *American Journal of Agricultural Economics*. The role of the editor would be to commission reviews of new and existing statistical data series. The reviewer would discuss the underlying concepts measured, the conceptual difficulties with the series, the collection procedure used, the period covered by the series, and the procedure for obtaining the data from the agency responsible for the data (see appendix).

(*d*) The Economic Statistics Committee recommends that an insert be made in the *Journal* publicizing the availability of the proceedings of the Agricultural and Rural Data Workshop.

Appendix

The AAEA Statistics Committee recommends that the Board of Directors of the American Agricultural Economics Association create the office of the statistics review editor of the *American Journal of Agricultural Economics*.

AAEA membership is made up predominately of applied economists with teaching, research, and extension interests in commercial agriculture and the rural economy. As applied economists, we need to be kept abreast of developments in the theoretical

and quantitative literature, and we need a vehicle for publishing such developments and their applications to commercial agriculture and the rural economy. The present structure of the *Journal* adequately performs these functions.

As applied economists, we also need to be kept abreast of developments in the statistical data system through which we take measurements on and with which we analyze commercial agriculture and the rural economy. We believe that the *Journal* is not currently serving its readers well in this regard. But, we believe that the institution of a statistics review editor of the *Journal* would rectify the situation.

Agricultural economists currently individually have the responsibility for keeping up to date with developments in the federal and state data system as well as discovering and obtaining relevant bodies of data lying outside the federal data system. Keeping abreast of the federal data system is difficult unless the individual is plugged in to a particular data collection agency, is an individual member of the Federal Statistics Users Conference (which is very expensive), or subscribes to *The Statistical Reporter* (an obscure publication of the Office of Management and Budget).

A statistics review editor could aid the membership greatly by (*a*) commissioning critical reviews of new data series or bodies of data that become available in the federal system; (*b*) commissioning critical reviews of old data series and existing bodies of data that are in the process of revision; (*c*) periodically making known new data sources that occur outside the federal system in much the same way as the book review editor currently publishes a list of publications received; and (*d*) commissioning critical reviews of new bodies of data emerging from outside the system. An example of (*a*) might have been a review of the public use tapes from the population or agricultural census. An example of (*b*) might have been a critical review of the changes in the consumer price index. Examples of (*c*) and (*d*) might have been to announce the availability of and perhaps to review the data set from the rural income maintenance experiment or data on dairy products consumption developed privately.

The work of the statistics review editor would also aid the agencies responsible for producing and maintaining the federal data system because the reviews would constitute important feedback to them.

The AAEA Statistics Committee does not visualize that the statistics review editor need have space in every issue of the *Journal*. Space should be provided only as data developments justify. The book review and the statistics review editors may be able to share the same space, working out a schedule format enabling both important books and important changes and developments in the data system to be critically reviewed as they arise.

Report of the Committee on Management, Structure, Methods, and Procedures

President Farrell appointed the above titled committee on 29 March 1977 and gave the committee an assignment with three principal objectives: (*a*) to review the management, structure, methods, and procedures of the AAEA and to then make recommendations that would enhance the quality of service to members and the efficiency in operations of the AAEA; (*b*) to examine the feasibility of establishing an AAEA executive office for program management; and (*c*) to review the performance of the secretary-treasurer during the past three to five years. The latter review is in keeping with the operating procedure prescribed for the Executive Board at the Edmonton meetings in August 1973.

The entire committee met in Minneapolis on 31 May 1977. After an extended discussion in the committee, we agreed to interpret our assignment as one with three principal focuses.

The first is to learn as much as possible about the current operation of the AAEA and to suggest useful improvements. The job here seems to be the one of learning as much as possible about each significant and identifiable activity of the AAEA. Then we need to develop some perspective on what the AAEA is locked into in the way of future activities. Finally, we need to project where future AAEA activities appear to be headed in terms of content and cost and then to suggest whatever useful improvements might be implemented. Our focus is intended to be on improving the efficiency and management of these operations, not to prioritize activities in which the AAEA should be engaged.

A second need is to examine in detail the control and decision-making framework within the AAEA. Here, the emphasis is on identifying the role played by individuals and groups, although it will also be necessary to obtain some information on performance in these various roles. At a minimum we would need to identify the role and performance of the secretary-treasurer, the AAEA board of directors, the president, the president-elect, and the past president. Our examination of the control and decision-making framework should include consideration of financial management, planning, implementation, and evaluation of services.

Finally, as quickly as feasible we need to undertake an inquiry into the possibilities for creating a managerial structure for the AAEA that would improve the effectiveness of its operation. This inquiry would likely involve an appraisal of several alternatives including but not necessarily limited to the following: (*a*) continuation of the current decentralized operation but with more specified coordination, (*b*) contracting with other professional groups, such as the American Society of Agronomy, for additional managerial services, and (*c*) establishing

a separate executive office for management either in Washington or at some alternative location.

Two subcommittees were appointed. A committee of Dick Crowder, Lou Eisgruber, Neil Harl, and John Stovall will have the responsibility for implementing the first assignment, that of learning as much as possible about the current AAEA operation. Lou Eisgruber agreed to chair this committee, which would also have the responsibility for establishing a procedure for initial inquiry into the third job.

A committee of Wally Barr, Olan Forker, Leo Polopolus and Burt Sundquist, chairman, will undertake the second assignment, that of examining the control and decision-making framework within the AAEA. One of the assignments of this second subcommittee would be the one of carrying out the required periodic evaluation of the office of the secretary-treasurer.

It was agreed that it would be desirable if the two subcommittee chairpersons or their representatives, could sit in a good part of the Board meetings at the San Diego meetings in order to become better acquainted with the current operation including the decision-making framework. President Farrell extended an invitation to do so to Eisgruber and Sundquist.

Subcommittee 1 decided to approach their assignment by asking four questions: (*a*) which individuals, groups, or institutions should be contacted, (*b*) what information should be acquired from them, (*c*) how should this information be acquired, and (*d*) when should the information be acquired?

The following suggestions were made. (*a*) Contact should be made with all AAEA committees (for this purpose a complete list of committees needs to be established, and President Farrell has agreed to provide the subcommittee with such a list) and with all members of the AAEA Executive Board as well as the secretary-treasurer, operator of the Registry of Agricultural Economists, editor of the *Journal*, individuals responsible for the organization and program of the annual meetings, the past and present AAEA presidents since 1967, all members of this committee, and others as identified.

(*b*) With respect to information that should be collected, the following was suggested. What was the specific charge of the individual or group perceived to be, what in fact did it turn out to be, what were the resources used including both human and monetary resources, what were the blockages to effective management of the activity, was the charge, in general, effectively met, to what degree was it met with respect to the adequacy of the following dimensions—information, organization, finance, and planning, was membership on the committee or board representative, what was the degree of participation on the committee or board, what are your suggestions for improvement of management, control, accountability, etc., who is (was) responsible for budget and membership of this group?

(*c*) With respect to the question of how the information should be collected, a personal or telephone interview was suggested for AAEA presidents since 1967. For the twenty-four past or current members of the Board of Directors, a printed questionnaire was suggested. A printed questionnaire was also suggested for use in soliciting information from AAEA committees.

(*d*) With respect to when information should be collected, we shall ask for the approval of the Executive Board of the AAEA at the San Diego meetings in order to initiate interviews as soon as possible. Approval should also be solicited at the San Diego meetings for a formal survey form to be used.

(*e*) With respect to the assignment for initiating inquiry into alternative organizational forms for AAEA management, the following suggestions were made: visit with Dave Boyne and Paul Barkley to obtain background on information which they have and select some of the more interesting professional associations and follow up with an in-depth interview on organization and style.

Subcommittee 2 suggested the following procedure for operation. Inquiries should be made relative to the role of all individuals occupying positions of significant control and decision making in the AAEA. We should try to obtain any available position description for officers and Board members. With respect to the office of secretary-treasurer, several duties of that office probably should be separated out and evaluated separately, since they are quite different functions. These include activities related to the membership function, the secretarial function, and the treasurer function. With respect to the office of secretary-treasurer particularly, it would be desirable to put together a brief historical account of the evolvement of that position in order to obtain perspective for evaluation. Some kind of a job description needs to be developed, if it is not already in existence, in order to serve as the benchmark for appraising performance of these several types of duties. Since the operation of the office of the secretary-treasurer is a very extensive one, an on-site inspection by at least a two-person subcommittee of the second subcommittee appears to be necessary. This subcommittee should also study the committee structure of the Board of Directors and of the total AAEA. This study should, however, pertain only to the issue of decision making and control.

In keeping with the time schedule suggested by President Farrell, we intend to ask approval of our procedures at the San Diego meetings, present an interim report at the 1977 winter meeting, and file a final report at the August 1978 meeting at Virginia Polytechnic Institute and State University.

Burt Sundquist, chairman

Report of the Professional Registries Committee

On 3 January 1977, the AAEA Executive Board adopted the following recommendations presented by the Professional Registries Committee in a report to the Board dated 28 December 1976: (*a*) take action declaring intent to enter into agreement with the Economic Research Service to operate a registry for agricultural economists, such agreement to be conditional upon development of a plan to generate the AAEA's share of project costs; (*b*) authorize the Professional Registries Committee to solicit commitments to fund the AAEA's share of project costs; and (*c*) approve the submission to the U.S. Department of Labor of new contract proposal to provide a final year's funding of the registry from the USDL. In addition, the Board directed the Registries Committee to continue explorations with the USDL regarding support to operate the registry beyond the period of the contract specified in (*c*) above.

On 6 January 1977, President Farrell submitted to the USDL a proposal for continuation of the USDL-AAEA demonstration project to operate and assess a computer-based employment system for agricultural economists. The extension to 15 February 1978 with additional funding in the amount of $32,800 was authorized by the USDL, and the contract modification was signed by President Farrell on 28 January 1977.

On 20 June 1977, Kenneth Farrell, Loys Mather, and David Boyne met with USDL officials in Washington. The primary purpose of the meeting was to explore possibilities for additional funding from the Department of Labor. The AAEA representatives participating in this meeting concluded that the chances are very slim for additional funding from any unit within the Department of Labor. It seems clear that we can not expect any funding from the Department of Labor as part of a financial package to support continuation of the registry beyond February 1978.

The Registries Committee has proceeded to solicit commitments to fund the AAEA's share of a joint AAEA-ERS project to operate a professional registry for agricultural economists. The 3 January 1977 report to the Board estimated the AAEA's share of joint project costs to be $14,100. The Registries Committee met on 10–11 March 1977 and agreed to map out a fund solicitation program with a minimum goal of $15,000. The following commitments have been received to date: agricultural economics departments in the United States and Canada, $7,750; Ford Foundation, $1,000; Statistical Reporting Service, $500; U.S. Agency for International Development, $5,000; Agricultural Marketing Service, $250; and Farmer Cooperative Service, indefinite. Ray Beneke and Richard Crowder are leading the business and industry effort. Beneke believes that we can reasonably expect at least $1,000 from this category.

The commitments received to date total $14,500, plus the minimum estimate of $1,000 from the business and industry category yields an expected total of $15,500. We believe that the commitments received and expected constitute a feasible financial plan for generating the AAEA's share of budget costs.

The Registries Committee in cooperation with the Employment Services Committee prepared an information flyer. Copies of this flyer were distributed to all U.S. and Canadian agricultural economics departments and to agencies of government and have been sent by the placement officer to other organizations and individuals. The Registries Committee also prepared an information leaflet entitled "Toward a Multiple Purpose Registry for Agricultural Economists." This leaflet has been used extensively in fund solicitation.

The committee recommends (*a*) authorizing the AAEA president on behalf of the AAEA to enter an agreement with the Economic Research Service to operate a Registry for Agricultural Economists (as a first step it is assumed that the president would designate an AAEA committee to work with ERS personnel in developing the terms and conditions of the agreement); (*b*) designating an AAEA committee to represent the AAEA in carrying out the terms of the agreement (it is assumed that one of the terms of the agreement would call for an AAEA committee to advise the ERS on matters related to the operation and further development of the Registry); and (*c*) authorizing the AAEA president to communicate in writing the Board's decision to consummate an agreement with the ERS to each organization that has made a commitment of funds and to confirm the amount of the commitment made by the respective organization or individual.

David Boyne, chairman

Report of the Employment Services Committee

In carrying out President Farrell's charge to the committee, the Employment Services Committee has been involved in the following activities during the past year.

U.S. Department of Labor Contracts

The committee took the leadership in developing proposals for one time extension of the AAEA-USDL contract (30 Sept. 1976 to 15 Nov. 1976) and for two project proposals obtaining an extension of time and additional funding (15 Nov. 1976 to 15 Feb. 1977 and 15 Feb. 1977 to 15 Feb. 1978). The current grant represents the final funding period with USDL for operation of the Registry. Arrangements for finance and operation of the Registry after expiration of USDL funding are being developed by the Professional Registries Committee.

Registry for Agricultural Economists

The committee is charged with supervision of the Registry. During the past year, the Registry assisted in placing ninety-six agricultural economists in either long-term or temporary job assignments. As of June, 181 job vacancies were listed and 2,192 agricultural economists were registered with the Registry. The committee commends George Vena, the placement officer, for the excellent service and leadership he is providing. The committee assisted the Professional Registries Committee in developing a bulletin board poster to provide information on the Registry and to promote its use among the profession.

Handbook-Directory

At President Farrell's request, the committee explored the feasibility of adapting the Registry for direct production of the next AAEA *Handbook-Directory* (i.e., providing camera-ready copy of biographical sketches from computer output). The committee recommends that the next *Handbook-Directory* be prepared from the Registry and that the necessary steps be taken to effect this change. These steps include making final determination of the content of biographical sketches printed in the directory and programming the necessary changes in computer format. If the Registry moves to another computer facility upon expiration of the

Table 1. Summary of Survey on Usefulness of Items in the *Handbook-Directory*, June 1977

Item	No Response	Rating: Of Little Use 1	2	3	4	Highly Useful 5	Weighted Score
Group I: Items that respondents indicated were highly useful							
Address (telephone)	3	9	11	17	33	196	4.44
Employer	5	5	5	45	75	134	4.16
Degrees held	4	10	8	34	94	119	4.09

Memberships in other associations	2	132	61	49	15	10	1.90
Listings in other directories	7	152	62	38	4	6	1.62

Note: 400 questionnaires were sent with 269 responses (67%).

Table 2. Estimated Costs for Computer Preparation of *Handbook-Directory*

One-time charges		
Direct program costs ($)		
Programmer, 1 month	1,200	
Computer	200	1,400
Joint costs of 1,000 additional persons added to the Registry ($)		
Labor ($3.50/hour)[a]	700	
Computer (60¢/registrant)	600	1,300
Charges associated with each *Handbook-Directory* edition		
Direct costs: computer output of 3,500 biographical sketches as camera-ready copy for printing ($)		
Computer	400	
Labor ($3.50/hour)[a]	28	428
Joint costs of updating biographical data of the additional 1,000 registrants prior to printing directory ($)[b]		
Labor ($3.50/hour)[a]	220	
Computer (30¢/registrant)	300	520

[a] Most of the labor charges could be absorbed by the Registry staff.
[b] Costs for updating biographical data of persons who are in the Registry for employment purposes are included in the Registry's regular budget. Their biographical data are updated each year.

USDL contract, some reprogramming will likely be required. If this reprogramming is done concurrently with the programming associated with the *Directory*, the AAEA should realize some cost savings.

Four hundred AAEA members were surveyed (67% response) to determine the opinion of members regarding content of directories. The survey results are summarized in table 1. Only a few minor changes in information collected by the Registry will be needed in order to provide the type of information the respondents considered useful in a directory. In addition, provisions can and should be made to allow each person to use the Registry for employment or directory purposes, or both. Table 2 summarizes estimated direct and joint costs. Direct one-time charges for developing the directory option are estimated at $1,400 for computer programming and related computer charges. Based on current operating costs, direct computer and labor charges are estimated to be under $450 per directory to prepare camera-ready copy for directory printing.

Annual Meeting Employment Services

As at previous annual meetings, employment services will be provided at the San Diego meeting. These services will be an extension of the year-round service provided by the Registry. The committee expresses its appreciation to the Illinois State Employment Services for equipment and supplies and to the agricultural economics departments at the Universities of Arizona, California–Berkeley, and California–Davis for labor to operate the service.

Report of the Membership Committee

Significant accomplishments during the past year include maintaining individual membership numbers at last year's levels despite higher dues and no *Handbook-Directory*, an increase in institutional members, full implementation and refinement of the target group approach to membership development, automation of membership lists of AAEA, regional associations and the Canadian Agricultural Economics Society, development and circulation of a membership information leaflet, and improved continuity of regional membership promotion by moving to joint appointment of regional and Canadian membership target group chairmen for three-year terms.

The primary challenge for the year ahead is to exploit the potential for increased membership made possible by developments of the past few years.

The Membership Committee now includes the chairmen of ten target group task forces, the AAEA secretary-treasurer, and the overall committee chairman. In addition, AAEA Executive Board member, Sylvia Lane, served as advisor to the Membership Committee and contributed a number of useful ideas.

It is difficult to relate the increased membership to specific activities of the Membership Committee or indeed to even attribute the increase to the committee's work. The effort by John Redman and his staff to contact all past members who had not rejoined and the action of the Executive Board to make membership a prerequisite to receiving certain benefits of the AAEA certainly had positive impacts on membership. Nevertheless, the efforts of the target group chairmen plus the mailing of the AAEA information leaflet to potential members hopefully had a "consciousness-raising" effect regarding membership in the AAEA.

The membership information leaflet was prepared with the assistance of the Division of Information, Economic Research Service, USDA, and distributed in a general mailing in late January. In addition, supplies of the leaflet were provided all target group chairmen.

At last year's committee meeting there was agreement that a more intensive membership development process required more information on potential membership and better methods for handling that information. Thus it was agreed that it would be highly desirable to have a computer tape and retrieval program for a master list of present and potential AAEA members. The tape could be

used to determine at any time who was a paid-up member and of which association. The retrieval program would allow sorting members and potential members according to a variety of criteria for use by the Membership Committee, by the president in making his appointments, and for reaching selected audiences with selective goods and services.

That tape has now been developed. It includes the names and other information provided on the 3,000 questionnaires returned in 1976 for the *Handbook-Directory*. In addition, the membership lists of the Southern Agricultural Economics Association, Western Agricultural Economics Association, and Canadian Agricultural Economics Society have been added to the tape and duplications eliminated. A membership list of the Northeastern Agricultural Economics Council will be provided soon and added to the tape. A software package has been developed that permits retrieval of any data on the tape for less than $5 per run. The program is operational and ready to be used. Special recognition is due William Freund of the ERS Data Services Center for contributing his time and ideas in the development of the tape and program. Emil Melichar of the Federal Reserve System provided editing services for the original tape and assisted in the development of the software package. Loyd Martin of the ERS developed information on AAEA committee assignments back through 1973, and this information has been added to the tape.

A challenge for the year ahead is to add to the usefulness of the tape by adding names of potential members of AAEA. Success in this regard will depend heavily on the effectiveness of the target group chairmen in developing a master list of potential AAEA members for their target populations. Some questions remain. A major effort and some expense will be involved in maintaining and updating the tape. This includes adding new names, identifying paid-up members, and address changes. The costs will be primarily human time and not machine costs. Another question: where should the tape be maintained? One possibility is to locate it with the secretary-treasurer and set up automatic update procedures. It could also be located with the Membership Committee chairman. Finally, it could be maintained by a private firm that specializes in such services. The tape and software are set up to be transferred easily and probably should stay with the committee chairman while the alternatives are being explored.

The relationship of the membership tape to other efforts needs to be resolved. It has been suggested that the *Handbook-Directory* could be printed from such a tape. Merger with the Employment Registry tape has also been suggested. Finally, it has been suggested that the tape could be used by the secretary-treasurer for an automated mailing list. The committee recommends that these possibilities be explored by the newly appointed Committee on AAEA Management, Structure, Methods, and Procedures. That committee was invited to have a member attend the Membership Committee meeting, 1 August 1977.

It is the view of the committee that the most effective means of increasing membership is to offer an attractive product. In that regard, the committee applauds the innovative efforts of the Board in recent years toward enhancing the variety, quality, and attractiveness of the goods and services of the AAEA. Many of these efforts will represent more potential than accomplishment, and their impact on membership will depend on the effectiveness and energy with which the potential is exploited.

The Membership Committee will meet on 1 August to develop plans and goals for the coming year, explore strategies for reaching potential members in each target group, explore means for working more effectively with the Canadian and U.S. regional associations, develop an effective plan for increasing the number of institutional members to at least 100, and develop recommendations for further use and management of the membership tape.

I wish to call the attention of the Executive Board and the AAEA membership to the unheralded, unselfish, and effective labors of the ten target group chairmen who constitute the Membership Committee. It has been my privilege and pleasure to serve with them.

John E. Lee, Jr., chairman

Report of the Industry Affairs Committee

The purpose of the Industry Affairs Committee is to promote the interest of the profession and the selective interest of industry economists within the framework of the AAEA. In line with this purpose, the committee decided that in 1977 we would work in three areas: sponsoring an industry banquet and professional sessions at the annual meetings, increasing industry membership and participation in the AAEA, and increasing interaction between industry members and the nonindustry members of the AAEA. This report includes our accomplishments for the year and recommendations for the future.

Last year the Industry Affairs Committee sent an open letter to the agricultural economics profession expressing our concerns on the education of agricultural economists for industry. Several responses were received as a result of that letter, all of them sympathetic with our concerns. However, some of the university people felt they needed help from the industry in improving their curriculums and education programs. As a result, the Industry Affairs Committee is cosponsoring an organized symposium at the annual meetings on the area of educating economists for industry. Also, we are

developing a list of industry economists who are willing to give seminars at universities to help improve university-industry interaction and information exchange. In the next few months we plan to distribute to the membership a paper outlining our ideas on curriculum needs for business careers.

Many agricultural economists are involved in forecasting, and industry economists have long expressed an interest in educational programs on forecasting. As a result, the committee has put together an organized symposium for the annual meetings that will be a forecasting methodology update.

Agriculture leadership is always of interest, and the speaker for our industry banquet will discuss a highly successful program of agricultural leadership.

Both the organized symposia and the banquet, sponsored by the Industry Affairs Committee, have industry people formally involved in the program. This is in line with our goal of increasing industry participation in the AAEA. In terms of industry membership, the Industry Affairs Committee has been working on increasing institutional membership and, as of the end of June 1977, we had signed up ten new institutional members.

Last year the committee submitted several recommendations to the Board of Directors. The prompt action taken by the Board on these recommendations was greatly appreciated. This year the Industry Affairs Committee has one recommendation: that serious consideration is given to the establishment of an award for research by a university agricultural economist that is particularly applicable to an industry problem. The Industry Affairs Committee stands ready to help with this task.

Thank you for your support.

Eugene E. Gerke, chairman

Report of the International Committee

The International Committee was reorganized by President Farrell in early 1977. The committee has engaged in two activities. The first was to assist in arranging the international events for the 1977 annual meeting and second to develop an agenda and plan of work to be carried forward during 1977–78.

The plan of work that is to be further developed by the committee at the annual meetings includes professional training for work on less developed country (LDC) problems. The AAEA International Committee carried out an assessment of international training in agricultural economics in 1973–74 and published a monograph through the Agricultural Development Council. This assessment now needs updating. The committee has identified these issues: (*a*) a substantial decline in U.S. support for students from LDC's, (*b*) the need to make U.S. training programs more meaningful for foreign students from LDC's and to involve U.S. universities in a wider range of training activities, and (*c*) the need for increased support for graduate student and postdoctoral research by U.S. and LDC scholars on LDC problems.

The committee has under consideration a proposal for further study of these issues and the development of a training strategy to be presented and discussed at the 1978 annual meetings. This would require some funding support for a professional who would spend up to one-third time developing a training strategy and assisting in its implementation.

The committee will offer assistance in planning the program for the 1979 meetings of International Association of Agricultural Economists to be held in Canada. The committee has a special interest in a program activity dealing with professional training and related research.

Other activities include liaison with the Title 12 staff group, the BIFAD Board and the joint committees; a professional roster of individuals that are interested and available for international assignments (the committee plans to explore possibilities for improving the roster now available through the AAEA Employment Registry and coordinating this activity with other rosters being developed by the Agency for International Development, IADS and other international agencies); a historical review of the agricultural economics profession in international activities; and offering advice and counsel on the operation of the Agricultural Development Council/Research Training Network. Currently the international committee has been asked for suggestions on the implementation of a small grants research program.

Harold M. Riley, chairman

Report of the Resident Instruction Committee

The primary emphasis of the committee for 1976–77 pertained to developing a program for the Resident Instruction Session of the summer meeting, directing and coordinating the undergraduate activities of the AAEA, and considering program ideas that would be meaningful to members of resident instruction.

First, the program for the Resident Instruction Session. Our committee agreed to have an invited paper discussing the principles related to the teaching-learning process. We felt that one competent resource person with a background in education would be appropriate. Therefore, Dayton Roberts, professor of higher education, Texas Tech University, was selected to make the presentation. He will use approximately one-half of the session on the formal presentation dealing with aspects of

teaching and learning and the other half of the session will be allocated to group discussion.

The format of the undergraduate program is very similar to that used at the Pennsylvania State University meeting. Undergraduates may submit papers this year to either the "regular" instructional paper session or to a "special" undergraduate contributed paper session. It is felt that the special undergraduate paper session has a definite professional posture and one that is meaningful to those participating. The papers and oral presentation are, by the way, going to be evaluated, allowing for special recognition (certificates) to the participants that excel.

Other program ideas that might be meaningful to members of resident instruction have been discussed. For example, sharing of course outlines with our peers, sponsoring workshops, seminars, symposia, etc. We tried the symposia route this year with the industry group. Perhaps these other possibilities can be pursued in future years as felt needs exist.

Our committee has no recommendations for major changes. It likes the present format but continues to do fine-tuning to make the efforts of the committee and the AAEA more relevant.

Glenn C. Himes, chairman

Report of the Visiting Lecturer Committee

The committee continued to consider ways of improving the AAEA's services and communication with colleges and universities whose primary mission is undergraduate agricultural education.

Members located at such institutions suggested assistance with instructional programs would be of most help to them. Moreover, this assistance could take the form of a specially designed session at the annual meeting. As a partial response to these suggestions, members of the committee worked in cooperation with members of the Industry Committee and designed a symposium entitled "Agricultural Business Curricula and Industry Needs." The symposium is scheduled as one of the sessions at the 1977 AAEA-WAEA meeting, San Diego.

The Visiting Lecturer Program was announced in a presidential newsletter. One request was received. However, because of the nature of the request, we were not able to provide direct assistance.

William Herr, chairman

Report of the Extension Affairs Committee

The Extension Affairs Committee has planned and conducted two major activities during the past year. The first was a survey of extension economists. This survey was constructed so as to seek criticism and suggestions in three major areas of AAEA activity: the annual meetings, the *Journal,* and professional services. Questions were included that would elicit suggestions for improvement as well as shed light on problem areas. The survey questionnaire was sent to all economists in the several fields covered by the profession who had a half-time or more extension assignment. A response rate of slightly over 55% was obtained.

A full report of the results of the survey is not appropriate here, but a brief summary of some of the constructive suggestions are presented. The *Journal* and its policies need examination with respect to relevance to extension. There appears to be general consensus that rather little of the current content of the *Journal* is useful to extension or industry economists. If the *Journal* is to serve adequately this group of professionals, something must be done to encourage submission and publication of more applied research and methodologies that are useful in the "real world." Suggestions include a separate section of the *Journal,* a special issue of the *Journal,* or a new *Journal* for applied agricultural economics.

The AAEA should consider special sessions at the annual meetings for extension. Other suggestions included AAEA sponsored conferences or workshops for extension in subject matter areas.

The AAEA should promote and suggest mechanisms for increasing research-extension interaction and collaboration. It is felt that the estrangement of the two groups is largely due to a withdrawal of extension people from the affairs of the AAEA due to lack of useful services and to the growing gap in the nature of research being conducted and the applied nature of most extension problems.

The AAEA should examine the awards program for extension. The diversity of subject matter, approaches, etc., makes it a practical impossibility to single out one worker or one program worthy of recognition. The structure of the awards program, which is alleged to favor some situations over others, is also an issue.

A significant number of extension people do not feel that extension should be considered as a separate group. They express the opinion that to do so would be unwise for several reasons. Specific policies that create separate sessions, publications, etc., would tend to increase the divergence between research and extension. Several stated that they felt no discrimination and that good extension economists should find the content of the *Journal* or the annual meetings useful. A well-trained professional should not regard himself in the functional role but as an agricultural economist.

The preliminary results of the survey and recommendations were communicated to the Board at their meeting on 31 July 1977. The Board received the report with interest and appreciation. The Extension Affairs Committee was urged to develop the

report of the survey as a potential article for the *Journal* and to proceed with proposals for AAEA sponsored activities for economists employed by extension.

The second major activity of the committee was a symposium held at the San Diego meetings. Under the leadership of Charles Rust, a program was developed to address the issue of the activities and services of the AAEA and the expectations and needs of extension economists. Included were the report from the survey mentioned previously, reactor papers, and a response from a member of the Board.

As chairman of the Extension Affairs Committee, I would like to thank the following members for their able and willing assistance during the past year: Norbert Dorow, North Dakota State University; W. S. Farris, Purdue University; Fred A. Mangum, North Carolina State University; Gene Nelson, Oregon State University; Bobby H. Robinson, Clemson University; Charles H. Rust, Montana State University; William W. Wood, University of California, Riverside; W. Fred Woods, Extension Service, USDA; and Charles Covey, University of Florida (who helped with the survey even though his term on the committee had expired).

Robert L. Christensen, chairman

Report of the Contributed Papers Committee

The Contributed Papers Committee represents a new approach to managing the contributed papers program of the AAEA. By building on experience carried over by committee members, the program can be improved from year to year. Previously, except through committee reports, information about factors leading to strengths and weaknesses in the program was lost between years as contributed papers chairmen were changed. It is too early to assess benefits of the new system.

The committee developed and approved a statement on "The Role and Conduct of the Contributed Papers Session" (see appendix). The statement includes purposes of the contributed paper program, criteria for paper selection, and an evaluation form used by the review committees in 1977.

The call for contributed papers was distributed in December 1976 with the submission date moved forward to 1 April, compared with 1 May to 1 June in recent years. Approximately 200 papers were received. The program has fifteen contributed paper sessions, including five sessions with four papers and ten sessions with five papers. In addition, an alternative paper was chosen for each session. Thus, 85 of the 200 papers were accepted. The faculty of the Departments of Agricultural Economics at the University of Arkansas and Oklahoma State University served as reviewers.

Several innovations were tried this year. The alternative paper allows recognition of more authors and will facilitate the program in case some authors cannot give their paper. The authors and titles of alternate papers are in the annual meeting program and the abstracts will be in the *Journal*.

At the annual meeting, abstracts for each session will be available at the registration desk for review of the membership prior to the session. Hopefully, the opportunity to review the abstracts will help members choose sessions and know something about the content of concurrent sessions they must miss. Abstracts and surplus papers (we required that 50 be provided) will be made available after the contributed papers session as long as available.

The authors and session chairman have been given special instructions and admonitions designed to improve presentations and discussions. As we say in the Southwest (in good years), "The hay is cut and down in the field." We now must simply wait to see how the plans for the contributed papers program work.

The committee would like the reaction of the AAEA leadership to an effort to increase the stature and recognition of contributed papers. Specifically, we propose that a numbered series be considered along with a standard cover page. Each paper accepted would be assigned a number, and the author would be required to put the standard cover page on his paper. The paper could be cited by the AAEA contributed paper number. The numbering system could be very simple by years, e.g., AAEA Contributed Paper No. 77-1, 77-2; 78-1, 78-2. The source of papers would be at the home institution of the author as is now the case.

My year as chairman was made most pleasant by the cooperation of committee members and others. My colleagues at Oklahoma State University, Dan Badger and Harry Mapp, did an outstanding job on the program for 1977, and I appreciate it. Faculties at Oklahoma State University and the University of Arkansas were willing and conscientious reviewers. Ken Farrell was always on top of the situation, very helpful, and a pleasure to work with.

Odell L. Walker, chairman

Appendix: The Role and Conduct of the Contributed Papers Session

A primary purpose of the annual meeting of AAEA is to share the newest ideas and latest advances in the profession. Professional interaction at the national level is one way that goals of the profession can be advanced. Some papers at the annual meeting are invited. As a result, the topics and speakers for invited papers are understandably determined by the interests and knowledge of those who put the program together.

Addition of contributed papers to the program allows maximum participation by AAEA members in submitting papers and having a diversity of pa-

pers to hear and discuss at the annual meeting. A general call for contributed papers and the response by the membership constitutes a sampling of current efforts across the profession. The procedure is not selective with respect to authors or subjects but depends initially on the contributor's judgment as to the worthiness of his effort. Contributed papers give anyone with an idea or research results an opportunity for a forum before the AAEA. New and relatively unrecognized people in the profession have traditionally used contributed papers as an outlet for their research and their ideas. The opportunity to present a contributed paper encourages their attendance. These are the people most likely to be overlooked for the limited opportunities to present invited papers.

In summary, contributed papers (*a*) provide an opportunity to sample the latest ideas and advances in the profession, (*b*) provide an opportunity for new, lesser known members to participate on programs, (*c*) add diversity and variety to the program, (*d*) encourage attendance at the annual meeting, and (*e*) afford a competitive challenge to submit a paper and gain acceptance.

A sound and thoughtful review process is needed to preserve the benefits possible from contributed papers. The number of contributed papers received by the review committee has ranged from 120 to 200 papers per year. Program and space limitations for contributed papers may vary from year to year. Thus, the amount of screening necessary, beyond eliminating clearly unacceptable papers, also varies from year to year. In all cases, evaluation criteria are needed. The following criteria are recommended. (*a*) The paper should present material relevant to the agricultural economics profession. (*b*) The paper should present a strong new idea or contribution to the profession in the area of teaching, research, or extension. Reviewers' judgments concerning the overall contribution of the paper are needed. For example, the paper might be graded on a scale between outstanding and not acceptable, as illustrated by table 1. (*c*) Because of the nature of the program and the setting for the presentation, the contributor should demonstrate through his paper that he can communicate the idea within the twelve-page limit and the few minutes allowed for oral presentation during the meetings. In general, the quality of the communication will determine the success of the presentation.

The review form is designed to record judgments of the reviewers concerning the above criteria. At least three people read and review each paper as the basis for selection or rejection. As always, the success depends very heavily on the judgment of reviewers. The 1977 Program Committee (Walker, Badger, and Mapp) used the reviewers' evaluations directly in final selection of papers. Reviewers were also asked to classify the papers by topics to aid in forming sessions. Reviewers for 1977 included the faculty of Oklahoma State University supplemented by a group of faculty from the University of Arkansas.

Report of the Advisory Committee for the Census of Agriculture

During this year the committee held two meetings, both dealing mainly with review of progress in assembling and publishing the 1974 census and with plans for the 1978 census. As you know, the 1974 census of agriculture had more than its share of difficulties, many of which arose from indecision and bungling within the Bureau of Census. Fussing over the definition of a farm, poor planning and execution of enumeration, respondent resistance, budget and summarization problems within the Bureau, and problems with publication were among the difficulties that beset the 1974 census. Most of these difficulties have now been mitigated or resolved in some way so that state and county data are now being published on a belated schedule. The quality of data in the 1974 census of agriculture is probably the most questionable of any agricultural census in this century.

Plans for the 1978 census seem to be progressing much better than the 1974 experience. In the first place, the Bureau has no doubt that they will take a census in 1978. Since Congress changed the traditional dates of the census of agriculture, pointing toward a coordination of all economic censuses by 1982, the 1978 census is viewed as something of an interim or transitional effort. I think it fair to say that the Advisory Committee has urged the Bureau to "get through" the 1978 experience with something of a minimum effort while preparing for meaningful coordination with the other economic censuses by 1982. I think it fair also to say the Bureau is striving for the minimum effort without as yet preparing for the meaningful coordination. The 1978 effort is still viewed chiefly as a "census of farms" rather than a "census of agriculture."

Three topics seem uppermost in the minds of Bureau planners and crowd the agenda of the Advisory Committee. One relates to the development of complete mailing lists of farm operators. Defining and finding farm operators is certainly no easy task, and better cooperation between the Bureau and the Statistical Reporting Service would seem to be in order. Another topic relates to reducing respondent resistance, and this includes requirements for a preenumeration educational program, design and content of questionnaires, and follow-up tactics with nonrespondents. The third topic relates to design and content of questionnaires, including items of information needed from the primary enumeration versus items to be obtained from subsequent sample surveys. Needless to say, requests for information always exceed the reasonable capacity of an enumeration, and the Advisory Committee has

Table 1. Evaluation Form for Contributed Papers for the AAEA Annual Meeting

Manuscript Title:
Author(s):

1. Does this paper present material relevant to agricultural economics for the contributed papers sessions of the annual meeting of AAEA?

( ) Yes (does qualify) ( ) No (does *not* qualify)

2. This item is designed to determine the nature and degree of contribution of the paper and to elicit your overall evaluation.

a. Is the central focus of the paper oriented toward:

( ) Teaching ( ) Research ( ) Extension

b. Indicate the nature and degree of contribution:

Item	Degree of Contribution: Much	Some	Little	None
New or modified theory				
New or modified method				
First empirical application of a method				
Report of empirical work				
Review or appraisal				
Proposal for action				
Chronicle of profession				
Other (Specify) _____				

c. Circle the numerical value that reflects your overall evaluation of the paper (the attached "quality scale" may be useful to the reviewer):

Out-standing[a]	Very Important	Important	Average	Acceptable	Not Acceptable
100 95	90 85 80 75	70 65 60 55	50 45 40 35	30 25 20 15	10 5 0

3. Does the paper communicate effectively and offer strong promise as a stimulating presentation at the annual meeting?

( ) Yes (does qualify) ( ) No (does *not* qualify)

4. If acceptable, indicate the contributed paper session topic in which the paper would best fit. _____

5. If not acceptable, please give a brief explanation of the primary deficiencies or weaknesses._____

[a] Rating guide is: not acceptable: falls below 15 points; acceptable (rated 15–30): fills narrow blanks in an existing framework of knowledge; or corroborates ideas and theory; or modifies known concepts and techniques to deal with a new situation; or restates or reviews previously published viewpoints and empirical information with only minor additions to established knowledge; average (rated 30–50): falls between acceptable and important; important (rated 50–70): establishes new concepts or techniques in teaching, research, or extension that are of considerable interest and considerable value to economic scientists or the general public; or reviews, analyzes, and interprets knowledge of broad scope; or raises significantly new substantive issues (material in this class has a good probability of being cited rather frequently in similar papers by the authors and occasionally would be discussed in references covering similar subjects in either teaching, research, or extension); very important (rated 70–90): falls between important and outstanding; outstanding (rated 90–100): makes a major advance in knowledge and opens the way for extensive further developments by elaborating and/or solving a teaching, research, or extension problem of great methodological or policy importance to the profession or to the public (material in this class has a high probability of being discussed (not only cited) in literature reviews for a given field and would at least be summarized in any related references). (Rating guidelines with adaptation are from Bryon T. Shaw, *The Use of Quality and Quantity of Publication as Criteria for Evaluating Scientists*. Misc. Publ. 1041, ARS, USDA, Jan. 1967.)

spent a great deal of fairly unproductive time discussing who wants what in and in what detail.

Despite the size and complexity of the task of taking a "census of farms," planning for the 1978 effort seems to be going about as well as one might expect. The Bureau will probably use a schedule much abbreviated from the one used in 1974, it probably will differ by regions to avoid asking Michigan farmers about oranges and Florida farmers about cranberries, and it will be pretested widely. Plans for summarization promise more expeditious reporting than we have had in the last census.

I am disappointed that the Bureau has not yet made visible progress toward coordination of the economic censuses. I have suggested that this topic be placed high on the agenda of the Advisory Committee, but the Bureau people have not yet been prepared to discuss it. As AAEA representative on the Advisory Committee I have no specific recommendations for the president or the Board. I suggest that the subsequent AAEA officers plan to keep the same person on the Advisory Committee for several years because one's effectiveness grows with the length of tenure on the committee.

M. L. Upchurch, chairman

Report of the Agricultural Statistics Committee of Federal Statistics Users' Conference

This is the second year of operation of the FSUC Agricultural Statistics Committee after being reactivated in late 1975. During the first year of operation, committee objectives and operating procedures were established. The committee was formed to include a broad representation of data users. Meetings were held to establish contacts with representatives of major data producer and user groups.

The second year of operation has included the following activities. (*a*) A November 1976 committee meeting was held in Washington, D.C., in conjunction with the 20th annual meeting of the Federal Statistics Users' Conference. The committee reviewed government statistics activities with special emphasis on the census of agriculture. As a member of the Census of Agriculture Advisory Committee, I find it helpful to counsel with the FSUC Committee on areas of concern. (*b*) John Aiken and Norman Coats of the FSUC Agricultural Committee participated in the Agricultural and Rural Data Workshop sponsored by the AAEA Economic Statistics' Committee and major divisions of the USDA. (*c*) The FSUC Agricultural Committee held a one-day meeting in February 1977 with representatives of major user and producer groups from various branches of the federal government. The purpose of the meeting was to discuss data producer plans for the year ahead and to present data user requirements and suggestions for additions, deletions, and direction relative to federal statistics. These discussions are most helpful in building relationships for future discussions as the need for change arises.

Plans for 1977–78 include the following: expand the FSUC Committee to include certain key areas of data users not now represented, continue a committee awareness of data needs and make suggestions and recommendations as necessary, maintain contacts with other agricultural committees to determine future requirements for agricultural statistics, and hold a meeting in early 1978 with representatives of major user and producer groups from various branches of the federal government. At this full-day meeting producer plans and user requirements for statistics in 1978–79 will be discussed. Suggestions relative to future activities of the committee will be appreciated.

Norman M. Coats, chairman

Report of the Committee to Evaluate Annual Meetings Programs

Activities underway at the present time are the following. (*a*) A questionnaire was prepared and circulated to the current membership early in 1977. The returns are being tabulated and summarized. (*b*) A questionnaire was prepared and circulated early in 1977 to those who have recently dropped membership and for which a current address could be obtained. The returns are being tabulated and summarized. (*c*) A questionnaire that serves as the centerfold for the printed program has been prepared. Those attending the San Diego meeting are asked to complete the form and leave it at the meeting. Results will be tabulated and analyzed following the meeting. (*d*) The chairpersons for each of the sessions for the San Diego meeting are being provided with an evaluation form that they are asked to complete and turn in to the committee. (*e*) Members of our committee along with two assistants each plan to complete an evaluation form for each session for the San Diego meeting.

The committee will meet 31 July 1977 to review progress to date and make plans for completing analysis of data being collected and preparation of a report. The committee anticipates being able to make a comprehensive report to the Board at their January 1978 meeting.

H. J. Meenen, chairman

Report of the Alternative Publications Committee

The Alternative Publications Committee was appointed 11 February 1976 by President James Bonnen. The charge to the committee was "to examine possible publication formats and purpose, design some sort of alternative formats and test their potential for member support . . . , recommend a course of action to the Board for creating some alternative publication(s) to fulfill some of the currently unserved needs of the profession . . . , pay close attention to the question of how such publication would be financed and whether demands were sufficient to sustain the cost."

The committee was reappointed by President Farrell, 16 November 1976. In addition to the original membership, Fred A. Mangum and James M. Neilson were appointed to serve with the committee. The basic charge to the committee was to appraise publication services of the AAEA, present and potential, basically looking toward publications in addition to the *Journal*. Further, the committee was requested to obtain input from the membership of the AAEA re desired services, to study the experiences of other professional associations, and to share information and exchange views with other AAEA committees having activities related to those of the Alternative Publications Committee.

The committee met in St. Louis, Missouri, on 8 April 1977 to develop plans for completing the committee's responsibilities and to initiate action to develop the final report. The committee agreed that its main concern should be in keeping a high quality, scientific journal with no diminution in quality. Cost will continue to be a major consideration in

expanding the current publication offerings. Currently, the *Journal* cost is about $64 per page for 7,000 copies of a 160-page issue. The composition charge is $32 per page, and the basic printing charge is $25 per page. Mats, tables, and other special items increase the cost further. The only likely possibility for reducing the per page charge is in reducing the composition charge.

The committee delineated five alternatives in addition to the *Journal* as follows: a newsletter, split the present journal into a theoretical mathematical issue and an applied issue, a journal of economic literature, a separately priced supplement for the proceedings issue, and a publication modeled after *Challenge* to meet a completely different audience. The newsletter alternative and the separately priced supplement for the proceedings issue appear to be the only alternatives that could be published at a lower per page cost. (The composition charge could be reduced by utilizing camera-ready typewritten, rather than cold-type copy.) Since some of the material presently published in the *Journal* (minutes, news notes, etc.) could be published in the lower cost newsletter, either the number of pages in the *Journal* could be reduced or additional pages made available for articles through adoption of this alternative. Arguments pro and con for each alternative as well as results of member reactions are being prepared.

A questionnaire developed by Paul Nelson and reviewed and revised by the committee was included in the late May/early June mailing to the membership to obtain their views about the alternatives delineated. To date, over 400 questionnaires have been returned, and the preliminary analysis is completed.

Plans now are to complete a preliminary draft of the committee's final report prior to the San Diego meetings, to revise the report with the committee membership at the annual meetings, and to submit a final report to the board including recommendations as soon as possible.

Verner G. Hurt, chairman

Report of the Committee on *Journal* Page Charge

The committee was asked to review the statement of policy and the administration of the page charge and to consider two recommendations of the Professional Activities Committee to the effect that (*a*) nonmembers be assessed a page charge of $75 on articles accepted for publication in the *Journal* and (*b*) that a submission fee accompany all refereed papers submitted to the *Journal*. In addition, the committee was asked to consider a suggestion that at least one author of articles accepted for publication in the *Journal* be a member of the AAEA.

Recommendation 1: The statement of policy with respect to the page charge should be changed. A final rule relative to the page charge and second class mailing privileges was published in the *Federal Register*, vol. 42, no. 103, 27 May 1977. The specifications of the final rule may be summarized as follows. "Voluntary" page charges that are "truly voluntary contributions" do not come within the specifications for advertising. The current page charge statement cannot be deemed voluntary (though in practice payment of charges is not a prerequisite for publication). Material published pursuant to a nonvoluntary page charge policy must be marked with the word "advertisement" on the first page of the article. The word "advertisement" must "be in bold or italicized print, or otherwise given emphasis so it can be plainly seen."

The committee considered three alternatives: (*a*) the loss of second class bulk mailing privileges representing approximately $5,000 in additional mailing costs; (*b*) no change in the current statement and a footnote on the first page of each article for which the page charge is honored, which would read "A page charge, to defray in part the cost of producing this article, has been paid to the American Agricultural Economics Association in accordance with established procedures for publication of materials herein; for the limited purpose of complying with regulations of the U.S. Postal Service the article is deemed an *advertisement*" (this alternative requires a change in administrative procedures so that a determination of whether or not the page charge will be honored can be made before the preparation of galley proofs); and (*c*) a change in the policy statement regarding page charges to read "Contributions published in the *Journal* are subject to a page charge of $40 per printed page, or fraction thereof, payable by the supporting institution or granting agency. Exemptions are granted for book reviews, the presidential address, fellows lecture and those invited addresses and papers receiving explicit written exemptions from the AAEA president. Payment of this page charge is not a prerequisite for publication. Instructions for making payment and for requesting an exemption are provided with galley proofs. If the page charge is honored 100 reprints are provided." This wording is identical in all substantive aspects to the statement in the *Journal of the American Statistical Association*.

The committee recommends the adoption of alternative (*c*) on the grounds that the labeling of scholarly papers as advertisements, even in a footnote, is inappropriate and the proposed change in the policy statement is consistent with the administrative procedures currently utilized with respect to the page charge.

Recommendation 2: The page charge for nonmembers should be the same as for members. Based on six issues, August 1975 to November 1976 inclusive, 82% of the pages eligible for page charges were by members and for 90% of those, the page charges were honored. Eighteen percent of the

pages were authored by nonmembers; of those, the page charges were honored for 45%. Authors with foreign addresses produced about 12% of the eligible pages. Of those pages, the page charges were honored on 36%, and all of those honored were by members.

Assuming 660 pages per year are eligible for page charges, that the distribution between member and nonmember authored pages remains as in the 1975–76 period, and that a $75 page charge would not diminish the number of nonmembers honoring the page charge, the increase in AAEA income resulting from the higher page charge for nonmembers would be less than $1,900. On the other hand, if it resulted in nonmember authors joining the AAEA to avoid the price discrimination, the increased income would be in the order of $200. Balanced against this are the increased difficulty and costs of administering the page charge. The membership list changes continually throughout the year. The membership list is maintained in the office of the secretary-treasurer, while the billing of page charges is handled by the editor's office! While these difficulties can be overcome at some cost to the AAEA, the potential income benefits do not seem to justify a discriminatory page charge for nonmembers.

Recommendation 3: A submission charge should not be levied on articles submitted for publication at this time. The benefits of a submission fee appear to be relatively modest. At the same time, an additional administrative burden would be placed on a new editor. However, if future financial conditions require additional income, a submission fee is a potential source of a modest increase in income. The current editor estimates that the costs for postage, mailing, and secretarial time for the review process is in the $15 to $20 range per submission. A $15 submission fee would recover most, if not all, of these costs. With about 300 submissions per year, the potential income would be about $4,500. Further, such a charge might encourage some authors to give more consideration to the decision to submit a manuscript.

Recommendation 4: Membership in the AAEA by at least one author should not be a condition for acceptance of an article for publication. The benefits resulting from publication of an article accrue both to the author and to the members who utilize the article in their work. The major function of the *Journal,* however, is to provide a high quality service to the membership. It is our view that the quality of the contribution should be the single criterion for publication decisions.

Lee M. Day, chairman

Minutes

Minutes of the Executive Board Meeting, Washington, D.C.

The meeting was called to order by President Farrell at 8:30 a.m., 3 January 1977.

Present: Voting Members:
Farrell, Bonnen, Barr, Crowder, Stanton, Lane, Mangum, Hildreth, Raup
Members ex officio:
Redman, Tomek, Ball
Guests:
Martin, Holt, Lee, Rasmussen, Mather, Boyne, Wunderlich, Witt, Worden

1. Farrell reviewed the agenda and stated that in accordance with revisions of bylaws all motions should be prepared in writing by the maker and that Bonnen will be responsible for incorporating all policy actions in the bylaws. Redman will have an updated set of governing regulations ready each meeting.

2. Farrell reviewed the committee appointments and some problems in selecting committees.

3. Stanton moved that the minutes of the Pennsylvania State University meeting be approved. Seconded. Passed.

4. Holt presented the final report on the meeting held at Pennsylvania State University. The need for a policy statement on financial arrangements between the AAEA and host institution was noted. Lane moved that the report be accepted with thanks and that Redman prepare a policy statement on how the potential surplus or deficit may be shared. Seconded. Passed.

5. Redman reported as secretary-treasurer.

6. Stanton reported briefly for the Finance Committee. Since the financial records of the AAEA are audited by a certified public accountant, there appeared no real need for an Audit Committee. Stanton moved to recommend to members at the next annual business meeting that the Audit Committee be eliminated and the bylaws amended accordingly. Seconded. Passed.

Stanton reported on the possibility of obtaining professional management for the AAEA's investments. Those contacted suggest that the minimum fee will run from $1,400 to $1,700 per year. Since it was uncertain whether benefits would cover the cost, the question was referred back to the committee for further study. The committee was instructed also to explore no load mutual funds for external management and to develop two or three alternatives for internal management.

7. Lee reported for the Membership Committee, setting forth plans for more effective recruitment.

8. Tomek reported as editor.

9. Redman reported on the progress of the *Handbook-Directory,* indicating it would be ready for the printers by 1 February. Lane moved that 7,500 copies be printed. Seconded. Passed.

10. Barr reported on the printing contract. Previously, the Executive Board had voted to award the contract to Edwards Brothers contingent on satisfactory negotiation on several items, particularly reprint costs. Because of a change in Heffernan's billing procedures for author's alterations and being unable to work out fully the contingencies with Edwards Brothers, it was decided to remain with Heffernan. Crowder moved that the print order for each issue of the *Journal* be set at 500 copies more than the AAEA membership as of 31 December or the membership at the time the print order is placed, whichever is greater. The intent is to have an inventory of 500 copies after the distribution to membership. Seconded. Passed.

11. Rasmussen reported on the literature retrieval activity. It was suggested that an item be inserted in a presidential newsletter indicating the university or agency and the number of citations submitted to the system.

12. Mather and Boyne reported for the Employment Committee and Professional Registry Committee, proposing a revised proposal for a computer-based employment system to the U.S. Department of Labor seeking to extend the project for one additional year with final additional funding of $32,800. Lane moved to approve the submission of the proposal to the U.S. Department of Labor and authorize the president to sign the proposal for the AAEA if there are no substantial modifications after a conference with the U.S. Department of Labor. Seconded. Passed.

13. The Professional Registries Committee recommended that the Board (*a*) take action declaring intent to enter into agreement with the Economic Research Service to operate a Registry for Agricultural Economists with the condition that a plan be developed to generate the AAEA's share of costs, (*b*) authorize the Professional Registries Committee to solicit commitments to fund the AAEA's share of project costs, (*c*) approve submission to the U.S. Department of Labor of a new contract proposal to provide a final year's funding of the Registry by the Employment Service, U.S. Department of Labor, and (*d*) continue to explore through the Professional Registry and Employment Service Committees the possibilities of U.S. Department of Labor support for the Registry on a continuing basis. Hildreth moved that items (*a*) through (*d*) of the report be approved. Seconded. Passed.

14. Ball reported for the Awards Committee and presented a proposal to establish a new AAEA award, Distinguished Policy Contributions, which may be granted annually beginning in 1978 for contributions to the advancement of public understanding of major issues related to food and agriculture, including natural resources and rural areas. Raup moved that the AAEA establish a Public Policy Award and that the Awards Committee be instructed to draft a revised description for announcement in fall 1977. Seconded. Passed.

15. Ball, on behalf of the Awards Committee, presented a slate of possible AAEA nominees for the Edward W. Browning Award of the American Society of Agronomy. The president was instructed to forward the nomination of Earl O. Heady, Iowa State University.

16. Possible nominations for the Alexander von Humboldt Foundation Awards were discussed. No nominations are to be forwarded by the AAEA in 1977.

17. Wunderlich reported for the Professional Activities Committee and presented a policy statement relating to AAEA sponsorship and endorsement of professional activities under conditions where the AAEA is involved in the planning, conduct, and evaluation in the interest of a significant proportion of the membership or a recognized subset thereof. Proposals are to be submitted to the president, who shall in turn seek the advice of the Professional Activities Committee. Hildreth moved that the report be adopted in principle and that it be studied again and possibly revised considering the suggestions and comments made. Seconded. Passed. (Note: A copy was sent to the membership in March 1977.)

18. Witt Reported for the Committee to Evaluate the Annual Meeting, summarizing the plans for a survey of members' and nonmembers' opinions regarding the annual meetings and also for a centerfold questionnaire for the printed program of the San Diego meeting.

19. Worden reported briefly for the Economic Statistics Committee.

20. Hildreth moved that the AAEA president prepare a foreword, if requested, for a forthcoming book of Fred Waugh's writings in cooperation with the Economic Research Service and Martin Abel et al. of the University of Minnesota. Seconded. Passed. The Board also approved the establishment of an AAEA ad hoc editorial committee, if requested, to work with Abel et al. in preparing the book. These motions do not imply any availability of AAEA funds for the effort.

21. Stanton moved that a special committee be appointed to prepare the text for a four-page printed brochure describing employment opportunities and careers for graduates in the field of agricultural economics. Seconded. Passed.

22. A proposal from J. C. Headley, University of Missouri, that the AAEA request CAST to develop a task force to study methodologies associated with estimation of costs and benefits of pesticides used in agriculture was reviewed and rejected.

23. In an executive session, the Board selected V. James Rhodes and Stanley R. Johnson of the University of Missouri as *Journal* editor and associate editor, respectively, for a three-year term beginning with the February 1978 issue. Eight persons had been nominated for consideration.

24. In an executive session, the Board reviewed the nominations for AAEA fellows. Eight nominations were forwarded to the Fellows Election Committee.

25. A letter from Marion Clawson, Resources for the Future, proposing that the AAEA undertake surveys of its members regarding agricultural policy issues was discussed. No action was taken.

26. Redman was instructed to review the offer of Iowa State University to include AAEA documents in the Iowa State University archives.

27. Farrell and Redman presented an outline of the program, arrangements, and preliminary budget for the AAEA-WAEA meeting to be held in San Diego, California, 31 July–3 August 1977.

28. Lane moved that a special committee be appointed to review the management methods and procedures of the AAEA and make recommendations to enhance efficiency in operations. Seconded. Passed.

29. Board adjourned at 4:00 p.m., 4 January 1977.

Respectfully submitted,
John C. Redman
Secretary-Treasurer

Minutes of the Executive Board Meeting, San Diego, California

The meeting was called to order by President Farrell at 8:05 a.m., 30 July 1977.

Present: Voting Members:
Farrell, Hildreth, Barr, Crowder, Stanton, Lane, Mangum, Raup, Bonnen
Members ex officio:
Redman, Tomek, Storey
Guests:
Sundquist, Forker, Day

1. Farrell reviewed the agenda for the Board and the procedures to be followed during the annual meeting. He emphasized that since the program was tightly scheduled all sessions should begin on time and end on time. Farrell also explained procedures for implementing the policy of requiring membership in the AAEA as a condition for participating in the program.

2. Redman reported on registration, indicating that 779 had preregistered and that over 200 addi-

tional members were expected to register. All arrangements seemed to be ready for the meeting.

3. Lane moved that the minutes of the Board meeting held in Washington on 3–4 January 1977 be approved. Seconded. Passed.

4. Farrell read the report of the tellers indicating that B. F. Stanton was elected as president-elect and Joseph Coffey and Edward Schuh were elected as directors. He also announced that Lowell Hardin, A. C. Hoffman, Sidney Hoos, and Earl Swanson will be installed as fellows.

5. Redman presented the secretary-treasurer's report, which will be given at the general business session (see committee reports).

6. Redman transmitted the report of the audit conducted by the certified public accountant. After a review, Stanton moved the acceptance. Seconded. Passed.

7. Redman reported for the *Handbook-Directory* Committee, indicating that it was mailed to all members and subscribers in February 1977 and single copy sales were not great. The committee has completed its assignment.

8. Stanton reported for the Finance Committee in two segments. One segment dealt primarily with plans for monitoring expenses and development of guidelines for handling cash flow by the secretary-treasurer. This involved following closely each of the major enterprises of the AAEA by a member of the committee and suggesting some maximum balances in individual accounts in the bank. Lane moved that the guidelines be adopted in principle. Seconded. Passed.

The second segment dealt with management procedures of the AAEA portfolio. The committee recommended a combination of internal and external options. The procedure would involve specification of goals concerning desired performance of the portfolio, periodic reviews by a brokerage house or investment service holding the account, and implementation of any recommendations concerning changes in the portfolio suggested by a committee of AAEA members. The recommendations of the Finance Committee with explanatory materials will be forwarded to all Board members and will be implemented with agreement of two-thirds of Board members. A Board member will have two weeks to indicate a negative response; otherwise, a positive response will be assumed (see committee reports). Hildreth moved to adopt the report on management of the AAEA portfolio with modifications as suggested by Crowder and Lane. Seconded. Passed.

9. Redman reported for Publication of Postwar Literature Review Committee. Publication of volume II is scheduled for December 1977. The publisher has taken steps to expand sales outside the United States, and the AAEA has sent materials to members informing them of special purchase price.

10. Day reported for the Page Charge Committee, which examined recommendations that nonmembers be assessed a page charge of $75 for published articles and that a submission fee accompany all refereed papers submitted (see committee reports). The committee recommended that the page charge for nonmembers be the same as for members and that a submission charge not be levied at this time. In addition, the committee recommended that membership should not be a condition for acceptance of an article for publication in the *Journal*. The committee examined at length the policy and administration of the current page charge relative to the regulations of the U.S. Postal Service. The committee considered three alternatives: (*a*) the loss of second class mailing privileges, which would add approximately $5,000 to mailing cost; (*b*) no change in current statement but, as required in postal regulations, add a footnote on the first page of each article for which a page charge is honored that would read: "A page charge, to defray in part the cost of producing this article, has been paid to the American Agricultural Economics Association in accordance with established procedures for publication of materials herein; for the limited purpose of complying with regulations of the U.S. Postal Service the article is deemed an *advertisement*"; (this alternative would require a change in administrative procedures to determine whether or not the page charge will be honored before preparation of galley proofs); and (*c*) change the policy statement to read: "Contributions published in the *Journal* are subject to a page charge of $40 per printed page, or fraction thereof, payable by the supporting institution or granting agency. Exemptions are granted for book reviews, the presidential address, fellow's lecture, and those invited addresses and papers receiving explicit written exemption from the AAEA president. Payment of this charge is not a prerequisite for publication. Instructions for making payment and for requesting an exemption are provided with galley proofs. If page charge is honored, 100 reprints are provided." After considerable discussion, Lane moved that the third alternative be adopted. Seconded. Passed.

Stanton moved the recommendation that the page charge be the same for nonmembers as for members be adopted. Seconded. Passed. No action was taken on the recommendation that no submission charge be levied. No action was taken on the recommendation that membership in the AAEA by at least one author should not be a condition for acceptance of an article for publication.

11. Tomek reported as editor (see committee reports).

12. Rhodes, reporting as incoming editor, indicated that he was receiving papers and that the policy and procedures would be essentially the same as under the previous editor. The Board offered no specific directions except to encourage the new editor to seek commission of papers, invite papers, etc.

13. Tweeten reported for the Statistics Committee, recommending the approval of two task forces

to lay out the conceptual framework and operational guidelines for determining the economic value of statistical information and on measuring agricultural productivity. Stanton moved that these two task forces be commissioned. Seconded. Passed.

The committee recommended an ad hoc task force on survey of agricultural and food outlook to investigate the feasibility of periodic surveys of specialists to evaluate their forecasts and to disseminate the results in a suitable manner. Stanton moved that the Statistics Committee be encouraged to appoint such a task force. Seconded. Passed.

The committee also proposed the appointment of a statistics editor for the *Journal*. The Board took no action except to encourage the chairman of the Statistics Committee and the new editor to work together on emphasizing the need for articles and other materials for the *Journal* concerned with new and old statistical series and their evaluation.

14. Barkley reported for the Professional Activities Committee, recommending (*a*) that the visiting lecturer program and committee be discontinued unless suitable funding can be found; (*b*) that a program committee be established to assist in planning content of the annual meeting; and (*c*) that the Professional Activities Committee have one of its members on the Alternative Publications Committee and on the Industry Affairs Committee. Hildreth, as new president, indicated that he planned to implement these recommendations unless objections are raised.

The committee was encouraged to work with the editor on the need for recommended commissioned articles on (*a*) accreditation and certification of agricultural economists; (*b*) the AAEA: a federation or guild; (*c*) keeping up with expanding boundaries of economic knowledge; and (*d*) complexity of present information systems. The committee was encouraged also to pursue further the National Science Foundation's "Science for Citizens" program.

15. Sundquist reported for the Committee on Management, Structure, Methods, and Procedures, summarizing the proposed plan of activity. By consensus, the Board accepted the report.

16. Boyne reported for the Professional Registries Committee, recommending (*a*) that the president, on behalf of the AAEA, enter into an agreement with the Economic Research Service to operate a Registry for Agricultural Economists. (As a first step, it is assumed that the president would designate an AAEA committee to work with ERS personnel in developing the terms and conditions of the agreement.) Stanton moved the approval of the recommendation. Seconded. Passed.

(*b*) That an AAEA committee be designated to represent the AAEA in carrying out the terms of the agreement. (It is assumed that one of the terms of agreement would call for an AAEA committee to advise the ERS on matters related to the operation and further development of the Registry.) Mangum moved the approval of this recommendation. Seconded. Passed.

(*c*) That the AAEA president be authorized to communicate in writing the Board's decision to consummate an agreement with the ERS to each organization that has made a commitment of funds and to confirm the amount of commitment made by the respective organization or individual. Barr moved the approval of this recommendation. Seconded. Passed.

17. Mather reported for the Employment Services Committee, indicating that the final funding period of the U.S. Department of Labor contracts will expire on 15 February 1978 and that arrangements for finance and funding of the Registry after expiration are being developed by the Professional Registries Committee.

The committee recommended that the next *Handbook-Directory* be prepared from the Registry and that necessary steps be taken to effect this change, i.e., determine the content of the biographical sketches and program the necessary changes in computer format. The estimated one-time reprogramming cost is $1,400, and direct computer and labor charge is under $450 per Directory to prepare a camera-ready copy for directory printing. Hildreth moved to authorize the Employment Services Committee to reprogram the Registry for multiple purpose uses, e.g., *Handbook-Directory*, with the contract funds available. Seconded. Passed.

18. Hildreth moved the dissolution of the Employment Services and Professional Registries Committees and the establishment of an Employment Services and Professional Registries Committee. Seconded. Passed.

19. Hurt reported for the Alternative Publications Committee, indicating the nature of study underway. Redman presented a brief report on the possibilities of using microform to capture the contributed papers and symposia at no cost to the AAEA. He also presented a possibility of publishing on demand through the use of microform to supplement the present *Journal*. No action was taken.

20. Rasmussen reported for the Literature Retrieval Committee, recommending that the committee be extended as presently constituted for another year, that the budget be approved and serious consideration be given to an additional sum of $12,000 to hire an additional person, and that the Board endorse further explorations with the Canadian groups and WAERSA to achieve further coordination of the information retrieval programs. Motion was made to extend the committee for another year, to approve the budget without the additional $12,000, and to encourage explorations with other groups. Seconded. Passed.

21. Trelogan reported for the Review of Fellows Selection Committee, making some recommendations to assure that all agricultural economists be

considered. Trelogan will work with Bonnen to formulate a policy statement.

22. Lee reported for the Membership Committee, indicating the nature of the organization set up and the plans underway to increase the membership in the AAEA.

Note: The following minutes were kept by V. James Rhodes while the secretary-treasurer was attending to registration and arrangements for the annual meeting.

23. Riley reported for the International Committee. The Board informally encouraged the committee to proceed on its plans.

24. Gerke reported for the Industry Affairs Committee. The Board informally encouraged the committee to proceed on its plans for facilitating industry speakers for university seminars.

25. Walker reported for the Contributed Papers Committee. It was suggested that the committee coordinate with the Alternative Publications Committee on their proposal of a numbered series for contributed papers.

26. Himes reported for the Resident Instruction Committee. The Board asked the committee to consider (in conjunction with other appropriate committees) the possibilities of the AAEA developing services to appeal to B.S.-level graduates in agricultural economics.

27. Herr reported for the Visiting Lecturer Committee. Hildreth moved the discontinuance of the Visiting Lecturer Committee and that the president be instructed to appoint an ad hoc committee to explore ways for the AAEA to serve agricultural economists in the non–land grant colleges. Seconded. Passed.

28. Ball reported for the Awards Committee. Motion was made by Stanton to approve the description of the award for the distinguished policy contribution. Seconded. Passed. The Board informally approved the statement that membership in the AAEA is not prerequisite to receipt of AAEA awards.

29. Coffey reported on plans for the meetings to be held on 6–9 August 1978 at Virginia Polytechnic Institute and State University at Blacksburg, Virginia. Hildreth moved that the differential in registration fees for the 1978 meetings at Virginia Polytechnic Institute and State University continue to be $25.00 ($12.50 for students) for those who are not members of either the AAEA or CAES. Seconded. Passed.

30. Hildreth reported on plans for the 1978 program. A program committee is planned to meet for 1-½ days on 20–21 December in Chicago. The committee will include those Board members who wish to be included plus a few others. The Board will meet on 27 December at the Allied Social Sciences meeting in New York.

31. Eckert reported as ASA-AAEA liaison representative. The suggestion of a multidisciplinary research award was referred to Awards Committee for consideration but that it include more than agricultural economics and agronomy. Eckert was encouraged to explore the possibilities of a symposium that he might then take to the Professional Activities Committee and to develop a proposal for a joint session with other disciplines at the annual meetings.

32. Christensen reported for the Extension Affairs Committee.

33. Schuh reported on his liaison contact with the National Bureau of Economic Research.

34. Bonnen moved a resolution on the fellows issue. (*a*) A Board Advisory Committee on Fellows Nominations shall be established from the Board to examine the lists of members of the AAEA to assure that members deserving of consideration as fellows not be overlooked and to examine the nominations received from the membership in order to advise the Board on the eligibility and the membership status of the candidates. (*b*) The committee shall consist of two members of the Board plus the secretary-treasurer. The secretary-treasurer should be prepared to report on the membership status of the candidates. The other two members, each serving two-year terms, are to be chosen by the president. (*c*) The committee shall transmit its findings to the Board by the time of the summer meetings. Thus, individual Board members will have this information for consideration before they meet in the winter to choose the nominees for forwarding to the Fellows Election Committee. Seconded. Passed. Schuh was appointed for a two-year term and Crowder for a one-year term.

35. Bonnen presented a draft modification of existing bylaws to reflect the last two years of Board actions. The Board approved modifications and/or additions to Bylaw Articles V, VIII, X, XII, and XIV. Bonnen proposed that a separate document entitled Policy Actions of the AAEA Executive Board be established to enroll the remaining policy actions of a continuing nature that the Board deemed not to belong in the bylaws. Seconded. Approved. Updated bylaws and a current copy of the enrolled policy actions will be provided the Board at its winter meeting each year.

36. Lane moved to accept the secretary-treasurer's report. Seconded. Passed.

37. The Finance Committee presented a proposed 1978 budget. Stanton moved that annual editorial support be raised to $22,500. Seconded. Passed. Barr moved a budget item of $15,000 for 1978 for Employment Committee agreement with the ERS. Seconded. Passed. Stanton moved to increase the secretary-treasurer's honorarium to $5,000. Seconded. Passed. Crowder moved the approval of the 1978 budget as amended. Seconded. Passed.

38. Hildreth discussed the 1977 winter program and discussed Board representation on various committees.

39. Farrell expressed appreciation to the Board

and especially to the departing Past-President Bonnen and the two departing Board members Mangum and Stanton. However, Stanton will be returning as president-elect.

40. Meeting adjourned at 5:35 p.m. on 31 July 1977.

Respectfully submitted,
John C. Redman
Secretary-Treasurer

Minutes of the Annual Business Meeting, San Diego, California

The 66th annual meeting was called to order by President Kenneth R. Farrell on 2 August 1977 at 11:15 a.m.

1. President Farrell presented for approval the minutes of the annual business meeting held at State College, Pennsylvania, 17 August 1976, as published in the proceedings issue of the *Journal*. Motion was duly made. Seconded. Passed.

2. Farrell announced officially the results of the election of officers. Bernard F. Stanton was elected president-elect, and G. Edward Schuh and Joseph Coffey were elected directors.

3. President Farrell highlighted the activities of the AAEA during the past years. (*a*) The affairs of the AAEA are conducted in large part through its committee structure. Currently, there are fifteen standing committees, seventeen special committees, three ad hoc committees, and six liaison representatives to other organizations, involving nearly 260 members. (*b*) An ad hoc committee was created to review policies and procedures concerning the *Journal* page charge. A special committee on business organization and management was created with the responsibility of reviewing the management structure, methods, and procedures of the AAEA and recommending steps that might be taken to improve effectiveness of operations and managerial processes. (*c*) V. James Rhodes and Stanley Johnson were selected as editor and associate editor, respectively, effective with the February 1978 issue of the *Journal*. (*d*) The *Handbook-Directory*, totaling over 600 pages, represents an important personal contribution of John Redman and Willetta Hager. (*e*) Volume I of *A Survey of Agricultural Economics Literature* appeared in February and volume II will be produced in late fall of 1977. (*f*) The Professional Registry has been financed solely by grants from U.S. Department of Labor. The Board has approved a plan whereby the Registry will be housed in the USDA (ERS) and be financed by annual grants from institutions that might use the services. (*g*) The Board has established a new Distinguished Policy Contribution Award, which may be awarded annually beginning 1977–78. (*h*) A policy statement has been adopted to encourage AAEA sponsorship of seminars, workshops, symposia, colloquia, and other professional activities. (*i*) No major difficulty has been experienced in following the policy to limit membership on committees and presentation and/or discussion of papers to members only unless waived by the president. (*j*) Membership has been maintained or increased in some categories; given the higher dues and the one-time membership increasing effect of the *Handbook-Directory* in 1976. (*k*) Upon recommendation of the Finance Committee, the Board has established guidelines for cash flow and account transactions in the secretary-treasurer's office. With specific financial objectives, the management of the portfolio will be vested with the Board with periodic reviews by an outside firm. (*l*) Other activities include work by various committees, some of which have been accepted and will become visable in the years ahead.

4. Redman presented the secretary-treasurer's report for fiscal year 1 January 1976 through 31 December 1976. Redman also presented a report on AAEA investments for 1976. Motion was made to receive the report. Seconded. Passed.

5. Stanton reported on the budget that was adopted by the Board for 1978.

6. Farrell presented the report of the certified public accountant on the financial condition of the AAEA. Motion was made to accept the report. Seconded. Passed.

7. Tomek reported as editor of the *Journal*. The report was accepted.

8. No old business was noted.

9. As an item of new business, Farrell presented a proposal to discontinue the Audit Committee since the AAEA is now using and plans to continue the services of a certified public accountant. Motion was duly made to amend the bylaws to discontinue the Audit Committee. Seconded. Passed.

10. Bonnen presented two resolutions: to express the appreciation to William Tomek and Cornell University for the services he rendered as editor and to express appreciation to John Redman and Willetta Hager for production of the *Handbook-Directory*. With no objections, copies will be sent to appropriate people.

11. Farrell announced the dates of future AAEA meetings. On 6–9 August 1978, the AAEA will meet at Blacksburg, Virginia; 29 July–1 August 1979 at Pullman, Washington; and 27–30 July 1980 at Urbana, Illinois.

12. Farrell commented on the meeting in San Diego, noting that this was the first time in over 40 years the AAEA has met in commercial facilities. The task of organizing the meeting fell on many people, particularly his secretarial staff—Mildred Evano, Carol Kotch, Sharon Warwick, and Geneva Riddle. Loyd Martin of the ERS worked hard in carrying out decisions with respect to travel, program, lodging, and committee activities. John Redman, in addition to regular duties, assumed responsibility for publicity, printing of program and brochures, catering arrangements, registration, and

a host of other duties. Pat Potter and the staff of the Town and Country Hotel were efficient, professional, and responsive to our needs. The Convention Bureau and the Pacific Telephone provided much appreciated assistance.

13. Farrell expressed appreciation to retiring Board members, Bernard Stanton and Fred Mangum and past president, James Bonnen, and turned the chair over to R. J. Hildreth, who became president.

14. Hildreth announced the date of the Allied Social Science Associations meeting in New York on 28–30 December 1977 and reviewed the program. He announced the Nominating Committee with Kenneth Farrell as chairman.

15. Meeting adjourned 12:30 p.m.

Respectfully submitted,
John C. Redman
Secretary-Treasurer

Objective

The AAEA seeks to further the systematic development of knowledge of agricultural economics in order to improve agriculture and agriculture's contribution to the general economy. The activities of the AAEA include:

—publishing the *American Journal of Agricultural Economics;*
—planning and conducting two annual meetings of the membership;
—sponsoring annual awards for outstanding extension programs, distinguished teaching, and outstanding research;
—recognizing outstanding agricultural economists through a fellows program;
—supporting a literature retrieval system in cooperation with the U.S. Department of Agriculture;
—publishing periodically a biographical directory of the AAEA's members;
—supporting an employment registry for agricultural economists in cooperation with the U.S. Department of Labor.

Membership and Subscriptions

Membership in the AAEA is open to individuals having a professional interest in agricultural economics. Dues, payable at the beginning of each calendar year, are as follows: regular members, $25, senior members, $12.50, and junior members, $12.50. Senior membership is open to persons, upon written request, who are sixty-five years of age or older and have retired from active professional work. Junior membership is for students and is limited to three years; students should use application forms available from and signed by the head of the department in which they are studying. Members receive this *Journal*.

Any firm, corporation, association, or partnership may become an institutional member upon payment of $100 per year; institutional members receive three copies of each issue of the *Journal*. Library subscriptions are $35 per year. Individual issues of this *Journal* are $10.00.

Payment of membership dues, correspondence regarding subscriptions, orders for individual copies of the *Journal*, changes in address, or inquiries about the general affairs of the AAEA should be sent to John C. Redman, Secretary-Treasurer, American Agricultural Economics Association, Department of Agricultural Economics, University of Kentucky, Lexington, Kentucky, 40506.
